important at the onset to be prepared to do a transfusion at any time and to have adequate donors available. Occasionally bleeding may occur 8 to 12 days after the operation in a patient who is apparently doing well. With this in mind measures to combat the hemorrhagic tendencies should not be discontinued too soon. In most instances it is advisable to do a transfusion immediately after the operation. Ordinarily these patients are much more comfortable in a semi Fowler's position and when given continuous intravenous glucose and saline solution for the first 24 to 48 hours. This insures an adequate intake of carbohydrates and fluids. Many of these patients are more comfortable in an oxygen tent for the first 24 hours after the operation and in addition to the easier respiration, the general appearance of these deeply jaundiced patients is improved. If a T tube has been inserted, it is advantageous to clamp the tube for 1 or 2 hours at a time as soon as possible oftentimes on the third day, to prevent an abnormal loss of bile. The question as to when the T tube is to be removed rests largely with the individual case for it will likely be an established routine to do a cholecystogram on many of these patients before the tube is removed. The tendency now is to leave these tubes in longer than formerly.

CONCLUSION

These cases then represent a group who present definite difficult problems in diagnosis and operative technique and if a low mortality rate is to be maintained they must be handled as bad risks, carefully prepared before and carefully watched after operation.

MEDICAL ASPECTS IN PRE-OPERATIVE AND POSTOPERATIVE CARE OF DIABETIC AND CARDIAC PATIENTS

JAMES E. PAULLIN, M D , Atlanta, Georgia

IN APPROACHING an understanding of what is to be and what can be accomplished in patients with diabetes mellitus or heart disease, from a medical point of view, it is necessary to have a clear understanding of the problems involved based on physiological, physical, and chemical facts, in order to justify any form of therapy. It is known that these disabilities increase the hazard of surgical procedures, but these hazards can be greatly diminished if there is a definite understanding of the existing condition by those who are vitally concerned in the success of a completed program.

I wish to stress the importance of a complete understanding of the problems involved in these handicapped patients by the anesthetist, the internist, and the surgeon. Working co-operatively, they offer the greatest security to these patients. In my opinion the anesthetist is not only a very necessary member of this group, but one to whom the internist and the surgeon look for help. He should be a well trained physician who has devoted time and study to his specialty and who has had sufficient clinical experience to detect and to evaluate correctly changes occurring in a patient during anesthesia. From his training and experience he is capable of advising the anesthetic of choice and the degree of anesthesia to be produced. What a comfort such an anesthetist is to the surgeon whose mind is free to perform the necessary operation as expeditiously as possible with a minimum of trauma, and to the internist who knows that his physically handicapped patient is in the hands of an understanding person. With such a group, surgical problems are approached with greater confidence and safety which otherwise are unobtainable.

Ordinarily patients with diabetes and those with heart disease present for solution problems which are in nowise related. After 50 years of age both groups develop mutual problems. It is generally known that patients with diabetes are much more likely to develop arteriosclerosis and

its complications than an equal number of patients of the same age group with other diseases. After 50 years of age the number of patients with heart disease seeking surgical relief will be found to have impairment of their circulatory mechanism, most frequently because of arteriosclerosis. The diabetic offers the greatest difficulty of these 2 groups because he has not only diabetes but also arteriosclerosis, whether the latter is demonstrable or not.

PATIENTS WITH DIABETES MELLITUS

The mild diabetic requiring immediate surgery becomes a patient with a potentially serious handicap, the seriousness depending upon the nature of the disease requiring surgical relief. Infection of any kind is most dreaded in a diabetic because it not only makes his disease worse but if uncontrolled leads to acidosis, coma, and death. It is most essential, therefore, for the patient and the internist to recognize the onset of infection at the earliest possible moment, and if amenable to surgical relief, to seek this as promptly as possible. Prompt treatment of infection helps the diabetic to rid himself more quickly of a pathological lesion which makes his disease worse. With our present knowledge of diabetes, our expert physician anesthetist, and with such wonderful surgical skill and experience in treating infection, the diabetic mortality from this cause should greatly decrease, provided we teach our patients to seek help early.

In acute surgical emergencies, arising during the course of diabetes, too much stress cannot be laid upon the necessity of quick operative relief. Delay in seeking this relief may, and frequently does, forfeit whatever chances the patient has for complete recovery.

PRE-OPERATIVE CARE

Those diabetics who do not require emergency surgery present certain problems of importance in their pre-operative preparation. The object of such care is to obviate the possibility of acidosis, to prevent other complications which might arise, and to hasten convalescence. In the care of pa-

From the Medical Department, Emory University
Presented in the Symposium on Surgical Procedures on the Handicapped Patient, before the Clinical Congress of the American College of Surgeons, New York, October 17-21, 1938

tients belonging to this group there are certain considerations which are of value in order to accomplish the desired results

1 To store glycogen in the body sufficient to supply the patient's needs during the period of operation and for several hours thereafter This is accomplished by feeding in the previous 24 hours at least 150 grams of carbohydrate and by controlling glycosuria by the administration of insulin in the necessary dosage at 2, 3 or 4 hour intervals

2 Giving a sufficient amount of fluids to take care of the body needs which ordinarily would amount to 2,500 or 3,000 cubic centimeters administered as water, broths fruit juices oat meal gruel, tea or coffee etc

3 It is desirable to administer easily assimilable foods in the form of carbohydrate until at least 4 hours before the time of operation

4 The established dose of insulin is continued without regard to the operation the only difference being a change in the time of administration If a diabetic is receiving protamine insulin and most of them are, this should be continued and supplemented when necessary with small doses of regular insulin every 3, 4, or 6 hours as the occasion demands The dose required is determined either by the presence of sugar in the urine or an increasing blood sugar

5 If the diabetic is an individual who is not under good control it is far better to have, if time permits dietary and insulin adjustment before operation is undertaken The diabetic is much safer if he goes to the operating room with a urine sugar free and a blood sugar which approaches normal

6 In acute surgical emergencies, which are usually accompanied by marked acidosis as evidenced by a lowering of the carbon dioxide combining power of the blood plasma, and the detection in the urine of diacetic acid as well as glucose, the immediate needs of the patients must be met by giving a sufficient amount of regular or quick acting insulin the administration of normal salt solution subcutaneously or intravenously cleansing the lower bowel with an enema and washing the stomach with plain water Such treatment followed in a regular and orderly manner over a period of a few hours will diminish the operative hazard and promote recovery

Little Mary Jane a well trained diabetic 10 years old living in a neighboring town developed an acute otitis media The ear drum was promptly punctured by her physician but fever continued glycosuria increased and the infection spread so that 36 hours later the mastoid was involved Despite increasing doses of insulin sugar and diacetic acid excretion steadily mounted and rather quickly

she developed a marked acidosis She entered the hospital with a temperature of 104 degrees F marked tenderness over the right mastoid and a thin purulent discharge from the right ear The urine contained 4.8 per cent of sugar the blood sugar was 383 milligrams per cent and the carbon dioxide combining power of the blood plasma was 20 volumes per cent She was given larger doses of insulin subcutaneously and immediate preparation made for operation Her stomach had previously been washed and she had received an enema before entering the hospital It was only necessary to give her salt solution by hypodermoclysis which was continued during the operation A mastoidectomy was done under nitrous oxide oxygen and local anesthesia Within 3 hours after her arrival in the hospital she had received treatment for her infection and her acidosis and within 3 days was well on her way to an otherwise uneventful recovery

7 In so far as possible it is extremely beneficial to allay the fear and anxiety of operation in patients who are afflicted with diabetes by the preoperative administration of suitable doses of the barbiturates and also when it is found necessary, the use of small doses of an opiate with scopolamine In my experience, this procedure has been most valuable and has been a great comfort not only to the patient but to the anesthetist and surgeon as well

POSTOPERATIVE CARE

In dealing with this phase of the discussion I feel it necessary to direct attention to 4 problems (1) Upon the return of the diabetic to his room he should at once receive fluid, preferably normal salt solution containing 2.5 per cent of glucose, administered subcutaneously and if not contraindicated by the nature of the operation at least 500 cubic centimeters of salt solution by rectum (2) The patient should be given small but frequent doses of regular insulin, the size of the dose and the frequency of administration depending upon the severity of the diabetes and the patient's preoperative condition (3) Every attempt should be made to begin feeding the patient by mouth as soon as possible after operation Our experience has demonstrated that it is possible to start this in the great majority of patients within 4 to 6 hours after the return of the patient to his room Such foods as oatmeal gruel ginger ale, fruit juices, tea or coffee with glucose and crackers are given Within the first 24 hour postoperative period an attempt should be made to furnish at least 100 grams of glucose either subcutaneously or by mouth with a sufficient quantity of insulin to keep the urine approximately sugar free (4) Constant stock taking and supervision of the sugar metabolism by employing frequent urinalyses and occasional blood sugar determinations are most essential for the intelligent handling of these patients

PATIENTS WITH HEART DISEASE

It has been customary among the laity and among physicians to suppose that in perfectly normal individuals, anesthesia in particular and surgical operations in general, impose a terrific burden on the heart and circulation. Such an assumption most likely arose as the result of impressions received in the early days when the administration of an anesthetic, usually ether, was accompanied by marked excitation, struggling, periods of apnea, cyanosis, increase in blood pressure, and increase in heart rate. Thanks to the introduction of more modern methods of pre-operative care, to the great advancement of the science of anesthesia, and the entrance into this field of skilled anesthetists, most of the alarming and distressing reactions observed years ago have disappeared. Generally speaking, there was greater apprehension because of the anesthetic than there was of the surgical operation. At the present time it is believed that the properly administered anesthetic throws no additional burden on the heart. We are also of the opinion that when such aforementioned alarming and distressing reactions occur, the modern surgeon attributes them, not to the anesthetic but to the lack of skill of the anesthetist.

In patients with heart disease, irrespective of the type, before advising surgical intervention it is necessary for the internist to know more about the condition of the heart muscle than the type of heart lesion he has. The internist therefore wants to know if the crippled heart is able to function as a good working pump, how much of a load it is now carrying and how much of an increase it will be able to take without showing evidence of fatigue, how much reserve strength the heart has which will be available in the event there are extra demands for its use, and how such facts can be determined beforehand.

To secure such information, must we depend on physical examination, on various instruments of precision, or are we to use these only as confirmatory evidence of facts which have been elicited from a careful history as to what the patient can do without producing discomfort? In arriving at an intelligent decision concerning the reserve strength of the heart, it is necessary to inquire of the patient how much physical activity he can undergo without producing uncomfortable sensations.

Such questions are directed to determine the functional capacity of the left rather than of the right ventricle, since obviously in the majority of patients, except those with mitral stenosis, the left ventricle will be the first to show evi-

dence of weakness. We, therefore, inquire if the patient is able to walk several blocks or to climb several flights of stairs at a reasonable pace, or to walk up a hill, or run a short distance for a street car without producing difficult breathing. Is he able to hold his breath for 40 seconds without discomfort? Can he sleep on 1 pillow? Does he have paroxysmal attacks of dyspnea? If these simple measures are carried out, together with a careful physical examination and such laboratory procedures as are indicated and it is found that the patient is able to undergo the usual exercise tests without respiratory distress, we are reasonably certain that he can undergo a surgical operation without increased danger.

In judging of a patient's heart condition it is important to bear in mind that there is considerable difference between heart disease and heart failure. A patient may have evidence of heart disease yet his myocardium is capable of performing as much work as though his heart had no disease. There is a group of patients with heart disease who, in so far as it is possible to tell, present questions for solution which cannot always be answered with any degree of certainty. I refer to the group with such diseases as angina pectoris, syphilitic aortic insufficiency, aortic stenosis, and complete heart block. It is well known that patients with these disabilities are those who are subject to sudden death. This is a frequent occurrence and such catastrophes are impossible to foresee or foretell even after a most careful history, physical examination, and the use of other laboratory procedures. For this reason it is impossible to predict the effect of surgical operations on this class of patients. Whenever they are subjected to operation it should be understood that the risk is considerable, irrespective of the fact that the heart is functioning satisfactorily at the time.

Patients with irregular action of the heart, if this be due to an occasional premature beat, cause very little or no concern. If the premature beats occur frequently and especially if they are increased after exertion, this should cause us to bear in mind the possibility of developing ventricular tachycardia.

Patients with auricular fibrillation, in the absence of congestive heart failure, will stand operations remarkably well. If the heart is totally irregular but contracting at a fairly normal rate without a marked pulse deficit, there is little danger. In those patients with great irregularity and a marked pulse deficit, the operative hazard is considerably increased because they will give evidence of poor cardiac function. If permissible,

preliminary digitalization will markedly decrease the operative risk.

Hypertension occurring in patients with good cardiac function without symptoms of angina pectoris and with a normally acting heart, is no contra indication for surgery. The usual pre operative preparation of this class of patients for surgery is quite efficacious in preventing the former transient rise in blood pressure which in times past was so frequently seen.

Patients with mild congestive heart failure as determined by finding fine râles at the bases of both lungs, will undergo operations with less risk if there is ample time for bed rest and digitalis, with consequent improvement of cardiac function before operation. In those patients with marked congestive failure, as evidenced by orthopnea, edema, congestion at the bases of both lungs, and enlargement of the liver, only acute surgical emergencies should be considered. Any operation on this class of patients should be done with the idea in mind that whatever procedure was adopted would have to be predicated upon the theory that surgical intervention gave the patient a better chance of living than if he were denied such relief. Should no emergency exist, improvement of the heart action by enforced bed rest, limitation of fluids, promoting urinary excretion and the administration of digitalis and other helpful drugs is indicated.

The preliminary digitalization of patients with heart disease, who have good cardiac function before undergoing surgical operations in my opinion, serves no good purpose. A heart which functions normally is a good heart surgically and no drug administered before operation will improve this, however, it might be stated that some times in elderly patients with arteriosclerosis, small doses of digitalis given 2 or 3 days before operation may be definitely beneficial but in this group of patients one should always be careful not to produce digitalis intoxication. It is the experience of most cardiologists that the arteriosclerotic group is rather susceptible to digitalis effects.

Medical emergencies which may arise during the administration of an anesthetic or after the return of the patient to his room are such conditions as auricular fibrillation, paroxysmal auricular tachycardia and premature beats. As a rule these should give very little concern since they are usually transient in nature and tend to subside. Should they persist the use of vagal compression, digitalis or quinidine sulphate is quite helpful. Patients with ventricular tachycardia offer a most serious problem. This occurs usually

in those with rather marked arteriosclerosis and who have degenerative changes in the myocardium. Treatment with quinidine sulphate is advocated and should be tried. It has proved beneficial on numerous occasions.

It is not my intention to discuss peripheral vascular collapse. As all know, this is not due to heart disease but is a collapse of the vasomotor mechanism, producing shock. Treatment directed to the heart is of no use whatsoever but on the other hand is more than likely to do harm. Well known measures for increasing the blood volume such as immediate transfusion of blood, intravenous salt solution, etc., are the accepted forms of treatment.

POSTOPERATIVE CARE

After completion of the operation in those with heart disease attention should be directed to the prevention of conditions which might cause some embarrassment to the circulation. Chief among these are abdominal distention, postoperative vomiting, straining at stool and allowing patient to remain in 1 position too long. Simple measures are always available for meeting such situations without throwing any unusual strain on the heart.

I wish to direct attention to 1 phase of the post operative care of patients with heart disease and even those without this condition which I see so commonly abused, and that is the administration intravenously of large amounts of fluids, either as salt solution or salt solution containing rather high percentages of glucose, within a short space of time. The fact is lost sight of that attempts to increase rapidly the volume of the circulating blood throw an additional burden on the heart and that the administration of concentrated solutions of glucose temporarily disturbs the osmotic balance of the blood. Should it become necessary to give fluids intravenously to this group of patients it is a much better procedure to administer small amounts at frequent intervals than it is to introduce a large volume into the circulation in a short space of time. Furthermore it is better to furnish fluids subcutaneously rather than intravenously.

At times it is necessary to give solutions of glucose intravenously. These are best given in a 50 per cent solution in amounts of 30 to 40 cubic centimeters and repeated frequently rather than administering a large volume at any 1 time. One should bear in mind that it is a rather hazardous procedure to disturb the osmotic balance of the blood by the sudden introduction into the circulation of concentrated solutions in large volumes.

SUMMARY

In this discussion it has been impossible to refer to all of the conditions which might arise in a given patient. However, I feel that if I have been successful in directing attention to the fact that the care of a patient affected with diabetes melitus and the care of a patient suffering from

heart disease is not a problem which can be handled to the greatest good of the patient by any one individual, but that the existence of co-operative team-work between the anesthetist, the internist, and the surgeon will lead to the greatest number of successes and the fulfillment of a completed program, my effort will not have been in vain

SURGICAL PROCEDURES IN THE PRESENCE OF DIABETES MELLITUS

LELAND S McKITTRICK, MD FACS Boston Massachusetts

ANY discussion of the surgical procedures upon diabetic patients must presuppose an understanding of the surgical problem of the patient, of the effect of the metabolic disease upon the patient himself, and of its effect upon the course, treatment, and progress of the surgical complication. Successful management of this complication will demand careful co-ordination of this knowledge together with the proper selection of an anesthesia, an operative procedure planned and carried out with particular reference to the individual patient, and meticulous attention to the details of pre-operative and post-operative care. Even then let no one feel that the patient with diabetes can be operated upon with the same degree of safety as the patient without this disease.

EFFECT OF DIABETES UPON THE PATIENT AND HIS SURGICAL DISEASE

In considering the surgical problem of a given patient we too often think in terms of the patient's metabolic disturbance, of its control during operation, and of the postoperative period. Too little do we consider the fundamental fact that this patient has had diabetes. Diabetes, controlled or uncontrolled over a period of years will result in varying degrees of arteriosclerosis. Too often have we seen a diabetic patient die suddenly from an unsuspected coronary thrombosis or be stricken with some other manifestation of cardiovascular disease not to be impressed with the significance of this complication. It is undoubtedly this arterio-sclerotic background which has prompted Dr. Joslin to say "A diabetic patient is as old as his age plus the duration of his diabetes."

Moreover, the patient is further handicapped by the effect of his metabolic disease upon his surgical complication and its management. Careless or inexperienced care of the diabetes may result in a continued glycosuria possibly coma, it will increase the incidence and severity of infection and may interfere with the healing of surgical wounds. Overzealous treatment on the other

hand, may result in insulin shock which, in the case of the older patient with cardiovascular disease, may be very serious.

Experience would suggest that in the controlled diabetic a clean surgical wound will heal in a manner comparable to a similar wound in a non-diabetic of similar age. On the other hand experience also tells us that the patient with diabetes is more susceptible to infection, that tissue necrosis is more frequently seen and is more extensive when present, that infection makes the diabetes more difficult to control and that the infection itself is more difficult to eradicate in the diabetic than in the non-diabetic patient. The past as well as the present of every diabetic patient facing a surgical procedure must be given careful consideration in any contemplated surgical undertaking.

PRE-OPERATIVE AND POSTOPERATIVE CARE

Careful consideration is essential to the satisfactory management of surgical patients with diabetes mellitus. There must be a surgeon interested in the care of these patients to take responsibility for the surgical aspects of the problem. In addition there must be an internist of wide experience in the care of diabetic patients to assume charge of the pre-operative preparation and postoperative care of the medical aspects of the problem and also an experienced anesthetist to assure the selection and administration of the anesthetic indicated for this particular patient. This should not be interpreted to mean that the surgeon is devoid of responsibility in the preparation of the patient for operation for after all his experience in the specific surgical procedure contemplated should be available to the internist and the patient both in preparation for the operation and in the care of the patient after operation. In other words close co-operation for a common end is essential for the best interest of the patient.

May I summarize in a few paragraphs what one might call the medical observations of a surgeon. For an operation of election the patient should go to the operating room well fed, his liver stocked with glycogen, acid free and with no more than a trace of sugar in the urine. These are important points.

2 An emergency operation may be done in the presence of acidosis if the urgency of the condition justifies the increased risk which this incurs. It must be recognized, however, that the presence of acidosis may well restrict the extent of the surgical procedure and the selection of an anesthetic, and puts a much greater burden upon the medical consultant.

3 It is unnecessary and dangerous to attempt to render the urine sugar-free within 3 days after operation. So far as I know there is no evidence that a moderate elevation of blood sugar to 180 milligrams per cent or the presence of a decreasing amount of sugar in the urine for 4 or 5 days after operation in any way interferes with the healing of a clean surgical wound.

4 Insulin dosage based on urine tests is simple and safe provided the doses are small, that the patient is emptying the bladder, and that hypoglycemia is guarded against by occasional blood sugar determinations as soon as the urine is sugar-free.

5 If intravenous glucose is given, it is dangerous and unnecessary to attempt to utilize all the glucose given by an estimated dose of insulin. It is even more dangerous to give insulin for the glucose which usually spills over in the urine after an intravenous injection. We have seen hypoglycemic reactions follow this procedure repeatedly. It is my belief that if intravenous glucose is to be given, it is safe to give insulin according to the urine passed just before the administration of the intravenous solution, and to disregard the glucose given intravenously and discard the first specimen of urine passed following the glucose injection. If in doubt, it is better to give glucose under the skin and to avoid its intravenous use.

6 Failure to recognize a marked increase in carbohydrate tolerance following the removal of an infected leg or drainage of a carbuncle or large abscess is a frequent source of hypoglycemic reaction.

SELECTION OF ANESTHESIA

Theoretically the ideal anesthetic should be one with little or no effect upon the diabetic state, it should not be toxic to the liver or kidneys, and should not be associated with anoxemia. From a practical point of view, however, the anesthetic for a given surgical procedure will depend upon (1) the surgical problem, (2) the age, duration and severity of the diabetes, and the general condition of the patient, (3) the experience and skill of the anesthetist, and (4) the experience of the medical man in the care of surgical diabetic patients. Regardless of other factors, the anesthetic selected must be one which will permit the surgeon to

TABLE I — OPERATIONS UPON PATIENTS WITH DIABETES MELLITUS AT THE NEW ENGLAND DEACONESS HOSPITAL

Region of operation	Major	Minor	Total	Deaths
Tongue, face, ear, and eye—carcinoma	2	4	6	0

Lower extremities	657	73	730	65
Totals	976	300	1276	102*

*This represents 8 per cent of the total number of operations performed.

complete the operation indicated in a minimum of time, with a minimum of trauma and a maximum of safety. Without going into detail, we may summarize a few of the more important facts from the literature and our own experience with the more commonly used anesthetics as follows. Ether causes hyperglycemia, acidosis, and is toxic to the liver.¹ Nevertheless, it is frequently our anesthetic of choice in operations in the lower abdomen.

Chloroform is too toxic to the liver, has all the disadvantages of ether, and we never use it.

Nitrous oxide and oxygen, ethylene oxygen, or cyclopropane and ether in conjunction with novocain block of the abdominal wall is our choice of an anesthesia for operations upon the gall bladder and stomach. If nitrous oxide and oxygen are used, great care must be taken to avoid cyanosis. Enough ether should be added to make respirations easy and permit good color.

¹Coleman in his recent work finds avertin most toxic to the liver, and in order of decreasing toxicity anesthetics range as follows: nitrous oxide, oxygen and ether vapor, spinal, nitrous oxide and oxygen, local procaine (Surgery, 1938, 3: 87).

TABLE II—COMPARISON OF OPERATIVE AND NON OPERATIVE TREATMENT OF GANGRENE AND INFECTION 1923-1938

Operation	Gangrene				Infection			
	No cases	Re-amputation at higher level	Deaths	Mortality per cent	No cases	Re-amputation at higher level	Deaths	Mortality per cent
Incision and drainage	4	1	1	25	8	0	1	12.5
Amputation of 1 or more toes	28	5	1	3.6	54	3	0	0
Lower leg amputation	2	0	0	0	3	0	0	0
Guillotine amputation	12	6	4	33.3	7	5	1	14.3
Crittch Spokes amputation	3		0	0	1	0	1	100
Thigh amputation	98	0	14	14.3	3	0	0	0
Total operations	147	12	20	13.6	75	8	3	4
No operation	259		8	3.1	235		4	1.7

Evipal is excellent for short operations when relaxation is not required especially in incision and drainage of carbuncles when the electro surgical knife is used. It must be used with care. The dosage varies greatly. We have seen the maximum dose of 10 cubic centimeters inadequate for the drainage of a septic finger in a young diabetic woman, frail but in good condition whereas in the next patient, a heavy man of 55, a large carbuncle was incised and drained with 4 cubic centimeters of the solution.

Procaine regionally and locally has little effect on the diabetes, liver or kidneys, and is used extensively alone or in conjunction with gas anesthesia as mentioned above. It is never used for the amputation of a digit or for incision of a carbuncle.

Spinal procaine is used almost exclusively for operations upon the lower extremities for most inguinal hernias and for minor procedures around the rectum and perineum. It is frequently used in operations upon the lower abdomen especially in women without extensive cardiovascular disease rarely for operations on the upper abdomen. Fifty to 75 milligrams are adequate for an operation on the lower extremities. The level of the anesthesia rarely reaches above the level of the iliac crest and except as noted below we have never recognized it as directly contributing to a mortality. In many of our patients we doubt that any other anesthetic could have been used with equal safety. We do not believe that relaxation of the sphincter and secondary to spinal anesthesia is an important cause of gas bacillus infection in an amputation stump.¹

Avertin we believe to be a dangerous anesthetic in the presence of cardiovascular renal disease, and we never use it in these patients.

PRE OPERATIVE MEDICATION

Diabetic patients are in general much more susceptible to drugs than are non diabetic patients of comparable size and age. Moreover diabetic patients as a group are accustomed to physical and mental insults and are much more tolerant of operations than are most people. In our earlier experiences I was uncertain lest in 2 instances heavy pre operative medication in preparation for operations had contributed to ward fatal outcomes. Our pre operative medication is therefore simple. One and one half grains of nembutal, $1\frac{1}{2}$ grains of phenobarbital or 3 grains of sodium amytal is frequently given to the more apprehensive patients the night before operation. One-eighth to one fourth grain of morphine sulphate with one one hundred and fiftieth grain of atropine, is used 30 minutes before an inhalation anesthetic. The older and more debilitated patients are frequently given no pre operative medication. None of our patients operated upon for gangrene are given pre operative sedation of any kind and in many instances I have seen these patients sleep through operations.

SPECIFIC OPERATIONS

In Table I are listed the operations performed by my associate Dr Theodore C Pratt and myself for the 10 year period preceding January 1 1938. A glance at the table shows that it is not a true cross section of all the surgical problems these patients present. Operations in the various specialties have not been done by us and practically all operations upon the thyroid gland in

¹ A total of 124 operations have been done on the lower extremities of 805 patients since 1913. The first and only postoperative gas bacillus infection of a stump occurred in 1924.

TABLE III — OPERATIONS FOR GANGRENE
1923-1938

Operations	No cases	Deaths	Mortality per cent
Amputation of 1 or more toes	53	4	7.5
Amputation of toe, then major amputation	35	4	11.4
Incision and drainage only	8	0	0
Incision and drainage, then major amputation	2	2	100
Gulotine amputation	33	14	42.4

Toe amputations	88	8	9.1
Major amputations	452	59	13.1

patients with diabetes at the Deaconess Hospital have been done by Dr F H Lahey and his associates

Major operations include those in which the abdominal or thoracic cavity had been opened, hernias of all types, dissection of the neck, amputation of a digit or extremity, incision and drainage of a carbuncle, open reduction of a fracture, amputation of a breast with or without dissection of the axilla, embolectomy, plastic operations upon the vagina, and ligation of the femoral or popliteal artery

Minor operations include a variety of lesser procedures such as skin grafts, local excision of superficial benign or malignant lesions, the evulsion of nails, closed reduction of fractures, removal of foreign bodies, drainage of superficial abscesses, high ligation and injection of the saphenous vein. Transfusions and a large number of smaller surgical procedures carried on in the wards are not included. *Multiple operations for the same condition are listed as 1 operation.* Thus a 2 stage resection of the colon or multiple operations upon a lower extremity for a single lesion are listed as 1 operation. As in all our statistics, any patient who, following a surgical operation, dies during that hospital admission is listed as a

surgical death regardless of the actual cause of death and regardless of whether or not he has entirely recovered from the condition for which he was operated upon

Gangrene of the lower extremities. Of patients who have entered the New England Deaconess Hospital during the past 3 years for treatment of some phase of arterial deficiency, 48 per cent have left the hospital without operation (Table II). The average age of those patients undergoing operation is 65 years. The mortality for all major amputations upon patients with gangrene from 1923 to 1938 has been 13.1 per cent (Table III). Ninety per cent of these patients who have come to operation have had a major amputation

The many factors entering into the selection of the level at which amputation should be done cannot be repeated here. If, however, one gives careful consideration to the various problems involved, the selection of the level of amputation is not difficult. It is our belief that *gulotine amputation*, preferably through the upper third of the lower leg, is indicated (1) for extensive infection in the presence of severe diabetes, (2) in patients with septicemia secondary to gangrene and infection of the limb, and (3) in debilitated patients whose general condition is so poor that primary healing is not anticipated. *Amputation of a toe* is dangerous in the presence of unlocalized infection and will rarely if ever be successful if pain is severe. It should only rarely be attempted in a pulseless foot if infection has involved the deeper structures of the foot. *Amputation of the lower leg* should never be considered in any patient whose general condition precludes the use of an artificial limb. It should never be done in the absence of pulsation in the popliteal artery, and it should

TABLE VI—OPERATIONS FOR APPENDICITIS JANUARY 1924 TO JUNE 1939

never be done in the presence of a lymphangitis above the level of the ankle. We have elected amputation through the lower leg in only 7 per cent of our patients with gangrene. *Gritti Stokes amputation* gives an excellent end bearing stump, but we are now convinced that in the patient with diabetes it should be used only in selected cases and then only when the surgeon has had considerable experience with the operation. A *supra condylar amputation*, using a circular incision without a tourniquet and with careful closure of the wound without drainage, is the safest amputation we know. In 100 consecutive amputations of this type done at the New England Deaconess Hospital the mortality has been 14 per cent (Table IV). First intention¹ healing has occurred in 93 per cent of the cases, and in only 2 cases was there deep infection of the stump. We have not used the operation of Callander because of the universal satisfaction from the simpler supra condylar amputations mentioned above.

Infection of the lower extremities. Probably the most important lesions we see involving the lower extremities are those in the feet of diabetic patients with adequate circulation as evidenced by (1) good pulsation in the dorsalis pedis artery, or (2) no primary pulsation but excellent collateral circulation as evidenced by a foot of normal appearance, warm and well nourished. Gangrene may be present but is secondary to infection and local thrombosis, rather than due to a primary arterial occlusion. It is of interest that in this

Stump completely healed & sutures out in 12 days

group of patients a marked degree of hypesthesia at times actual anesthesia is frequently noted. Only recently we removed the great toe of such a patient in the ward without anesthesia because of the extensive infection which was present and we have frequently incised and drained infections of the feet in this group of people without anesthesia of any kind. It is in this group of cases that osteomyelitis of a phalanx is so common. Amputation of a digit for osteomyelitis of an interphalangeal joint on a foot with good pulsation in the dorsalis pedis artery is one of the safest and most satisfactory procedures we know (Table V).

We have successfully removed one or more toes in 186 patients, with a mortality of 1.1 per cent. In 18 instances a higher amputation was necessary, and in these unsuccessful cases the infection had already extended to the deeper structures of the foot. It is also of importance that in this group of cases removal of one toe, particularly the great toe, is frequently followed by the development of a callus and then ulceration in the tip of the adjacent toe (Fig. 1). It is in cases of this type that amputation of all the remaining toes for prophylactic reasons may be indicated (Fig. 2). Amputation through the lower leg is not infrequently advised in this group of patients in preference to long continued and extensive infection involving the deeper structures of the foot.

Amputation of a digit for osteomyelitis of an interphalangeal joint is done with a racquet incision through the proximal phalanx. In cases in which the infection has involved the deeper

Fig 2 Same as Figure 1, after amputation of remaining toes

structures of the foot, the position and character of the incisions used for drainage are of extreme importance (Figs 3, 4, 5). In most instances adequate drainage will require the removal of one or more toes. In general, incisions should be made too long rather than too short. They should be so placed that, with the foot in the normal resting position, the lower part of the incision will represent the most dependent part of the wound. If infection involves a metatarsophalangeal joint, all of the head of the involved metatarsal should be removed (Fig 6). For drainage of the great toe, fourth, or fifth toes, lateral incisions are used, and in the case of the fourth toe the head of the fifth as well as of the fourth toe must be removed so that the wound is one wide, open cavity (Fig 6).

For removal of the middle toe and at times the second toe, a wedge is removed with the incision on the plantar surface of the foot being extended sufficiently to give adequate dependent drainage (Fig 7). Whenever the head of a metatarsal is excised, all sesamoid bones or cartilaginous tissue should be removed.

We do not use any complicated treatment of the cut plantar tendon. A clean, sharp knife is used. Great care is taken not to pull on the tendon and let it snap back into its sheath. Rather the tendon is cut so as to allow a few millimeters of tissue to project beyond the cut end of the sheath. In an

open, infected wound a piece of dry gauze is immediately placed over the cut tendon. A second small piece of dry gauze is then packed loosely over this. After 24 hours the packing is moistened with Dakin's solution morning and evening and is removed in 3 or 4 days. Thereafter the packs are changed daily and are kept moist with Dakin's solution. In larger wounds one or more Dakin's tubes are inserted and 5 cubic centimeters of solution instilled in each tube every 2 hours. In clean wounds to be closed, the tendon is cut with a clean, sharp knife. No other method of treatment is needed.

Infections of the hand In the splendid symposium on diabetic surgery before the forty-fifth *Congres français de Chirurgie*, Jeanneney (5) gave an excellent résumé of the difficulty experienced in controlling these infections and offered definite suggestions as to their management. Bothe refers to the large amount of necrosis and the difficulty in controlling palmar abscesses. There is otherwise very little mention of this serious and important problem in the literature. Dr. Walter Garrey and myself carefully studied the 70 patients admitted to the New England Deaconess and Massachusetts General Hospitals between January 1, 1933, and January 1, 1937. Seven and one-tenth per cent of these patients died, and another 7 per cent survived an amputation through or above the forearm. Thirty per

Protection of the surrounding skin is important. It is washed daily with tincture of green soap and water, wiped off with alcohol, and painted with compound tincture of benzoin. Even with this precaution small pustules may develop. Necrotic tissue is removed as it separates, but great care is taken not to subject the patient to the painful removal of tissue before separation is complete. The large carbuncle always begins as a small one, and early adequate treatment should prevent the development of a fatal lesion.

ABDOMINAL SURGERY

Abdominal symptoms due to acidosis Most of the more recent articles on diabetic surgery give ample space to the syndrome of pain, vomiting, spasm, fever, and leucocytosis, not infrequently associated with acidosis and without any demonstrable organic lesion within the abdomen. We have seen a white count in such a condition as high as 80,000. The mere fact that a diagnosis of perforated ulcer, perforated appendix, or acute pancreatitis is frequently made is evidence that the pain may be severe and the findings diffuse rather than localized. Accurate differentiation can usually be made by a careful history obtained from a member of the family or the patient, and by the generalization rather than the localization of findings. In most instances the diagnosis can be confirmed following a few hours of insulin treatment, since the pain and abdominal signs clear very quickly in the absence of a surgical lesion and usually become more definite in its presence. Although the occasion has never presented itself, we would have no hesitancy in making a small incision under novocain anesthesia did we feel that the findings were such as to make delay unsafe.

Appendicitis With an increasing number of children maturing and entering adult life, there will be an increasing number of cases of appendi-

betic patient with a spreading infection involving the deeper structures of the hand.

Carbuncles It is our belief that carbuncles are surgical infections and as such are best treated by adequate incision at the proper time. Four, or 5 per cent, of the 71 patients we have operated upon for this infection in the 10 year period have died. All deaths have been in patients with large lesions, 10 centimeters or more in diameter. Careful treatment of the patient's general condition and his diabetes, local heat and x-ray to hasten localization, then crucial incision with undermining of the flaps, using the electrosurgical knife is, we believe, the procedure of choice. The wound is packed with dry gauze. This packing is removed as it loosens, usually in 3 or 4 days. Thereafter the wound is repacked loosely each day with gauze saturated with Dakin's solution or azochloramid.¹

¹Azochloramid, 1:3300 in normal saline solution is used 3 times daily, or the oily solution 1:500 in triacetin is used once daily.

Fig. 3 Incision used for drainage of infection involving the subcutaneous tissues at the base of the toes. This may be combined with removal of one or more toes or connected with drainage on the dorsum of the foot if necessary.

cent of these patients lost all or a part of one or more fingers. Certain facts seemed to contribute toward these poor results: (1) late hospitalization and inadequate incisions, usually after ambulatory treatment in spite of the known difficulty in controlling infection in patients with diabetes through small inadequate incisions, and (2) the presence of a mixed infection as noted in most cases when finally hospitalized.

Our experience in the management of these cases particularly of the tendon sheath infections, is too limited to warrant any dogmatic statements at this time. We believe we are justified however in advocating that any patient who is seen with an infection of the hand and diabetes should be immediately hospitalized that operation if indicated should be in a bloodless field and painstakingly done under general anesthesia and that incisions should be adequate so that the infected area is completely opened. For the simpler paronychia we advocate early removal of the entire nail. For felons we advocate the complete fish mouth incision and for infections of the tendon sheath we suggest that the sheath be completely opened throughout its entire length. In case of extension to the radial or ulnar bursa or

both we believe that the crucial ligament should be divided. If there is beginning necrosis of the tendon at the time of operation it is our present belief that the tendon can best be removed at the primary operation. Early amputation of a finger for involvement of the bone or joint may greatly shorten the convalescence, but we believe that amputation of the hand should be undertaken only as a life saving procedure or when destruction beyond hope of usefulness has taken place and this latter is rare indeed. In our own experience there is no group of patients in which the judgment and experience of the surgeon will be so thoroughly tried as in the management of a dia-

Certain facts seemed to contribute toward the poor results: (1) late hospitalization and inadequate incisions usually after ambulatory treatment in spite of the known difficulty in controlling infection in patients with diabetes through small inadequate incisions; and (2) the presence of a mixed infection as noted in most cases when finally hospitalized.

Our experience in the management of these cases, particularly of the tendon sheath infections, is too limited to warrant any dogmatic statements at this time. We believe we are justified however in advocating that any patient who is seen with an infection of the hand and diabetes should be immediately hospitalized, that operation if indicated should be in a bloodless field and painstakingly done under general anesthesia and that incisions should be adequate so that the infected area is completely opened. For the simpler paronychia we advocate early removal of the entire nail. For felons we advocate the complete fish mouth incision and for infections of the tendon sheath we suggest that the sheath be completely opened throughout its entire length. In case of extension to the radial or ulnar bursae or

TABLE VIII—OPERATIONS UPON THE BILIARY TRACT

January 1924 to June 1938

Operation	Cases	Stones	Death	Mortality per cent
Cholecystectomy	30	33	3	7.7

Total	70		3	7.1

*In 7 cases stone was present in the duct.

both we believe that the crucial ligament should be divided. If there is beginning necrosis of the tendon at the time of operation, it is our present belief that the tendon can best be removed at the primary operation. Early amputation of a finger for involvement of the bone or joint may greatly shorten the convalescence but we believe that amputation of the hand should be undertaken only as a life saving procedure or when destruction beyond hope of usefulness has taken place and this latter is rare indeed. In our own experience there is no group of patients in which the judgment and experience of the surgeon will be so thoroughly tried as in the management of a dia-

Fig. 4 Incision for amputation of the great toe proximal to the head of the first metatarsophalangeal joint showing the line of extension of the incision to drain the subfascial area of the medial ball of the foot. A similar type of incision is used for the fifth toe.

Fig 7 a, Plantar and, b, dorsal views of incision following amputation of the second toe through the metatarsal for infection involving the metatarsophalangeal joint. The incision has been extended on the plantar aspect because of infection involving the deeper structures of the foot. The patient, a 72 year old diabetic woman, was discharged from the hospital with the foot completely healed 67 days after operation.

cellulitis of the abdominal wall, and Case No 3080, a woman of 53 supposedly in good condition for a diabetic of her age, died in a coma not of diabetic origin and not too satisfactorily explained, a third patient recently operated upon also had an unlooked for reaction, characterized by a semi-conscious state and other symptoms at first thought to be due possibly to cerebral hemorrhage, but this patient, after a somewhat delayed convalescence, recovered satisfactorily with no evidence of a cerebral accident. It is these experiences which make me feel that I cannot operate upon the diabetic patient with gall stones without accepting a slightly higher mortality than in non-diabetic patients of comparable age and with comparable pathology (Table VIII). It is also these experiences which make me feel that the indications for operation in this group should be clear-cut.

Our experience with acute cholecystitis in patients with diabetes is limited. This experience suggests, however, that the so called acute gall bladder in a patient with diabetes will not subside with the same frequency that it will in the non-diabetic patient. We have seen 5 such patients and in only 1 instance did the acute process subside so that a procedure of election could be done. Others progressed and operation had to be undertaken during the presence of an acute inflamma-

tory process. It is now our feeling that if a patient is admitted with an acute cholecystitis, we should probably be inclined toward operation as soon as the diabetic state is under reasonable control.

During the past 10 years we have done 10 anastomoses between the stomach or duodenum and the biliary system (Table VIII). It is our impression that this procedure can be carried out with a mortality not materially greater than that in non-diabetic patients. Almost without exception these operations are done under novocain anesthesia. A minimum of exploration is done and the gall bladder or, in its absence, the common duct is anastomosed to the stomach or duodenum. A simple type of anastomosis such as is commonly used in gastro-intestinal work has proved adequate. In none of these cases has there been leakage, and we see no indication for the use of a foreign body such as a button or rubber tube.

Operations on the gastro-intestinal tract. That extensive operations on the gastro-intestinal tract may be carried out in patients with long-standing diabetes was well shown by a recent patient seen and operated upon by us at the request of Dr Joslin.

CASE No 5963. A man of 57 with a diabetes of 15 years' duration entered the George F. Baker Clinic on March 20,

Fig 6 a Roentgenogram showing a portion of the head of the fourth metatarsal inadvertently left following amputation of the fourth and fifth toes for osteomyelitis at another hospital b wound through which the head of the fourth metatarsal was completely removed and the fifth metatarsal shortened c roentgenogram following second operation showing satisfactory treatment of the metatarsals

citis among patients with diabetes. Moreover the diagnosis of appendicitis in these children is somewhat more difficult to make than in a non diabetic patient, and failure to recognize the presence of the disease may result more seriously. It is, therefore, a problem of increasing importance particularly since it would seem reasonable to suppose that an inflamed appendix which in a non diabetic child might well subside, might in a diabetic patient progress to perforation and peritonitis. We have seen a number of diabetic children entering the hospital for attacks of abdominal pain in which we were unable to make a diagnosis of appendicitis and at the same time the pain and symptoms were not associated with acidosis or with any evidence of urinary tract infection. We have operated upon at least 3 of these patients who have had previous attacks which we have seen them through and in whom we were unable to make a diagnosis primarily because of the absence of demonstrable localized tenderness. We deliberately operated upon each of these 3 children after the acute symptoms had subsided but before any inflammatory process of the appendix would have had time to disappear completely. In none of these 3 children did we find any evidence of pathology in the appendix, the regional glands or the lower 3 feet of ileum. We nevertheless feel that it is safer to remove a normal appendix in a diabetic child having recurring attacks of pain not otherwise explained than it is to run the risk of overlooking a mild appendicitis which at a later date and under less favorable circumstances may become acute and progressive.

In the child with diabetes which is controlled and has been controlled it would seem as though operation under proper conditions could be done with a mortality little if any higher than that in a non diabetic patient (Table VI). Early hospitalization and early operation for signs and symptoms suggestive of appendicitis is, we believe even more clearly indicated in the patient with diabetes than in the patient without it.

Operations upon the biliary tract. We do not believe in operation upon the so called stoneless gall bladder with indefinite digestive symptoms. We do advise operation upon a diabetic patient with digestive symptoms referable to gall stone demonstrated by x ray or because of recurrent attacks of pain characteristic of or consistent with that due to gall stones when associated with roentgenological evidence of cholelithiasis. We believe that the finding of stones even in the presence of very few symptoms is an indication for operation in a diabetic patient in otherwise good condition.

We believe that the risk of biliary tract disease as well as of biliary tract surgery is greater in the diabetic than in the non diabetic patient. Some of the patients operated upon in this group were extremely poor risks in which a mortality even in a non diabetic patient might have been accepted as a definite possibility. On the other hand a study of the fatal case shows at least 2 instances in which a fatal outcome was not anticipated and in our judgment should not have occurred (Table VII). Case No. 3469 died of a streptococcus

FACTORS DETERMINING SELECTION AND ADMINISTRATION OF ANESTHETICS

WESLEY BOURNE, M D , F R C P , Montreal, Canada

IN ANESTHESIA it is axiomatic that the drugs employed be chosen to suit the general condition as well as the surgical requirements of a given individual. This is equally true concerning the methods of their administration. Both become extremely important if the patient suffers some definite additional disability. It is well known that anesthetics are apt to disturb metabolism and to depress function. If these are already interfered with, the selection of the materials used and the modes by which they are given must be considered with the greatest care. While the desired and beneficial actions of anesthetics cannot be forgotten, the harmful effects may turn out to be manifold, indeed, all too often multiform, like *the wretchedness of earth*. Let us review a few of these ill-effects, those on the blood, the liver, and the kidneys, and let us remember, at this time, that the disturbances which take place in these parts do so concurrently and in an interdependent manner with the many other upsets in the rest of the organism. These disturbances are as various as the hues of the rainbow, as distinct, too, yet they are as intimately blended

EFFECTS OF ANESTHETICS

In the blood Of the many changes which anesthetics may produce in the blood, I shall confine my remarks to the two which seem more closely related to the subject under consideration, namely, blood concentration and acidosis. Barbour and I (1, 2, 3) have shown that ether anesthesia causes the blood solids to increase by 2 to 3½ per cent of the total weight of the blood. This enormous blood concentration was found to be due chiefly to the migration of water from the blood to the tissues, considerable increase in the water content of the muscles having been shown following the anesthetics of the more powerful drugs, chloroform and ether. This blood concentration effect can be lessened markedly by the copious use of water or dilute solutions before, during, or after narcosis.

This brings us to that very grave feature of dehydration so often seen in the handicapped

patient, and to an important point in the selection of anesthetics. Intravenous injections of blood and isotonic solutions should be made prior to anesthesia, and the less toxic substances, nitrous oxide and cyclopropane chosen for administration, or, at least in some instances, it may be more propitious to resort to some form of regional anesthesia. More attention, than is generally customary, ought to be paid to the dehydrated patient who is about to be operated upon.

That acidosis is very liable to occur as a result of anesthesia has been abundantly proved, and Roscher has shown that it may take place even after local or spinal anesthesia. Stehle and I (4, 25) have demonstrated that phosphoric acid leaves the muscles during ether anesthesia and is neutralized by the bases, sodium and potassium. The phosphates are stored to some extent in the liver and, after recovery, when kidney function is resumed, they are then redistributed and partly excreted. Ronzoni, Koechig, and Eaton have given evidence that the lactic acid of the blood is increased, which harmonizes with the idea that phosphates and carbohydrates are intimately associated in metabolism, there being a common precursor, a hexose phosphate, called by Embden *lactacidogen*. Just recently, Pratt has shown that there is considerable variation in the effects of anesthetics on the blood-sugar level, and that even cyclopropane is capable of raising the blood-sugar. He states, "There is little evidence to suggest that the rise of blood-sugar is other than a welcome physiological compensatory phenomenon." Be this as it may, acidosis becomes a serious matter for the handicapped patient, especially he who comes to operation already in a condition of acidosis, as for example, the child with severe vomiting or the diabetic. It is our bounden duty, therefore, carefully to select those anesthetic agents and methods of administration which are least likely to produce or to enhance the acidotic state.

The choice lies between cyclopropane with nitrous oxide as a diluent, and spinal or local anesthesia. Of this latter, I shall have more to say later on. Of the former, it is timely to point out that the superfluity of oxygen, which is always given with cyclopropane, will very considerably lessen and prevent what little acidosis this gas

Presented in the Symposium on Surgical Procedures on the Handicapped Patient, before the Clinical Congress of the American College of Surgeons, New York, October 17-21 1938

1938 because of abdominal pain diarrhea and loss of weight and strength. He had had a posterior gastroenterostomy for duodenal ulcer performed 10 years before. His surgical convalescence at that time was not a smooth one nor had he ever been completely relieved of his symptoms. In recent years he had had several severe hemorrhages and about 2 years before we saw him a diagnosis of gastrojejunal colic fistula had been made. In spite of this condition he had remissions when he was reasonably comfortable and was able to carry on with his work as a wool broker. Bowel movements in the hospital numbered from 10 to 15 in 24 hours sometimes more and followed immediately the ingestion of food or fluid by mouth. Palliative treatment was wholly unsuccessful. On April 6th 2 weeks after he was first seen a jejunostomy for feeding purposes was done. In spite of intensive efforts to improve his nutrition 2 weeks later his blood serum protein had diminished further from 5.3 per cent to 3.5 per cent and the diarrhea persisted just as though food were taken by mouth. On April 20th 1 month after he was first seen and 2 weeks after his jejunostomy laparotomy was performed. A clypeal type of operation was carried out. The transverse colon jejunum and lower two thirds of the stomach were removed between clamps. A he end-to-end anastomosis was done on the transverse colon and on the jejunum and fortunately the third portion of the duodenum was so placed that it was readily anastomosed to the open end of the stomach. A cecostomy was then done. The patient made an uneventful postoperative convalescence except that 19 days after operation he had a sudden massive hemorrhage in the middle of the night and 4 days later a second hemorrhage though not so large requiring in all 3 transfusions. From then on there were no further complications and he left the hospital on June 6th, 2½ months after admission symptom free and in excellent condition.

Examination of the specimen showed the stomach connected with the jejunum by an opening 2.5 centimeters in diameter the edges of which were smooth. The jejunum was connected with the colon by 3 openings the largest 3 centimeters in diameter each of the other 2 measuring 1 centimeter in diameter. In addition to these openings there was a jejunal ulcer 1.2 centimeters in diameter.

The number of operations which we have performed on the gastro intestinal tract is not large as shown in the accompanying table (Table IV). It is our belief however from this small experience and from a larger experience with gastro-intestinal surgery in non diabetics and in diabetic patients with other lesions that (1) whenever possible every resection of the large bowel should be a 2 stage procedure regardless of the apparent condition of patient (2) a preliminary transverse colostomy is preferable to cecostomy preceding resection and anastomosis in patients with an obstructing lesion of the left colon provided the patient is having obstructive symptoms and a cleansing of the bowel above the obstruction is found to be impossible in all other instances a preliminary cecostomy should be under-

taken and (3) because of the relationship between infection and diabetes great care should be taken in the selection and execution of the surgical procedure so as to assure a minimum of local soil ing.

SUMMARY

One thousand, two hundred and seventy six operations upon patients with diabetes mellitus are reported. The case mortality is 8 per cent.

The importance of considering the effect of the diabetes upon the patient's cardiovascular renal system is stressed.

Five hundred and thirteen operations for gangrene are reported with a mortality of 13.1 per cent. The mortality for major amputations is 13.1 per cent. A primary supracondylar amputation was done in 51.8 per cent of the cases. In 100 consecutive supracondylar amputations for gangrene 93 per cent healed by first intention in only 2 of the infected cases did the infection involve the fascia.

Two hundred and four patients with good local circulation have had amputations of 1 or more toes for osteomyelitis or recurrent ulceration. There were 4 deaths a mortality of 2 per cent. In 18 cases a higher amputation was necessary, in 184 or 90 per cent of these patients complete healing occurred.

Important technical considerations for the drainage of infected feet are given. The importance of early hospitalization and adequate surgical treatment of infections of the hand is stressed and the results in 70 such cases are summarized.

Carbuncles are considered as surgical lesions. Electrosurgical drainage after adequate local and general preparation is advocated. Results after operations for appendicitis and cholelithiasis are given and a successful resection of the jejunum transverse colon and stomach for gastrojejunal colic fistula is reported.

olism and of the effects of anesthetics on hepatic function, it is easy to see the importance of careful selection and administration of anesthetics in surgical procedures on the patient who suffers from liver disorders. Here again both methods and materials must be suited to the general condition as well as the special surgical requirements of a given individual. So much for some of the manifold amazements to be met in one organ.

In the kidney As changes, analogous to those which anesthetics produce in the liver, undoubtedly occur simultaneously in other organs, those which may take place in the kidney will be dealt with peremptorily. It has been known for a long time that anesthesia, generally, diminishes the volume of urine secreted, and data exist concerning the effect of anesthetics on metabolism as represented by the composition of the urine. In 1928, Stehle and I (26), by using dogs with fistulas in the bladder, showed that in ether anesthesia there is either a complete cessation in the formation of urine or a decided oliguria, that if the urea and the chloride concentrations are low in the control period, they may rise under ether anesthesia, but, when the initial concentrations are high, anesthesia causes a fall in the amounts and concentrations of the urea and chloride concentrations of the urine, and that a secretory mechanism is involved in contradistinction to the filtration-re-absorption theory regarding the secretion of urine. The previously mentioned blood concentration (1) found in ether anesthesia may now be seen to be closely associated with this diminished efficiency of the secretory process. Bruger, Dreyer and I (11) have made observations with avertin on dogs with bladder fistulas, and on man. We found that in the former anuria always occurred immediately after administration and lasted for a period varying between 15 minutes and 1 hour, after which marked oliguria supervened, whereas with the human cases, who received only one-fifth of the dose given to dogs, anuria did not take place, but there was pronounced oliguria. Nevertheless, throughout the periods of oliguria for both dog and man the percentage excretions of urea were always increased, which indicates that there is no evidence of severe kidney depression. During the postanesthetic period there is invariably an enormous excretion of phosphoric acid which is undoubtedly involved in the acidosis which was found to be present, and similar to that produced by ether. It has been shown by Waters and Schmidt that the urinary output is usually suppressed during cyclopropane anesthesia and a compensatory increase in excretion occurs several hours following anesthesia.

In fine, it may be said that all general anesthetics cause some depression of kidney activity, wherein the rate of secretion and composition of the urine is lowered. The degree of depression varies directly with the depth of narcosis and the effects are influenced by the condition of the kidneys, by the water content of the blood, and by the duration of anesthesia. With these factors in mind, it is evident that in surgical procedures on a patient handicapped by kidney disease, both the selection and the administration of anesthetics become matter and actuality of grave consequence.

CHOICE OF ANESTHESIA

Although it has been done rather discursively, yet I have attempted to show the close interrelationship of these 3 sets of ill-effects which occur in anesthesia, that is, upon the blood, the liver, and the kidney. So close is the connection that broadly they may be regarded as good examples of the disturbance which anesthetics produce on metabolism as a whole. This interpenetration of ill-effects simulates the great interlocking of the normal vital functions. It is timely, therefore, to consider more specifically a few of the salient features concerning the choice of anesthetics and the conduct of narcosis.

At once, that real emotion, fear, presents itself. In this most strenuous of Iron Ages, not nearly enough is being done adequately to assuage the throes of fear. We should cultivate the psychological approach rather than pooh-pooh it. We should win the patient's reliance by reassurances through soft voice and gentle gesture. Not until full confidence is gained will sedative drugs give their most favorable results. I believe that such drugs should be given more freely than is customary, but in smallish, repeated doses (especially for the aged or handicapped patient), begun sufficiently ahead of the time of operation in order that enough may be administered to almost completely obtund the activities of the cerebral cortex. Of the lot, it would seem that the combination of morphine and scopolamine is generally most desirable, and Waters (28), of the University of Wisconsin, who has been making observations with increased doses, finds "little if any change in oxygen consumption, a decreased minute volume with morphine alone, a slight increase with scopolamine alone, and a distinctly less reduction in the minute volume with the combination." These findings constitute an example of real synergism. Of course, when it is desirable to use avertin, this drug takes the place of morphine, and atropine only may be given with it. The most important reason for increased premedication is the removal

may perchance produce. With the proper alkaline state of the blood in view, whenever it is possible, the glycogen reserves of the body should be supported well before operation and after complete recovery from anesthesia. I dislike using glucose during operation because at this time there is apt to be hyperglycemia. It has long been my practice to administer a specially balanced hypotonic alkaline sodium and potassium phosphate solution immediately after operation, having demonstrated that nausea is markedly reduced and that this solution tends to stimulate the depressed individual (5). One pint of solution to every 50 pounds of body weight is given rectally. This bulky, watery and alkaline solution not only reduces the acidosis but lessens the blood concentration and hastens recovery. This solution contains potassium ions which have been shown by Nothmann and Wagner, and Nothmann and Guttmann to be the most stimulating to any depressed, living thing, especially when the phosphate anion is present and when the medium is alkaline. Thus in particular, the handicapped patient is led more readily to a salubrious state. Needless to say fluids are not to be given to the patient with edema such as that from cardiorenal insufficiency.

So much then from a pharmacological point of view for a consideration of some of the ill effects which anesthetics may produce on the blood. So much, too, in consequence, concerning the choice of the drugs and the conduct of narcosis.

On the liver. The liver, with its immensity, its double blood supply, its 200,000 (Sappey) lobules possessed of orderly innermost arrangements, its many vital processes assimilatory and secretory and its diurnal rhythmic activity is truly a prodigious organ, the greatest in the body. Notwithstanding the redundancy of this huge structure it is very vulnerable and its cells are extremely susceptible to insult, so that in the very performance of their functions these cells succumb all too easily. Yet they are endowed with remarkable regenerative powers as has been shown separately by several sets of careful observers and reviewed extensively elsewhere (6). Suffice it to say now that Mann and Magath have demonstrated that it is possible to remove all but the two lower right lobes of the dog's liver, or approximately 70 per cent without serious damage to the portal and vena cava circulation. The animals do not seem to suffer from such loss. The reason for this may readily be ascertained by examination a few months after operation when the two remaining lobes will be enlarged and the amount of tissue practically the same as before operation. However despite liver regeneration despite the normal

appearance of the tissue under the microscope it has been conclusively proved, since the introduction of dye tests, that complete functional recovery is not fully established for some considerable time later, at least following the administration of certain poisons like phosphorus or chloroform. In other words, such a physiological test is more sensitive than any estimate based on histological evidence.

More recently, Rosenthal and I (23) studied the effects of various anesthetics on the liver, as indicated by bile pigment disturbances and by the bromsulphalein dye test for hepatic function. One result of our study was the conviction that the dye test affords a much more definite index of injury to the liver cells than do estimations of bile pigments in the blood and urine. Even after 15 minutes of chloroform inhalation healthy dogs always show considerable impairment of liver function, indeed, the damage is frequently so severe that recovery is not effected for 8 or 9 days. Two hours of chloroform anesthesia requires all of 6 weeks for return to normal. When ether is used similarly, the functions of the liver are definitely affected and proportionately to the degree and length of narcosis they return to normal in about 48 hours even after a 2 hour period of anesthesia.

Our experiments with nitrous oxide, as well as with ethylene, showed that when sufficient oxygen is supplied, anesthesia from 1 to 2 hours produced neither immediate nor delayed impairment of hepatic function, whereas when the percentages of oxygen were purposely reduced, all the animals sustained an immediate impairment of function, which did not return to normal as with ether, but required about 6 days for recovery. This is an important lesson to learn, namely most carefully to avoid anoxemia during anesthesia.

Still more recently as investigations have revealed, that is, at least from a practical point of view, liver function is not disordered following the anesthetics produced by the derivatives of barbituric acid (7), by avertin (8) by univether (9), and absolutely not at all by cyclopropane (20). In each of these instances the basic work was done on dogs, and with each drug verification was obtained from observations made on man. It may be pointed out at this juncture that in so far as we are presently concerned, the physiology of the dog's liver is identical with that of man's except that the dog's is somewhat more resistant to poisons and most cogently, the dog's dose of each of these substances is much greater than that of man's. For example, in the case of avertin it is 5 times larger. With these apposite, but cursory, considerations of the rôle of the liver in metab-

Since ephedrine possesses a stimulating action upon the central nervous system in general, as has been shown by various authors and recently studied more specifically by Raginsky and Bourne (21), it seems reasonable to suppose that in conjunction with the prolonged effects upon the heart and circulation, the central nervous system action of ephedrine plays some rôle in the complete restitution of the shocked animal." The united action of these 2 chemical entities constitutes perhaps the best known example of synergism in pharmacology.

Recently, O'Shaughnessy and I, at the Grace Dart Home Hospital for Pulmonary Tuberculosis and at St Mary's Hospital, Montreal, have had cause to administer these 2 drugs 86 times, during that many spinal anesthetics, 23 in thoracic surgery and 63 for abdominal operations. Figures 2 and 3 are respectively illustrative. It may be stated that "2400" is the same "laboratory preparation" as used by Dr Melville and was made in the department of pharmacology of McGill University. In the period of time over which this analeptic mixture was given during anesthesia on 86 occasions, there were 199 spinal cases at the two hospitals. The 113 others did not require analeptics during their operation periods, thus, herein is a proof of the firm belief which I have held for some time, namely, that analeptics should not be used routinely nor in anticipation of shock. They tend to stimulate the central nervous system. Raginsky and I (21), have shown that ephedrine reverses the effects of avertin and will undo the desired and purposely produced actions of morphine and scopolamine. What is more, it is known that stimulating drugs may cause contrary results when used in normal beings or prior to an indication. Again, the fact that analeptics were not needed in so many of these cases tends to prove the statements made above in favor of complete sedation, particularly that "there will be much less fall in blood pressure than otherwise."

Figures 2 and 3, with their legends, require little further elucidation. It will be seen in Figure 2 that the mixture of ephedrine and pituitary extract was given twice. This is seldom necessary. Usually, when it is deemed advisable to use these materials, their hypodermic administration will suffice. The intravenous avenue is not recommended unless the patient is very far gone (it was hardly indicated in the case recorded in Figure 2), because, on occasion, when this mixture is placed directly into the blood stream, the blood pressure and pulse rate will rise very alarmingly high.

¹Of the pituitary extract preparations on the market, that known as pitressin has the greatest amount of pressor principle.

Fig 2 M L, a male, 24 years of age, date of operation was January 19, 1938, thoracoplasty performed first, second, and third ribs, left. At 2:00 p.m. one-fourth grain of morphine and one-hundredth grain of scopolamine were administered, at 3:00 p.m. one-fourth grain of morphine and one-hundredth grain of scopolamine were again administered. In both instances these were injected subcutaneously. A, Spinal injection of 14 cubic centimeters of one-fifteen hundredths of percaine solution, Etherington-Wilson technique, patient sitting up for 55 seconds, B, 5 units of "2400" with three-eighths grain of ephedrine injected hypodermically, C, operation begun, D, 5 units of "2400" with three-eighths grain of ephedrine given intravenously, E, operation finished, one-fifteenth grain of strychnine was administered subcutaneously, and 1000 cubic centimeters of 5 per cent dextrose was given intravenously.

In the case recorded in Figure 3 there was a moderate fall in blood pressure attendant on the intrathecal injection of percaine, a subsequent marked fall during the manipulations of the pylorus, and an excellent recovery following the hypodermic administration of the mixture of ephedrine and pituitary extract. It is pointed out at this time that we should not expect too much from this analeptic mixture. Other well established measures must not be neglected, indeed, the body fluids ought all the more to be sustained. Recently we have been in the habit of giving strychnine, 1/15 of a grain at the end of operation, and 1/30 of a grain every 4 hours after, for 3 more doses. This practice is rather empirical, but it is thought

Fig 1. Respiration and blood pressure tracings time recorded in minutes dog female 6.4 kilograms operative procedures under ether anesthesia. A Injection of histamine (0.5 milligram per kilogram per minute for 16 minutes) was started. B histamine stopped. C 10 minutes later a mixture containing 1 milligram per kilogram of ephedrine sulfate and 0.5 milligram per kilogram of pituitary extract (laboratory preparation) was injected. D E and F were 15, 30 and 60 minutes later respectively ether was required after E to keep the animal quiet.

of fear. The apprehensive, the frightened individual will all too often become severely shocked, particularly in spinal or other forms of regional anesthesia. If sedation is complete, there will be much less fall in blood pressure than otherwise little or no nausea and an agreeable grade of amnesia. With the exception of those who are *in extremis* I see no contraindication to the use of sedative drugs in the case of the handicapped patient, all the more as it is recommended that small doses be given and only repeated in accordance with their effects.

Analeptics. At this juncture it may not be amiss to turn our attention to the analeptics. We have so little of exact knowledge about this group of drugs. I shall do no more than draw attention to some more or less recent work on the subject. Melville of the department of pharmacology of McGill University has demonstrated that when the pressor principle of posterior pituitary extract is mixed with ephedrine and administered to experimentally shocked dogs, the result is more effective than larger individual quantities of these

drugs in restoring blood pressure and respiration and in abolishing general collapse. Histamine causes a precipitous fall in blood pressure with marked slowing and irregularity of respiration so that the dog finally dies. If to such a shocked dog 2 milligrams per kilogram of ephedrine or 1 milligram per kilogram of pituitary extract is injected in either case, there results a temporary rise in blood pressure with some temporary restoration of respiration, but the animal rapidly relapses and dies shortly. If now, as is shown in Figure 1 (by permission of Dr Melville), a similarly shocked dog is given intravenously a mixture containing 1 milligram per kilogram of ephedrine sulphate and 0.5 milligram per kilogram of pituitary extract, there occurs a sudden marked rise in blood pressure which is well maintained, the respiration becomes also definitely improved and soon owing to the apparent recovery of the animal, ether must be again administered. 'The effects are presumably not due solely to the circulatory actions of ephedrine and pituitary extract to arteriolar (ephedrine) and capillary (pituitary) constriction

Since ephedrine possesses a stimulating action upon the central nervous system in general, as has been shown by various authors and recently studied more specifically by Raginsky and Bourne (21), it seems reasonable to suppose that in conjunction with the prolonged effects upon the heart and circulation, the central nervous system action of ephedrine plays some rôle in the complete restitution of the shocked animal." The united action of these 2 chemical entities constitutes perhaps the best known example of synergism in pharmacology.

Recently, O'Shaughnessy and I, at the Grace Dart Home Hospital for Pulmonary Tuberculosis and at St. Mary's Hospital, Montreal, have had cause to administer these 2 drugs 86 times, during that many spinal anesthetics, 23 in thoracic surgery and 63 for abdominal operations. Figures 2 and 3 are respectively illustrative. It may be stated that "2400" is the same "laboratory preparation" as used by Dr. Melville and was made in the department of pharmacology of McGill University. In the period of time over which this analeptic mixture was given during anesthesia on 86 occasions, there were 199 spinal cases at the two hospitals. The 113 others did not require analeptics during their operation periods, thus, herein is a proof of the firm belief which I have held for some time, namely, that analeptics should not be used routinely nor in anticipation of shock. They tend to stimulate the central nervous system. Raginsky and I (21), have shown that ephedrine reverses the effects of avertin and will undo the desired and purposely produced actions of morphine and scopolamine. What is more, it is known that stimulating drugs may cause contrary results when used in normal beings or prior to an indication. Again, the fact that analeptics were not needed in so many of these cases tends to prove the statements made above in favor of complete sedation, particularly that "there will be much less fall in blood pressure than otherwise."

Figures 2 and 3, with their legends, require little further elucidation. It will be seen in Figure 2 that the mixture of ephedrine and pituitary extract was given twice. This is seldom necessary. Usually, when it is deemed advisable to use these materials, their hypodermic administration will suffice. The intravenous avenue is not recommended unless the patient is very far gone (it was hardly indicated in the case recorded in Figure 2), because, on occasion, when this mixture is placed directly into the blood stream, the blood pressure and pulse rate will rise very alarmingly high.

¹Of the pituitary extract preparations on the market, that known as pitressin has the greatest amount of pressor principle.

Fig 2 M L, a male, 24 years of age, date of operation was January 19, 1938, thoracoplasty performed first, second, and third ribs, left. At 2:00 p.m. one-fourth grain of morphine and one-hundredth grain of scopolamine were administered, at 3:00 p.m. one-fourth grain of morphine and one-hundredth grain of scopolamine were again administered. In both instances these were injected subcutaneously. A, Spinal injection of 14 cubic centimeters of one-fifteen hundredths of percaine solution, Etherington-Wilson technique, patient sitting up for 55 seconds, B, 5 units of "2400" with three-eighths grain of ephedrine injected hypodermically, C, operation begun, D, 5 units of "2400" with three-eighths grain of ephedrine given intravenously, E, operation finished, one-fifteenth grain of strychnine was administered subcutaneously, and 1000 cubic centimeters of 5 per cent dextrose was given intravenously.

In the case recorded in Figure 3 there was a moderate fall in blood pressure attendant on the intrathecal injection of percaine, a subsequent marked fall during the manipulations of the pylorus, and an excellent recovery following the hypodermic administration of the mixture of ephedrine and pituitary extract. It is pointed out at this time that we should not expect too much from this analeptic mixture. Other well established measures must not be neglected, indeed, the body fluids ought all the more to be sustained. Recently we have been in the habit of giving strychnine, 1/15 of a grain at the end of operation, and 1/30 of a grain every 4 hours after, for 3 more doses. This practice is rather empirical, but it is thought

Fig. 1. Respiration and blood pressure tracings time recorded in minutes dog female 6.4 kilograms operative procedures under ether anesthesia. A Injection of histamine (0.5 milligram per kilogram per minute for 16 minutes) was started. B histamine stopped. C 10 minutes later a mixture containing 1 milligram per kilogram of ephedrine sulfate and 0.5 milligram per kilogram of pituitary extract (laboratory preparation) was injected. D E and F were 15, 30 and 60 minutes later respectively ether was required after E to keep the animal quiet.

of fear. The apprehensive, the frightened individual will all too often become severely shocked particularly in spinal or other forms of regional anesthesia. If sedation is complete, there will be much less fall in blood pressure than otherwise little or no nausea and an agreeable grade of amnesia. With the exception of those who are in extremis, I see no contra indication to the use of sedative drugs in the case of the handicapped patient all the more as it is recommended that small doses be given and only repeated in accordance with their effects.

Analeptics. At this juncture it may not be amiss to turn our attention to the analeptics. We have so little of exact knowledge about this group of drugs. I shall do no more than draw attention to some more or less recent work on the subject. Melville of the department of pharmacology of McGill University has demonstrated that when the pressor principle of posterior pituitary extract is mixed with ephedrine and administered to experimentally shocked dogs, the result is more effective than larger individual quantities of these

drugs in restoring blood pressure and repiration and in abolishing general collapse. Histamine causes a precipitous fall in blood pressure with marked slowing and irregularity of respiration so that the dog finally dies. If to such a shocked dog 2 milligrams per kilogram of ephedrine or 1 milligram per kilogram of pituitary extract is injected in either case there results a temporary rise in blood pressure with some temporary restoration of respiration, but the animal rapidly relapses and dies shortly. If now as is shown in Figure 1 (by permission of Dr. Melville) a similarly shocked dog is given intravenously a mixture containing 1 milligram per kilogram of ephedrine sulphate and 0.5 milligram per kilogram of pituitary extract, there occurs a sudden marked rise in blood pressure which is well maintained the respiration becomes also definitely improved and soon owing to the apparent recovery of the animal ether must be again administered. The effects are presumably not due solely to the circulatory actions of ephedrine and pituitary extract, to arteriolar (ephedrine) and capillary (pituitary) constriction

But, in execution, local infiltration, field block, and the different forms of nerve block anesthesia are found by a large number of surgeons to be tedious and time consuming. Spinal anesthesia, on the other hand, has become more particularly a part of the duties of the anesthetist and, in consequence, not only is the surgeon freed of the bother of it, but, through increased individual experience, the dangers have become almost negligible. The advantages of spinal anesthesia are very great, especially on account of the muscular relaxation and the excellent recovery. O'Shaughnessy and I (10, 14), have had very satisfactory results with the Etherington-Wilson technique for spinal anesthesia in more than 1200 cases. It would seem that spinal anesthesia is only contraindicated wherein, for one reason or another, the fall in blood pressure, which it frequently causes, is to be feared, as for example, in advanced cardiovascular disease. As mentioned before, it is very strongly recommended that relatively large quantities of depressant drugs be given prior to the production of all forms of regional anesthesia, that is, sufficient to thoroughly subdue the activity of the cerebral cortex and so replace fear by considerable bemusement.

General. Even for the patient who comes to operation without some additional disability, it is becoming more and more universally conceded that even ether anesthesia may be eschewed and place given to less disagreeable and less harmful substances. If this be true, then, how much more so must it be in the case of the handicapped individual. For the production of general anesthesia, I know of no better combination than avertin as a clyster to the patient in bed, about half an hour before the operation time—atropine may be given simultaneously—followed in the operating room by a mixture of cyclopropane, nitrous oxide and oxygen. The main object of the nitrous oxide is that of a diluent. More often than otherwise, it is advantageous to give these gases by the intratracheal method. In all cases of operations about the head, neck and chest (one thinks more particularly of those on the brain and on the thyroid gland) this method precludes respiratory obstruction and obviates interference with the surgical procedure from the anesthetist. This method also gives absolute assurance of a plentiful supply of oxygen directly to the lungs. Oxygen is always beneficial in anesthesia, and especially so in the incidents of blood dyscrasias, cardiac disorders, liver or kidney affections, and disturbances in general metabolism. Again this intratracheal method affords quieter breathing and a softer abdomen even though narcosis is not profound.

Combination of regional with general anesthesia. With respect to a combination of regional and general anesthesia, exigencies may arise in which there exist some good reasons against the use of pre-anesthetic drugs, or, at least, of large doses of them, then, for psychological purposes, the gases may be given together with the production of whatever form of regional anesthesia is chosen. The one supplements and enhances the power of the other, much loss of the gases is required, and, then, too, the patient is all the better for the copious supply of oxygen contingent upon the performance. There are several surgeons and anesthetists who are very much in favor of the combination of these 2 procedures.

SUMMARY

1. Some of the effects of anesthetics on the blood, the liver, and the kidney are reviewed. As their interrelationship is explained, these effects are shown to be good examples of the disturbances which anesthetics produce on metabolism as a whole.

2. The blood concentration, the acidosis, and the impairments of the functions of the liver and kidney as well, which anesthetics may cause, are shown to be alleviated by the rectal administration of large quantities of a hypotonic solution of alkaline sodium and potassium phosphates.

3. In order properly to allay fear, relatively large doses of cerebral depressants are advocated, principally avertin or morphine and scopolamine.

4. It is shown that comparatively large amounts of morphine and scopolamine do no harm.

5. Analeptics are considered, and a mixture (Melville) of ephedrine with the pressor principle of posterior pituitary extract is recommended.

6. Data are presented concerning the clinical use of this mixture in spinal anesthesia.

7. The present liberal use of carbon dioxide is strenuously deprecated and reasons are given (Waters, 29).

8. For the handicapped patient, one of three procedures is recommended, namely, regional anesthesia, particularly spinal, general anesthesia with the gases, nitrous oxide and cyclopropane, especially by the intratracheal method; or, a combination of the two.

that through the action of strychnine on the spinal cord, muscle tone might be improved following spinal anesthesia

Before we leave the topic of analeptics a few remarks upon carbon dioxide are relevant Waters (29) has shown that carbon dioxide may produce convulsions that surgical shock is not the result of low carbon dioxide in the blood and tissues, that anesthesia does not cause a lowering of the carbon dioxide content of the blood and tissues that postoperative pulmonary atelectasis is not necessarily prevented by carbon dioxide and oxygen and that carbon dioxide is a waste product of body metabolism just as are the constituents of urine Waters advises never to apply carbon dioxide therapy or rebreathing to prevent or ameliorate shock Simple oxygen therapy is more satisfac-

tory During anesthesia, dead space and rebreathing ought to be avoided as much as possible, and the carbon dioxide of the expired air removed by soda lime Waters uses carbon dioxide solely as an analeptic when it is desirable to accomplish rapid elimination of toxic volatile gases and then a small stream of pure carbon dioxide is directed toward the face These teachings, although directly antithetical to those of Vandell Henderson seem sound It may be that untold harm has been done during the widespread employment of carbon dioxide, especially in anesthesia It may be that the more its value as a drug is magnified, by so much the more will its true physiological significance be forever kept in mind We must be wary of its use in the case of the handicapped patient

ANESTHETIC PROCEDURES

Thus far I have repeatedly emphasized the importance of carefully selecting those anesthetic agents and methods of administration that are least likely to supplement any pathological condition which may exist in a patient about to be operated upon I shall now be more specific, and state positively that in the light of our present knowledge we may make selection from 1 of 3 procedures, namely regional anesthesia that is local or spinal general anesthesia with the gases nitrous oxide and cyclopropane or, a combination of the two All other forms of anesthesia seem to be contra indicated in the case of any kind of handicapped patient In discussing these 3 procedures, I shall consider the anesthetic materials jointly with the means of their administration and try to show their suitability to the various types of handicapped patients which, broadly, may be regarded under the themes anesthesia in brain surgery anesthesia in cases of toxic goiter, that for thoracic surgery, chiefly pulmonary for those with cardiovascular disorders, wherein there is myocarditis or failing compensation, those with impairment of liver function, for those suffering from the effects of intestinal obstruction those with diseased kidneys, and, anesthesia on the occasion when the additional of safety is some blood dyscrasia Properly to investigate such a large question, or set of questions while it might yield great advantages is beyond the scope of this paper, yet some relevant inklings will be made

Regional Procaine nupercaine and pontocaine are the drugs just now in favor for producing regional anesthesia Virtually they cause little, if any impediment in the vital processes Their employment should therefore be encouraged

SYMPOSIUM ON UROLOGIC INFECTIONS

RENAL INFECTION AND NEPHROLITHIASIS

GEORGE GILBERT SMITH, M D , F A C S , Boston, Massachusetts

THE number and excellence of recent articles dealing with nephrolithiasis bear witness to the importance of this disease. It is no longer sufficient for the surgeon to remove the calculus, he must make every effort to secure satisfactory drainage of the affected kidney, he must take cognizance of the composition of the stone, so that by proper diet the patient may render his urine as unfavorable as possible for the formation of a similar stone, he must seek to uncover any metabolic disorder such as cystinuria or hyperparathyroidism predisposing to stone formation, and perhaps most important of all, he must clear up whatever infection exists in the kidney. Unless these objectives are achieved, the stone is likely to recur, and recurrent renal stone may be almost as fatal as is cancer.

These facts are well recognized, but we are far from having reached the point where we can prevent recurrence in all cases. This paper is concerned with a discussion of the infectious phase of the problem. The material upon which it is based comprises some 30 cases. These patients with renal stone were operated upon within the past 5 years, and the laboratory data are reasonably complete. Within that period, at least in our clinic, we have become much more aware of the value of chemical and bacteriological studies. Our education in this direction has in large measure been due to the co-operation of Doctor Fuller Albright, who has contributed a great deal to our understanding of the underlying causes of stone formation.

In working over this series of cases, one finds many regrettable gaps in the recording of cultures, stone analyses, and urinary findings. However, enough factual evidence has been recorded to enable us to make a number of deductions.

It is possible that infection outside the urinary tract is a factor in calculus formation, Randall (13) has shown that many renal stones develop on calcareous plaques located beneath the mucosa

at the apices of the pyramids, and has reproduced this lesion in animals by the administration of stable streptococcus hemolysin leucocidin. The experiments of Rosenow, in which he brought about the formation of stone in rabbits by injecting into their blood stream streptococci from devitalized teeth, suggest another possible cause of stone formation from extrarenal foci of infection.

Aseptic stones In this series, 5 patients had sterile urine when first examined. The stones in 4 were predominantly phosphatic in spite of the fact that the bladder urine was acid in reaction. There was no record of the composition of the fifth stone. In 4 the stones were multiple, in 1, single. One patient was proved by operation to have a parathyroid tumor. Although this small series of cases does not show it, we believe that many oxalate stones are not infected when first seen.

A discussion of the causation of aseptic calculi does not come within the scope of this paper. We must recognize the fact that in perhaps the majority of cases of nephrolithiasis, urine from the affected kidney shows no growth. Schneider, in a series of 181 stones, both renal and ureteral, found the urine infected in but 57.

Bacillus coli When we considered the bacteriological findings, both pre-operative and post-operative, in these 30 patients, we found that the *Bacillus coli* was the most frequent invader. It occurred 17 times, chiefly in conjunction with other bacteria and following operation. In 4 patients the *Bacillus coli* was found alone at the first examination, the calculus in 1 of these patients was phosphatic, in another it was composed of uric acid. There was no record of its composition in 2. Fisch states that *Bacillus coli* infection tends to form stones of calcium oxalate. It is my impression that as regards the problem of recurrent stone, the *Bacillus coli* is of no great importance. The organism can usually be killed by mandelic acid or prontosil, or even by methenamine plus acidification, provided there is good renal drainage. None of the patients with recurrent stones showed the *Bacillus coli* alone. Von Illyès says that the *Bacillus coli* can reduce the acidity

you will find *Bacillus proteus*. On reviewing the history of the patient, you may find one critical moment when a more determined effort to clear up the infection, more radical surgery for the improvement of renal drainage, or even nephrectomy might have saved the second kidney from disaster.

The chief reason why a *proteus* infection is so troublesome is that this bacillus is one of the most active of the urea-splitting organisms. The importance of these bacteria was pointed out years ago by Rovsing, who found that 71 per cent of all recurrent stones developed in kidneys which were infected primarily or secondarily by organisms with this characteristic. Hager and Magath in 1926, wrote an excellent paper on the rôle of the *Bacillus proteus* in alkaline cystitis. Hellstroem has found that if sterile urine is inoculated with the *Bacillus proteus* and incubated, it becomes alkaline and crystals of ammonium and magnesium phosphates are formed. In kidneys infected with this organism, calculi composed of triple phosphates may form very rapidly, sometimes within a few months. Occasionally one finds a *Bacillus proteus* which grows in an acid urine. In determining this point, one must not accept the reaction of the bladder urine at its face value. The acidity of the total urine may be due to a highly acid urine from the uninfected kidney, whereas that from the infected kidney is definitely alkaline. This evidence is easily obtained by means of nitrazene paper, and should be routinely checked whenever ureteral specimens are obtained.

The significance of these infections has been emphasized in all recent articles on renal stones. Twinem, writing on recurrences after operations for nephrolithiasis, says that in 10 cases of this type, he found the *Bacillus proteus* in 6, staphylococcus in 2, the *Bacillus lactis aerogenes* in 1, and the *Bacillus proteus* and the *Bacillus fluorescens* in 1. Barney and Sulkowitch give an excellent summary of the situation.

Staphylococcus. In 6 patients, the staphylococcus was found in the stone-bearing kidney prior to operation. In 1 of these patients, it was in combination with the *Bacillus proteus*. In the kidneys from which it was obtained in pure culture, the calculus was composed of phosphates in 2, of ovalates in 1. In 2 of these patients a primary nephrectomy was done. In the other, the urinary infection cleared up after operation.

The staphylococcus is often referred to as one of the urea-splitting bacteria. Pillet and Hellstroem have demonstrated this, Eisenstaedt tested 23 strains of staphylococci for this characteristic and found that 7 strains were definitely able to

Fig 1 Recurrent phosphatic calculus

split urea. Ammonium carbonate was formed. In the cases we are reporting, the staphylococcus has not been associated with recurrent stones. Albright is under the impression that the *Staphylococcus albus* splits urea and is susceptible to prontosil, whereas the *Staphylococcus aureus* is not a urea-splitter and is prontosil resistant.

Bacillus pyocyaneus. The *Bacillus pyocyaneus* occurred once. The patient showed bilateral renal calcification. His cultures showed in addition the *Bacillus proteus*, the *Bacillus coli*, and the alpha hemolytic streptococcus. After 2 series of treatments with prontosil, the above organisms disappeared, leaving the *Bacillus pyocyaneus* in pure culture. Intensive treatment lasting a full year failed to clear up this infection.

Roedelius reports a case of recurrent stone formation after pyelolithotomy in which the *Bacillus pyocyaneus* was the infecting agent. The first stone was an aseptic ovalate calculus, Roedelius believed that the *Bacillus pyocyaneus* entered the kidney by way of the drainage tract, starting from an unsterile, urine-soaked, outer dressing. The second stone was phosphatic, although the urine was acid. All known measures directed toward eradicating this organism were tried without success and eventually nephrectomy was done. The kidney showed a number of small abscesses,

of the urine (an important factor in the formation of recurrent stone), but clinical experience seems to show that it is not an organism to be feared.

Bacillus proteus The organism next in frequency to the *Bacillus coli* was the *Bacillus proteus*, public enemy No. 1 in the field of renal stone. We found it in 13 of our 30 patients. In only 4 instances was it present in pre-operative cultures, in the remaining 9 it appeared at varying intervals after operation. There were 5 patients whose kidneys were drained by a nephrostomy tube who did not develop a proteus infection, and 5 in whom the proteus first appeared after a nephrostomy. Seven pyelotomies without renal drainage were done, none of these developed a proteus infection. Fuller Albright has said that he has seen no instance of proteus infection in a patient who had not been subjected to urological instrumentation. In this series there were 2 patients who showed the *Bacillus proteus* in ureteral specimens at the time of their first cystoscopic examination. Both were women who had borne children so it is possible that they might have been catheterized at some time in the past. We believe, however, that primary proteus infection may occur, and we shall continue to search for an example of this which shall be beyond question.

It is disturbing to believe that so useful a procedure as nephrostomy may carry with it the danger of introducing the *Bacillus proteus*. Some of our urological staff hold the opinion that the continued presence of a rubber tube within the kidney is in some way responsible. It seems to me that the most probable explanation of the development of a *Bacillus proteus* infection after nephrostomy is that the organisms gain entrance to the kidney pelvis through the open channel of the tube during the postoperative period. We have not always been careful to keep the outer end of the tube free from contamination, and in a ward where there are always several patients with proteus infection, the bacillus may be introduced through careless handling of the tube through irrigations, or by letting the tube lie in infected urine.

Recent infections by the *Bacillus proteus* usually have not been difficult to eradicate, provided one realized the situation and at once applied the proper measures. The nature of these measures will be considered later.

A case which illustrates the importance of a proteus infection is that of a man 37 years of age who in October 1937 had a stone removed from his left kidney by pyelotomy. He was operated upon at another hospital, so we have not all the details of his history, but we do know that the stone was composed of a nucleus of uric acid and an outer layer of carbonates. The uric acid must have been

precipitated from an acid urine; the uric acid stone may then have led to infection, an alkaline urine and finally precipitation of carbonates. The surgeon found some constriction at the ureteropelvic junction which he dilated. Following operation the patient was given protilyn for 5 days, was put on an acid ash diet, and had the renal pelvis lavaged a number of times. His bladder urine which he tested frequently, remained acid. We do not know about the urine from his left kidney. In July 1938 9 months after his operation x-rays showed a 2 by 1 centimeter calculus in the left renal pelvis. A pyelogram showed a definite dilatation of the pelvis with apparent narrowing at the ureteropelvic junction. The urine from the right kidney showed a hydrogen ion concentration of 5.0 that from the left a hydrogen ion concentration of 7.5. The *Bacillus proteus* in pure culture was obtained from the left kidney. Both renal functions were good.

On September 9, 1938 the stone was removed through a pyelotomy incision, and proved to be composed of phosphates. A plastic was done on the ureteropelvic junction and the pelvis drained by a No. 24 French catheter drawn through the cortex. This was removed in 12 days as it was not draining too well, the sinus closed promptly. Between September 15 and 20 the patient was given 500 grains of sulfanilamide but did not tolerate it well. An intravenous pyelogram on September 29, 3 weeks after operation showed some dilatation of the pelvis. A left ureteral specimen on September 30 was slightly cloudy with 30 to 50 pus cells per high power field. The hydrogen ion concentration was 5.5. The culture showed the *Bacillus proteus* and the *Bacillus coli*.

In vitro studies on the susceptibility to protilyn of his strain of *Bacillus proteus* as advocated by Long and Ehlers showed the following results. With an inoculation of about 200 organisms per cubic centimeter of urine, bacteriostasis started at 100 milligrams of protilyn per 100 cubic centimeters; the bacteria were killed by 500 milligrams per 100 cubic centimeters but not by 300 milligrams. The pelvis was irrigated and 1 per cent mercurichrome instilled. The patient was discharged from the hospital October 1 with instructions to force fluids, to take an acid ash diet, methenamine and ammonium chloride and to return for observation and possibly further pelvic lavage. If other measures fail, another more heroic trial of protilyn therapy would be considered.

Of the 5 patients in this series with recurrent stones 4 were infected with the *Bacillus proteus*. One was a typical stone former. In February 1935 this patient passed a stone from his left kidney. In November of the same year left ureterolithotomy was done. In February 1936 a left pyelolithotomy in October 1936 a right nephrolithotomy. Eventually the *Bacillus proteus* and the *Bacillus coli* infection cleared up under protilyn and mandelic acid therapy, but the left kidney showed no excretion of skodan and by retrograde pyelography irregular dilated calyces were demonstrated.

Cases similar to this can be called to mind by any urologist. Perhaps one kidney has been destroyed by repeated attacks of stone and has had to be removed. The other kidney meanwhile has become infected and possibly has required a permanent nephrostomy to keep it functioning at all. Stones continue to form, the renal tissue due to infection and poor drainage becomes increasingly inadequate. It is amazing to see on the autopsy table how little renal tissue suffices to support life. In most cases of this type I believe

you will find *Bacillus proteus*. On reviewing the history of the patient, you may find one critical moment when a more determined effort to clear up the infection, more radical surgery for the improvement of renal drainage, or even nephrectomy might have saved the second kidney from disaster.

The chief reason why a proteus infection is so troublesome is that this bacillus is one of the most active of the urea-splitting organisms. The importance of these bacteria was pointed out years ago by Rovsing, who found that 71 per cent of all recurrent stones developed in kidneys which were infected primarily or secondarily by organisms with this characteristic. Hager and Magath in 1926, wrote an excellent paper on the rôle of the *Bacillus proteus* in alkaline cystitis. Hellstroem has found that if sterile urine is inoculated with the *Bacillus proteus* and incubated, it becomes alkaline and crystals of ammonium and magnesium phosphates are formed. In kidneys infected with this organism, calculi composed of triple phosphates may form very rapidly, sometimes within a few months. Occasionally one finds a *Bacillus proteus* which grows in an acid urine. In determining this point, one must not accept the reaction of the bladder urine at its face value. The acidity of the total urine may be due to a highly acid urine from the uninfected kidney, whereas that from the infected kidney is definitely alkaline. This evidence is easily obtained by means of nitrazene paper, and should be routinely checked whenever ureteral specimens are obtained.

The significance of these infections has been emphasized in all recent articles on renal stones. Twinem, writing on recurrences after operations for nephrolithiasis, says that in 10 cases of this type, he found the *Bacillus proteus* in 6, staphylococcus in 2, the *Bacillus lactis aerogenes* in 1, and the *Bacillus proteus* and the *Bacillus fluorescens* in 1. Barney and Sulkowitch give an excellent summary of the situation.

Staphylococcus In 6 patients, the staphylococcus was found in the stone-bearing kidney prior to operation. In 1 of these patients, it was in combination with the *Bacillus proteus*. In the kidneys from which it was obtained in pure culture, the calculus was composed of phosphates in 2, of oxalates in 1. In 2 of these patients a primary nephrectomy was done. In the other, the urinary infection cleared up after operation.

The staphylococcus is often referred to as one of the urea-splitting bacteria. Pillet and Hellstroem have demonstrated this, Eisenstaedt tested 23 strains of staphylococci for this characteristic and found that 7 strains were definitely able to

Fig 1 Recurrent phosphatic calculus

split urea. Ammonium carbonate was formed. In the cases we are reporting, the staphylococcus has not been associated with recurrent stones. Albright is under the impression that the *Staphylococcus albus* splits urea and is susceptible to prontosil, whereas the *Staphylococcus aureus* is not a urea-splitter and is prontosil resistant.

Bacillus pyocyaneus The *Bacillus pyocyaneus* occurred once. The patient showed bilateral renal calcification. His cultures showed in addition the *Bacillus proteus*, the *Bacillus coli*, and the alpha hemolytic streptococcus. After 2 series of treatments with prontosil, the above organisms disappeared, leaving the *Bacillus pyocyaneus* in pure culture. Intensive treatment lasting a full year failed to clear up this infection.

Roedelius reports a case of recurrent stone formation after pyelolithotomy in which the *Bacillus pyocyaneus* was the infecting agent. The first stone was an aseptic oxalate calculus, Roedelius believed that the *Bacillus pyocyaneus* entered the kidney by way of the drainage tract, starting from an unsterile, urine-soaked, outer dressing. The second stone was phosphatic, although the urine was acid. All known measures directed toward eradicating this organism were tried without success and eventually nephrectomy was done. The kidney showed a number of small abscesses,

Fig 2 A pyelogram obscures the calculus and shows a constriction at the ureteropelvic junction

Fig 3 An intravenous pyelogram 3 weeks after removal of stone

the pelvic mucosa was raw and in places necrotic. A somewhat similar case had been reported by Fraenkels who according to Roedelius was the first to describe the serious consequences which might follow infection by the *Bacillus pyocyaneus*. That it is not always so pathogenic is shown by a patient recently examined, from whose ureteral specimens the *Bacillus pyocyaneus* was grown in pure culture. In spite of a considerable degree of lower ureteral obstruction due to cancer of the cervix and radiation this patient showed little evidence of toxicity or of renal damage due to infection.

Although they are not included in this series I would like to mention 3 cases of renal infection with an organism thought to be the *Bacillus influenzae*. These have already been reported by Fuller Albright. Two of these patients showed bilateral stones with a tendency to calcification of the kidney tissue. The third who was the wife of one of these had a bilateral infection with the same organism but with no calculi. The urine of the 2 patients with stones was alkaline, the stones were phosphatic.

The treatment of renal infection for the purpose of preventing recurrent stone formation resolves itself largely into the eradication of the *Bacillus*

proteus. The bacteria which do not split urea are relatively unimportant as regards stone formation as a matter of course every infection should be cleared up if it is possible to do so. The staphylococcus infections have usually disappeared after the removal of the stone. If they persist I believe that intravenous administration of 0.3 of a gram of neo arspenamin every 3 to 5 days for 4 to 6 treatments, is highly effective. I have used this treatment only in 3 cases but in every instance the infection cleared up. It is advised by Braasch, Anson, Clark, Keyser and other urologists of experience.

The treatment of the *Bacillus proteus* infection may be divided into its medical and its surgical phases. The use of drugs such as mandelic acid and methenamine which are active only in highly acid urine is of course irrational since it is very difficult to alter the urinary reaction when urea splitting organisms are involved. Our most effective acidifier ammonium chloride simply provides more urea for the bacteria to act upon. Chute has cited an instance in which stone recurred very quickly following its use in a kidney infected with the *Bacillus proteus*. Sulkowitch has suggested the use of strontium chloride. Sick has employed gluconic acid.

Fig 4 Bilateral calcification of the kidney due to the *Bacillus influenzae*

With the introduction of prontylin, the need for an acidifying agent has seemed less urgent. Reports as to the success of this drug have been somewhat conflicting. In my own experience, the infection has yielded to a relatively small dose—40 grains a day—with improvement evident 4 or 5 days after treatment was started, or the infection has not yielded at all. I must confess that in some instances my courage has not been equal to the occasion. I have been so terrified by the appearance of the patient who is blue, apathetic, sometimes almost comatose that I have not had the hardihood to continue the drug. Having had one man of 75 years of age almost die from a bronchopneumonia which seemed to be directly due to such a state as this, and still carry his proteus infection, I have become a half-hearted therapist so far as large doses of prontylin are concerned.

A highly satisfactory discussion of the mode of action and the clinical use of sulfanilamide in urinary tract infections has been published recently by Long and Bliss. They suggest that the effect of sulfanilamide upon the particular strain of bacteria should first be tested *in vitro*. When the lethal concentration has been ascertained, one is in a position to give the drug in quantities suf-

Fig 5 Bilateral calculi in a horseshoe kidney. The largest stone has been removed from the right kidney and a tube has been left in the pelvis. The stone on the left has caused the destruction of that kidney.

ficient to produce the same concentration in the urine. About one half of the organisms tested were inhibited in their growth by a 50 milligrams per cent concentration of sulfanilamide, and practically all were inhibited by a concentration of 200 milligrams per cent. Since they found that only about 50 per cent of sulfanilamide is excreted in the active form, to obtain the latter strength, a dosage of 120 grains of sulfanilamide per day with a urinary output of around 2000 cubic centimeters would be required. Four strains of the *Bacillus proteus* were tested *in vitro* by these authors. Even with a concentration of 200 milligrams per cent sulfanilamide, bacteriostasis was only slight in 2, and moderate in 2. This concentration was not bactericidal in any of the strains.

Since, therefore, we have no reasonably certain internal medication upon which we can rely, we must turn to the direct application of therapeutic media to the kidney pelvis. This may be done through the ureteral catheter, or through a nephrostomy tube. Randall (12), in 1932 suggested the use of 1 per cent phosphoric acid in the renal pelvis as a deterrent to the activity of the urea-

ficient to produce the same concentration in the urine. About one half of the organisms tested were inhibited in their growth by a 50 milligrams per cent concentration of sulfanilamide, and practically all were inhibited by a concentration of 200 milligrams per cent. Since they found that only about 50 per cent of sulfanilamide is excreted in the active form, to obtain the latter strength, a dosage of 120 grains of sulfanilamide per day with a urinary output of around 2000 cubic centimeters would be required. Four strains of the *Bacillus proteus* were tested *in vitro* by these authors. Even with a concentration of 200 milligrams per cent sulfanilamide, bacteriostasis was only slight in 2, and moderate in 2. This concentration was not bactericidal in any of the strains.

Since, therefore, we have no reasonably certain internal medication upon which we can rely, we must turn to the direct application of therapeutic media to the kidney pelvis. This may be done through the ureteral catheter, or through a nephrostomy tube. Randall (12), in 1932, suggested the use of 1 per cent phosphoric acid in the renal pelvis as a deterrent to the activity of the urea-

splitting bacteria. He obtained a number of cures by this method. Von Illyes employed silver nitrate, Albright has suggested the use of a solution of sulfanilamide as a pelvic irrigation.

Of the 13 patients with the *Bacillus proteus* infection 2 had primary nephrectomies and their urine became sterile. One, however, has passed a stone from his remaining kidney. Three had secondary nephrectomies, all about one year after the first operation. All 3 had obstruction at the ureteropelvic outlet; their kidneys were in various stages of disintegration. Stone had recurred in 1; in another, 2 fragments left behind at the first operation showed little increase in size. These patients had had nephrostomies, but were victims of faulty drainage. Four that had nephrostomies got rid entirely of their infection. One patient who had a nephrostomy remains infected; one is still in the hospital but with a strongly acid urine he promises to become free from infection. One was cured by sulfanilamide and mandelic acid. In one the *Bacillus proteus* continued in spite of sulfanilamide: 100 grains a day for 8 days were administered.

The surgical measures to be employed in patients with infected stone-bearing kidneys are various and should be based upon a thorough knowledge of the facts. The size, shape and distribution of the stones, the separate functions of the kidneys, the type of infection present, the condition of the other kidney, all influence one's treatment of the diseased organ. Two ends must be kept in mind: prevention of stasis and eradication of infection. If it appears unlikely that all fragments can be removed, nephrectomy should be considered if the other kidney is sound for in my experience it is seldom that one can sterilize a kidney in which are left pieces of stone. This rule is not absolute of course but generally speaking a bit of infected stone is a sure cause for recurrence. The same principle holds in cases of stasis; even if the kidney is not infected previous to operation it probably will become so afterwards. With a kidney which shows a marked degree of hydronephrosis the operator should consider nephrectomy. Conservative renal surgery about which so much has been written is eminently desirable but a better guarantee of future health is to remove a kidney which has too many potentialities for getting into trouble. If the upper or lower calyx is dilated resection of the corresponding renal pole is a wise precaution.

Nephrostomy is a time honored procedure which has been thought well of by many urological surgeons. Cumming, writing on the value of prolonged nephrostomy drainage after removal of

calculi cited von Lichtenberg, Chute, Cabot, Bugbee, Winsbury, White, Papin, and Crossie as favoring nephrostomy in some instances for long periods. Counseller and Hoerner agree that nephrostomy aids the eradication on infection and the restoration of function. After analyzing a series of 187 patients operated on for renal stone at the Mayo Clinic in the years 1929 to 1933 these authors concluded that the results when nephrostomy was done were better than those when it was not done despite the fact that the kidneys subjected to drainage were more severely damaged originally.

Von Illyes writing on recurrent calculi said that he had 6 per cent recurrences after 81 nephrotomies, against 8.7 per cent recurrences in 510 cases of pyelotomy or ureterotomy. He comments on the value of transrenal drainage when clots are present, especially if infection exists and in kidneys with dilated, stiff walled calyces. It is his custom to remove the tube in 6 to 8 days.

In the series of cases upon which this paper is based a catheter was drawn through the renal cortex into the pelvis in 11 patients. The tube was left in for 12 or 14 days in almost all of these cases but in one patient it was left for 4 months.

The value of prolonged kidney drainage is illustrated by the following history:

The patient, a man 44 years of age, entered the Baker Memorial Hospital on January 20, 1936 with an anuria of 5 days' duration. His non-protein nitrogen was 125 milligrams per cent. X-rays showed a horseshoe kidney, the left half of which had been destroyed by a stone impacted in the upper ureter. On the right there were 4 stones, one 3 centimeters in diameter and 3 smaller ones. The ureters were catheterized; only a bougie could be passed to the left kidney. A catheter was left in the right kidney for 3 days. As drainage through this catheter was inadequate on January 22 the large stone on the right was removed through a pyelotomy and a catheter drawn into the pelvis through the cortex. The urine at this time showed no growth. Eighteen days after operation it showed the *Bacillus coli* and the *Bacillus proteus* and one month after the *Bacillus proteus* alone. Three weeks after the operation upon the right kidney the left kidney which was found to be functionless was removed. The patient was discharged from the hospital with a catheter in the right kidney; this catheter he kept closed but he irrigated his renal pelvis twice a day with potassium permanganate. He took prochrome orally for 4 weeks then methenamine. Three months after his first operation he passed the 3 small stones that had been left in the kidney. Four months after operation his urine was clear and constantly acid; the catheter was removed for good having been changed several times in the meantime. For 3 1/2 years he has been under observation. No new stones have formed and his urine is acid and free from pus.

The employment of nephrostomy in an infected kidney is in accordance with surgical principles. It provides free drainage which is essential in the clearing up of infection. It enables one to

wash out old blood clot, bits of fibrin and necrotic tissue, and to irrigate the renal pelvis with bactericidal solutions, with those designed to change the reaction of the urine, and with those calculated to dissolve the bits of crystalline material which may be adherent to ulcerated areas in the pelvis or calyces. All these factors are important in preventing the formation of new stones, and in bringing about the sterilization of the kidney. I am not sure that it matters greatly what solution is employed. Potassium permanganate, 1:3000, is a good solvent of mucus, mercurochrome, boric acid, silver nitrate, phosphoric acid, acriflavine, and doubtless many other solutions have been used. The mechanical effect is probably the most important.

The same holds true with postoperative lavage of the renal pelvis through a ureteral catheter. This measure is often neglected, but I believe it to be of great value in certain situations. It is especially useful if there is any question of obstruction to drainage, both because of the effect of irrigation and that of dilatation. Keyser emphasizes the latter effect; he dilates the ureter, sometimes to a No. 16 French catheter.

If simple pyelotomy is done, one should not discharge the patient until his urine is sterile. The administration of appropriate urinary antiseptics and if necessary, lavage of the renal pelvis, should be continued until the infection is eradicated.

CONCLUSIONS

1 Renal infection is not a factor of major importance in the formation of the majority of primary renal calculi.

2 In the formation of recurrent stone, with the exception of those due to hyperparathyroidism and to cystinuria, infection is of the greatest importance.

3 In such cases, the *Bacillus proteus* is the organism most commonly found.

4 The urologist's duty is not fulfilled with the removal of the stone; he must then employ

every possible known measure to eradicate the renal infection.

5 In order to do this successfully, he must vary his surgical procedure according to the circumstances of the case. This may mean nephrectomy, partial nephrectomy, nephrostomy, or pyelotomy.

6 No case of renal stone should be regarded as satisfactorily concluded until the urine has become sterile.

PYELONEPHRITIS AND ITS TREATMENT

WILLIAM F. BRASCH, M.D., F.A.C.S., Rochester, Minnesota

BEFORE we go any further, let us first get straight what we mean by the term pyelonephritis. It is generally recognized that there are two distinct types of renal infection, namely, a primary hematogenous infection predominating in the renal cortex and a lesion predominating in the central portion of the kidney, which is usually called pyelonephritis. The path of infection with pyelonephritis is generally regarded as ascending rather than blood borne and the bacteria usually belong to the bacillary group. To repeat, there are two distinct types of renal infection: type 1, the cortical hematogenous infection often requiring surgical treatment; and type 2, pyelonephritis, usually ascending from the lower levels of the urinary tract, with predominant bacillary infection and seldom requiring surgical treatment.

The subject of renal infection, however, is not as simple as this schematic outline would suggest, since many variations and a mingling of the two types are often observed. Nevertheless, there are definite clinical data which differentiate these two groups and which should be recognized in the clinical consideration of the subject. The type of renal infection that I am discussing is the ascending form of infection or pyelonephritis. If pyelonephritis is an ascending infection, how does it get up into the kidney from the genital and lower urinary tract? That is a problem which remains unsolved. However, the two most probable avenues are through the ureter and through the lymphatics. How can the infection ascend directly up the ureter in the face of peristalsis? This is explained by a combination of possible back pressure, incompetent ureterovesical valve and reverse peristalsis; the latter occurring more frequently than is generally realized.

TYPES OF PYELONEPHRITIS

In the discussion of pyelonephritis let us recognize that there are three clinical phases of this disease, namely, the acute, recurring and chronic forms. Acute pyelonephritis is by far the most common lesion in the genito-urinary tract. In fact, next to respiratory infection, it probably is more common than infection in any other field.

From the Section on Urology of The Mayo Clinic, presented at the Symposium on Urological Infection, 1st Year of the Clinical Congress of the American College of Surgeons, New York, October 7-22, 1938.

Pyelonephritis occurs more frequently in the female in its acute form and more often in the male in its chronic form. This is due to the greater susceptibility of the urinary tract in the female to acute ascending infection and on the other hand to the fact that there are chronic foci of infection in the prostate and adnexa which are the usual basis for chronic pyelonephritis in the male. Most cases of acute pyelonephritis in either child or adult are of short duration and are self-limiting. The medicine we give these patients is often given credit for clearing up infection which in reality has been overcome by natural resistance. However, when the infection persists longer than 4 or 5 days and when it is accompanied by fever and chills, nature is materially aided by the administration of any of the various chemotherapeutic agents now available.

The second form of pyelonephritis to be considered is characterized by recurring attacks of acute pyelonephritis. The periods of infection may persist over several weeks or months and recur after a variable lapse of time. In the interval, although the patient is free of symptoms, careful and persistent search of the urine will often show the presence of a few bacteria, indicating that the renal infection in most of these cases is dormant rather than eliminated.

The third type of pyelonephritis is its chronic form and this is the most difficult to overcome of the three. The first two types of renal infection usually will respond to recently developed chemotherapy and control of the etiological factors, but chronic pyelonephritis offers an entirely different problem. In using the term chronic pyelonephritis I refer only to those cases in which renal infection has persisted over a period of at least 1 year. Chronic pyelonephritis involves both kidneys with rare exceptions. In fact, when only one kidney is found to be infected over a long period of time, it can be assumed that a secondary complication is present which in most cases will necessitate surgical treatment. Chronic pyelonephritis often runs a course of many years without great curtailment of life or its activities. Unless complications occur, patients usually suffer only from dysuria and frequency and in many cases become inured to it. In about 50 per cent of cases immunity is developed and the infection is gradually

eliminated. In others, however, such complications develop as secondary lithiasis, hematuria, and ureteral or pelvic obstruction as the result of cicatricial deformity. In still other cases the infection and cicatricial changes in the renal tissue curtail glomerular activity so that the renal function suffers materially, with the usual symptoms. In a few cases this destructive process is confined to one kidney and the condition may then require surgical treatment.

There is no doubt that the infecting organism in the female ascends through the urethra into the bladder much more frequently than is generally recognized. Countless women who complain of urinary frequency and dysuria—the so called irritable bladder—in most cases will be found on endoscopic examination to have evidence of infection in the urethra. The treatment in these cases should start with elimination of vaginal infection, chronic cervicitis, and infection in the periurethral glands and tissues. Urethritis, so often overlooked, lends itself readily to such simple treatment as dilatation of the urethra if this is found to be cicatricial, and the application of antiseptics, such as protargol or argyrol, by

Fig 2 Bilateral pyelonephritis with cicatricial changes in pelvis of left kidney, characterized by constriction of infundibulum and bulbous enlargement of upper calyx. Contraction of other calyces.

Fig 1 Chronic bilateral pyelonephritis. Deformity predominant in ureter, characterized by cicatricial irregularity and atonic dilatation in the upper third.

means of urethral suppositories or tampons. Urethritis is frequently accompanied by an eroded or prolapsed urethral mucosa. This should be treated by a combination of local applications and soothing ointments, never by cautery. Of primary importance also is the elimination of all possible distant foci of infection. By taking these simple precautions in the female, most cases of persisting or recurring acute urinary infection can be overcome. Similarly in the male, recurring attacks of pyelonephritis can usually be traced to a persistent, virile infection in the prostate. In curbing reinfection, the usual treatment of massage is greatly aided by liberal doses of sulfanilamide compounds.

Another form of renal infection which assumes the clinical character of a glomerular nephritis rather than that of pyelonephritis is sometimes observed and requires special consideration. Although the clinical data resemble those accompanying nephritis and are frequently influenced by a variable degree of renal insufficiency, nevertheless its infectious nature is disclosed by the presence of pus cells in the sedimented urine, and with persistent effort and refined methods of culture, bacteria can often be found. Its infec-

Fig 3 Bilateral pyelonephritis. Cicatricial changes involving calyces characterized by constriction of infundibula and clubbing of lower calyx. Atonic dilatation in the lower segment of ureter on both sides.

tious nature is corroborated by the fact that the administration of sulfanilamide and its derivatives has been followed by definite improvement. Although these drugs may not be eliminated in the urinary tract when the renal function is reduced nevertheless their systemic action may have a bactericidal effect. I have observed a number of patients with acute exacerbation of renal infection accompanied by renal insufficiency who could not tolerate oral administration but who improved to a marked degree following the subcutaneous injection of prontosil and sulfanilamide.

Retention of urine is a common and often serious complication following intra abdominal and pelvic operations. It almost invariably follows resection of the lower bowel for malignant lesions because of temporary injury to the innervation of the bladder. Unless the retention is relieved distention of the bladder with renal back pressure and infection will result. Catheterization is usually necessary and should be done promptly. Otherwise secondary infection which usually follows will ascend to the kidneys. By the simple expedient of giving the patient 5 grains

of 0.3 grams, of sulfanilamide 3 or 4 times a day starting immediately after the operation renal infection from postoperative catheterization usually can be overcome.

In the treatment of recurring or chronic renal infection the first step to take is to make sure that the infection is primary and not secondary. Pyelonephritis which is secondary to some underlying lesion such as stone tuberculosis or obstruction in the bladder or ureter probably occurs more frequently than does primary renal infection.

These factors having been excluded the next thing is to determine the type of bacteria present. If there is any one thing that has been learned in the development of modern therapy of urinary infection, it is the necessity of a working knowledge of bacteriology.

It would seem that necessity has made bacteriologists out of urologists or to be more accurate has made urological bacteriology. For the purpose of the average clinician however, it is necessary to be familiar with only a few simple observations in bacteriology. Microscopic differentiation between the two main groups of bacteria namely bacilli and cocci is essential to adequate diagnosis.

Fig 4 Bilateral pyelonephritis. Cicatricial changes in calyces with bulbous enlargement of all calyces and atonic ureteral dilatation in the lower segment of the right ureter.

Why is it necessary to differentiate the bacteria? For the simple reason that some bacteria respond better to certain drugs than to others. It is true that it may not be necessary to know the exact bacteria involved if the infection yields readily to routine chemotherapy. However, this is not the rule, and when the infection persists or recurs a bacterial study is essential to successful treatment. The main types of bacteria can be recognized easily and without elaborate laboratory facilities. For practical purposes the simple Gram stain of the dried urinary sediment may suffice. Microscopic examination will readily determine the presence of cocci or bacilli and whether they are gram-negative or gram-positive. Although gram-negative bacilli are most commonly observed with pyelonephritis, any type of bacterium may be present and in many cases the bacteria are mixed.

When it is desirable to identify the various types of gram-negative bacilli, cultures can be made from the urinary sediment. The 3 bacilli which occur most frequently and have the greatest clinical significance are the colon bacillus, its tough little cousin aerogenes, and the tenacious *Bacillus proteus*. It is desirable to distinguish the latter because it splits urea, causes alkaline urine, and may be hard to eliminate. Of the cocci the gram-positive cocci, including staphylococci, are more frequently seen than streptococci. One form of streptococcus, however, the weakly *Streptococcus faecalis*, is frequently found in the urine, either alone or more often in conjunction with bacillary infection. It can usually be recognized by its shape and its peculiar appearance with the Gram stain.

Let me warn the readers, however, about one thing. Just because the patient's symptoms disappear and there is no longer pus in the urine, it does not mean that the infection is completely eliminated. Time and time again I have seen symptoms disappear completely after a short course of treatment, microscopic examination of the urine revealed no pus cells and the patient was allowed to go rejoicing. Within a few weeks or months, however, the symptoms recurred and often an acute infection followed. This could have been obviated easily by remembering the fact that bacillary infection frequently persists when symptoms and pus cells disappear. It is essential, therefore, in the employment of any form of treatment, that Gram stains or cultures of the urine be made for some time after the symptoms disappear and that the treatment be continued for several days after cultures have become negative.

RECENT DEVELOPMENTS IN THE TREATMENT OF URINARY INFECTION

In no other field of medicine has there been a more revolutionary change in therapy than has taken place during the last 3 years in the treatment of infections in the urinary tract. Recent developments in chemotherapy have completely altered our theories and methods of treatment. The genesis of these recent therapeutic agents reads like a romance. Progress from acidification of the urine to the ketogenic diet and the use of mandelic acid in the treatment of urinary infection now seems logical and simple, but in reality it represents giant strides.

Mandelic acid is being largely replaced by the more efficient sulfanilamide-like compounds. Its use is limited largely to certain bacillary infections and it is effective only when the urine is made highly acid, which in itself is often either objectionable or impossible. However, occasionally it will eliminate bacilli when the sulfanilamide compounds fail to do so, and it is peculiarly bactericidal against *Streptococcus faecalis*. Occasional cases are observed in which bacillary elimination is possible only by the combined use of mandelic acid preparations and a modified ketogenic diet. Mandelic acid is often used when the patient is unable to take sulfanilamide.

It was only in 1935 that Domagk discovered the bactericidal properties of prontosil with infection in mice, and soon after this the observation was applied to human infection. Since then this drug and its derivatives have swept like wild fire across the therapeutic horizon, so that today it probably is used more widely and for a greater variety of infections than any other drug in the history of medicine.

These two drugs have given us means to combat infection in the urinary tract far more efficaciously than ever before. It will be impossible in this paper to give adequate consideration to these therapeutic agents. It will be possible only to refer to some of their more important qualities and to a few recent observations which have been made on their use.

Sulfanilamide is bactericidal against all bacteria appearing in the urinary tract. Its efficacy varies in degree, however, with the type of bacteria present, the pathological condition of the tissues involved and the degree of immunity on the part of the patient. Sulfanilamide is particularly efficacious in urinary infections with the colon bacillus, *Aerobacter aerogenes*, proteus and their brethren. It has been a godsend in the cases of infection with proteus, which in the past has been most difficult to eradicate from the urinary

tract. It is less efficacious with coccal infections, although more often than not it will eliminate them. Sulfanilamide is almost impotent against *Streptococcus fecalis*, and it will usually be necessary to fall back on mandelic acid therapy in order to eradicate this organism.

The action of sulfanilamide varies widely so far as the patient is concerned. It is most effective in children and in younger adults, who seldom experience any toxic reaction. In the elderly patient it should be given with care, since it seems to be far more toxic and its use is often accompanied by marked acidosis. The greatest objection to it is undoubtedly its toxic effect, which limits its use in many adults over 40 years of age.

The drug manifests its toxicity in many ways, which by this time are well known to almost everyone such as malaise, gastric symptoms, weakness, skin eruptions, and so forth. Most dangerous and insidious are changes in the blood characterized by agranular leucopenia. It is curious that those who use it most widely and in the largest doses seem to observe less violent reactions than those who use it occasionally. It should be made emphatic, however, that where blood changes and the subjective symptoms of toxicity are apparent, its use must be discontinued immediately or resumed with great caution and in small doses.

In regard to the tissues involved, experience has shown that sulfanilamide is not of much value in tissues which have recently been traumatized as at operation. For instance following renal plastic operations or transurethral prostatic resection the drug has little or no influence on the infection in the tissues involved. However if the infection persists a month or so after the tissues in the operative field are healed sulfanilamide may be of value in eliminating the infection.

Sulfanilamide seems to be least efficacious with advanced chronic pyelonephritis because of secondary anatomical changes in the renal tissues. There is a vast difference in the results obtained in therapy for chronic and for recent renal infection. With chronic pyelonephritis the cicatricial changes surrounding a localized area of infection are such that the drug apparently cannot function. It is true that many patients with chronic pyelonephritis will respond to the drug to a remarkable extent and in many cases the infection may eventually be eliminated. However, when the infection is widespread when accompanied by such complications as hematuria, secondary lithiasis, or interference with renal drainage the chances for improvement are not too good. In

former years several hundred patients with chronic pyelonephritis were observed annually at The Mayo Clinic. In spite of the fact that recent chemotherapy has been employed only a few years, the number of these patients observed today is only a fraction of that formerly seen. This reduction is probably due to two causes: first, the efficacy of chemotherapy in the uncomplicated cases of chronic pyelonephritis and second the fact that chronic pyelonephritis is being prevented by overcoming the infection in the acute and subacute forms. There is no doubt that sulfanilamide and its derivatives have already reduced the incidence of chronic pyelonephritis and they bid fair to control if not eliminate one of the most trying diseases involving the urinary tract.

Repeated efforts have been made to modify sulfanilamide or to find substitutes which would not have its toxic qualities. Although prontosil was first employed in combating infection it was supplanted in clinical use by sulfanilamide because the latter seemed more bactericidal. In view of the fact, however, that prontosil is less toxic, there has recently been a tendency to return to its wide employment. Modifications were made which rendered prontosil more soluble and the resulting compound is called neoprontosil soluble. This compound which will soon be available for general use apparently has the same bactericidal qualities as sulfanilamide, but is much less toxic. It probably will be widely employed as soon as it is released by federal authorities for general use.

It is now being realized that large doses of sulfanilamide compounds are unnecessary in many cases of infection in the urinary tract. Smaller doses, frequently as small as 5 to 15 grains, or 0.3 to 1 gram daily will often suffice to keep the infection under control and will usually cause no toxic reaction. This is particularly true with chronic or recurring attacks of pyelonephritis. If these small doses are administered continuously to the patient in the interval between attacks, recurrence is frequently prevented. Small doses may also be of value with chronic inoperable pyelonephritis complicated by either primary or secondary ureteral obstruction or stone. I have observed patients suffering from advanced chronic pyelonephritis with poor renal drainage and others with extensive bilateral renal lesions and secondary renal infection who when given 5 grains or 0.3 gram, of sulfanilamide daily over a period of a month reported that the urine cleared to a large extent and that the febrile attacks were prevented. However, when

sulfanilamide is given preliminary to renal operations, it will seldom eliminate secondary renal infection unless the primary lesion is corrected.

Theoretically, it would seem that if correctly prepared, vaccines, antigens and the like should be of therapeutic value. Although vaccines were formerly employed widely in combating renal infection, as a result of unsatisfactory experiences their use has been gradually discontinued. Recently attempts have been made to modify their preparation with some success. These modifications consist largely of greater care in obtaining the infecting organism, dilution of the strain in culture, preparation of the vaccine after shorter incubation, and detoxication by means of salines. They should be of value particularly with coccal and proteus infections, which often resist all forms of chemotherapy.

Although surgical intervention is not usually indicated in the treatment of chronic pyelonephritis, certain secondary complications may develop which can be relieved only by operation. Included among these complications are ureteral obstruction causing inadequate renal drainage, unilateral infection accompanied by recurring febrile attacks which resists all forms of chemotherapy, and unilateral destruction of renal function, with renal atrophy. In a recent review of 526 cases of chronic bilateral pyelonephritis observed at The Mayo Clinic, surgical treatment was found necessary in but 17, or 3 per cent. It goes without saying that with pyelonephritis developing secondary to primary lesions such as pyelectasis and renal lithiasis it is necessary to relieve the underlying condition by surgical measures. One of the best reasons for urging early operation for renal lithiasis or hydronephrosis is that, if secondary renal infection exists too long, it may be difficult to eliminate, even if the primary lesion is removed. Attempts made to overcome primary chronic pyelonephritis by such surgical means as drainage, nephropexy, and decapsulation, as suggested by von Lichtenberg,

did not meet with much success in a series of 11 patients operated on at The Mayo Clinic.

SUMMARY

Since pyelonephritis is usually secondary to infection in the lower portion of the urinary tract, treatment must be directed to this source in order to prevent recurrence.

A working knowledge of urological bacteriology is essential to the intelligent treatment of urinary infection, since some bacteria respond better to certain drugs than to others.

Elimination of pus from the urine and cessation of symptoms do not necessarily mean that infection is completely eliminated. Repeated cultures must be made subsequently to insure recovery.

Recent developments in chemotherapy have given us two compounds which are much more efficacious in the treatment of infection in the urinary tract than any other drug previously employed and often give miraculous results. They are sulfanilamide (and its related drug, prontosil) and mandelic acid. Sulfanilamide compounds should be used more frequently as a preventive of infection such as occurs with post-operative retention of urine. Its bactericidal influence in small doses is employed for this purpose and in other types of urinary infection.

With the increasing efficacy of chemotherapy and the development of special vaccines, it may be predicted that primary pyelonephritis will be largely limited to its acute and subacute stages and that chronic pyelonephritis with its complications will develop only occasionally. This will, however, entail a thorough study of all the factors involved, including the bacterial, physiological and anatomical factors.

SYMPATHECTOMY FOR THE RELIEF OF VESICAL SPASM AND PAIN RESULTING FROM INTRACTABLE BLADDER INFECTION

REED M NESBIT, M D, F A C S, and FREDERICK C McLELLAN, M D

Ann Arbor, Michigan

SYMPATHECTOMY for the relief of pain in the urinary bladder was first performed by Piere in 1926. Since that time numerous authors have reported the results obtained from the employment of this procedure. A careful review of the literature devoted to this subject fails to reveal any unanimity of opinion regarding the indications for or the limitations upon this operation, and discloses a surprising variation in the end results of reported cases. During the past year several reports have appeared advocating various types of sympathectomy designed to relieve pain of bladder origin. It thus appears entirely proper that the subject be discussed critically in the hope that an understanding of the rationale of operation, its indications, and limitations might be evaluated. To that end a review of the literature pertinent to the subject is given and a critical analysis of the cases here reported is presented in an effort to shed further light upon this question.

The nervous anatomy of the bladder has been ably described by many exhaustive and complete reports. We will therefore, pass over the subject with but a brief mention of the essential pathways which comprise the innervation of the bladder and will present a resumé of its neurophysiology. The parasympathetic or sacral outflow arises from the anterior divisions of the second, third, and fourth sacral nerves (Fig 1). These trunks pass mesially in the lower pelvis to the inferior hypogastric ganglia situated on each side of the rectum and beneath the bladder and here join the sympathetic or thoracolumbar outflow. Mixed fibers from both systems then supply the various parts of the bladder.

The sacral or parasympathetic outflow carries both sensory and motor components and supplies all the necessary reflex pathways for normal micturition. Many observers have pointed out that the sympathectomized bladder not only functions normally in so far as micturition is concerned but

also has normal tactile, thermal and pain sense. Denny Brown refers to such a case in which complete sympathectomy was performed for mega colon. This patient showed no discernible alteration in urinary function. Our sympathectomized patients here reported, all showed normal sensations to touch, heat, cold, and to painful stimuli in all parts of the bladder. Interruption of the sacral (parasympathetic) pathways produces an autonomic bladder the function of which is independent of voluntary control. Dribbling incontinence with residual urine is the rule, although this bladder may develop some degree of autonomic periodic emptying. Such a bladder innervated solely by the sympathetics is insensitive to heat and cold, and sensation of filling is essentially abolished although this is present in some. Pain sense is inconstant in this type of bladder.

The sympathetic or thoracolumbar outflow reaches the bladder by two routes. The route is first the presacral or hypogastric nerves which course downward in front of the sacrum as a single, or many branched nerve or, as is generally the case, as a plexus of interlacing nerve fibers termed the superior hypogastric plexus. In the region of the hollow of the sacrum these fibers divide into two trunks termed the inferior hypogastric nerves and enter the inferior hypogastric ganglia where they are joined by the parasympathetic outflow. The second source of sympathetic fibers is tiny branches which arise from the lateral sacral sympathetic ganglionic chain and also enter the inferior hypogastric ganglia.

The exact function of the sympathetic or thoracolumbar outflow is still open to debate. However, most observers agree that impulses carried by these pathways importantly regulate the tonicity of the so called internal sphincter of the bladder, the trigone of the bladder and the ureterovesical orifices. They also regulate contraction of the prostate, seminal vesicles, and ejaculatory ducts.

Vasoconstriction of the blood vessels over the trigone area has been reported by some observers, who have further noted a vasodilatation of this

Clinical Congress of the American College of Surgeons, New
York, October 17-21, 1933.

area following sympathectomy. Whether or not pain sensations are conducted over these trunks is, we feel, open to debate. Denny-Brown, Learmonth, and others have expressed the affirmative view regarding this function. Neuro-anatomists agree that somatic fibers, inconstant in number, are to be found in the hypogastric nerve bundles, accompanying the purely autonomic non-myelinated fibers. While it is accepted that these fibers may represent afferent (sensory) components, it has not been definitely established that such is the case. Surely experimental and clinical evidence does not fully support or contradict the point.

Learmonth reported having stimulated the proximal cut end of the presacral nerve during operation. His patient complained of a crushing or spasmodic pain in the region of the bladder. On the basis of this observation he concluded that the presacral nerve contained afferent components and expressed the belief that sensations of bladder spasm were conducted by these nerves. Denny-Brown had the opportunity of studying a patient who had a cauda equina lesion with complete destruction of the fourth and fifth lumbar vertebrae, and all of the sacral roots. He was thought to have his sympathetics intact because he could sweat. This patient could perceive pain in his bladder. In these 2 instances it is evident that sensory components accompanied the hypogastric nerves. Riddock has also presented evidence to show that the hypogastric nerves conduct painful impulses.

Our own observations in a small series, provided contrary evidence to that quoted above.

An illustrative case (Chart I) showed destruction of the parasympathetic pathways. That the patient's sympathetics were intact was revealed by the fact that he was able to ejaculate normally and that he had a tonic internal sphincter. Electrical stimulation to all parts of his bladder failed to elicit the sensation of pain, and heat and cold sensations were likewise lacking. It is to be noted that he did have sensation of bladder distention, however. An attempt was made to induce pain from bladder spasm in this case since some authors have accredited this function to the presacral nerve. One hundred cubic centimeters of a 2 per cent unbuffered mandelic acid solution was introduced into the bladder. This solution had previously been quite accidentally introduced into a normal bladder producing spasm with paroxysms of pain and was found to produce no lasting damage to the bladder. The mandelic acid solution was introduced in this instance through a catheter, using a burette for a reservoir. Although this autonomic bladder went into spasm, as shown by the fact that the solution was immediately forcibly expelled out through the end of the burette, the patient suffered no discomfort and was, in fact, aware of no sensation whatever.

Identical observations have been made upon 2 other cases presenting similar cauda equina lesions. From these studies we feel justified in con-

cluding that the hypogastric nerves may carry no afferent sensory components although in cases reported by other observers the contrary appears to be true.

This brief résumé of the bladder neurophysiology points out two essential facts pertinent to the discussion: first, that the parasympathetic pathways carry a constant and abundant supply of sensory components, and second, that the sympathetic pathways may or may not carry sensory components. It is further evident that sectioning of the sympathetic pathways alone does not interrupt the normal perception of pain in the bladder.

Complete sensory denervation of the urinary bladder has been accomplished by excision of the inferior hypogastric ganglia and by cordotomy. Removal of the inferior hypogastric ganglia was first performed by Rochet and reported in 1921. This was done for the relief of painful, tuberculous cystitis but was found to be an extremely hazardous procedure and carried the disadvantage of producing urinary incontinence. Learmonth reported that he performed this procedure for relief of pain resulting from malignancy but felt that the hazards of operation overbalanced the advantages of it. Cordotomy, occasionally resorted to for relief of bladder pain resulting from advanced malignancy, achieves this end with a minimum of risk and operative trauma. It presents the disadvantage of producing disturbances in urinary function with incontinence, but this objection should not contra-indicate its use in relieving the agonies of hopeless cancer.

Three techniques of sympathectomy have been described for the relief of bladder pain. The first operation of Piere, in 1926, consisted of simple resection of the presacral nerves (hypogastric plexus) which he performed for intractable cystitis. This operation did not provide complete relief of pain. Later, in 1930, he described a more extensive sympathectomy (Fig 2), including division of both paravertebral sympathetic chains at the lower border of the fifth lumbar vertebra and section of the gray rami from the first, second, and third sacral ganglia to their corresponding nerves. It was felt that this procedure would interrupt more sensory pathways than presacral neurectomy alone. The third technique, a simplification of Piere's second, was recently described by Scott and Schroeder. This method consists of performing presacral neurectomy and interrupting the lateral sacral sympathetic ganglionic chain by means of exeresis.

Practical experience has not demonstrated that the complete operation is more advantageous than

Fig 1 Schematic view of nerve supply of the bladder After Mueller *Lebensnerven und Lebensstriche*

simple presacral neurectomy Learmonth concluded that relief of pain was obtained as effectively by the simpler procedure as by the more extensive one. Our own experience has borne out this observation.

A review of the cases reported in the literature disclosed that in the aggregate about 50 per cent of patients sympathetomized for bladder pain had, in reality, been relieved of their pain. For the purposes of critical analysis and evaluation, it is unfortunate that practically none of the reports disclosed the types of pain for which operation was performed or what types of pain were found to be relieved. The manner in which certain types of bladder pain are relieved by sympathetomy is we believe demonstrated by an analysis of the cases herewith presented.

CASE HISTORIES

CASE 1 A M. No. 160733 a 43 year old housewife had chronic pyelonephritis intractable cystitis with mixed non tuberculous infection for 9 years which was resistant to all forms of therapy. The symptoms were frequency rate of 15 to 30 minutes day and night burning and severe spasmodic pain at every urination which was relieved only by narcotics for 2 years and 20 to 30 cubic centimeters were voided at each urination. The cystoscopic examination given by means of spinal anesthesia revealed a bladder capacity of 30 cubic centimeters and diffuse inflammation of bladder mucosa. Pyelograms showed hydronephrosis and hydro-ureter grade 2. A presacral

neurectomy was performed. Immediately after operation there was no spasmodic pain the patient voided every 30 to 60 minutes with burning in the urethra and the amounts varied from 30 to 100 cubic centimeters. Two months after the operation the patient voided about 50 to 100 cubic centimeters every hour with slight burning. There was occasional slight incontinence. A second cystoscopic examination given by local anesthesia showed the following: bladder mucosa normal throughout, normal sensations in bladder pain on overdistention of the bladder and infection greatly reduced. Ten months post operatively there was no bladder pain voids up to 150 cubic centimeters every 1 to 2 hours with only slight urethral burning. The cystoscope used by means of local anesthesia at that time revealed a normal mucosa, normal bladder sensations, pain on overdistention of the bladder and a very slight amount of infection.

The patient has experienced some improvement in frequency and bladder capacity and complete relief from the intolerable paroxysms of spasmodic pain which had incapacitated her. She is entirely satisfied with the improvement of her status and has used no morphine since her operation.

CASE 2 J. G. No. 30361 a male farmer aged 25 years had Hunter ulcers of the bladder with moderate intractable bacillary infection of the bladder for 8 years which was resistant to all forms of therapy. There was no prostatic infection. The symptoms were frequency of urination every 1 to 2 hours by day and 4 or 5 times during the night burning on urination pain when bladder filled, severe spasmodic pain on urination and voids amounting to from 90 to 150 cubic centimeters. Cystoscopic examina-

Chart 1 The autonomous neurogenic bladder Rupture nucleus pulposus April, 1938, with pain in back and saddle anesthesia June, 1938, developed practically total urinary retention with slight overflow incontinence, catheterized intermittently There was bowel incontinence Patient seen in University Hospital on July 11, 1938, with neurological findings of lesion of second, third, fourth, and fifth sacral cord segments with sensory loss only Cystometric study July 11, 1938, demonstrated autonomous neurogenic bladder Laminectomy and excision of ruptured intervertebral discs of fifth lumbar and first sacral on July 19, 1938 Cystometric studies August 1, August 16, and September 27, 1938, show autonomous bladder Patient voids only with straining, overflow incontinence at night, controlled by Credé every 2 hours during the day Sensations of heat, cold, tactile, and electric stimulation are absent, first desire and filling diminished or absent Ejaculation, erection, and tonus of internal vesical sphincter are preserved There is no pain on inducing bladder spasm

tion, made with spinal anesthesia, showed a bladder capacity of 150 cubic centimeters, several typical Hunner ulcer lesions in the bladder, and hemorrhage on overdistention Pyelograms revealed the right side to be normal and on the left side a slight hydronephrosis A presacral neurectomy and exeresis of the lateral sacral sympathetics were performed Immediately after the operation there was urinary retention with severe pain This was relieved by an indwelling catheter drainage for 10 days followed by frequency every 15 to 30 minutes with severe burning in the urethra which subsided in 1 week The patient was discharged on the forty-second day, voiding amounts from 100 to 150 cubic centimeters with complete comfort Four months later voids continued to amount to 100 to 150 cubic centimeters with complete comfort There was slight bladder pain on overdistention but urine was normal Cystoscopic examination still showed active lesions of the Hunner ulcers, but there were normal sensations throughout the bladder to various stimuli Ten months

after operation he voided normally, without pain, and output amounted to 150 to 175 cubic centimeters The patient wrote "Am riding tractor every day and am grateful to be relieved of those awful spasms I used to have"

CASE 3 A S, No 413118, a housewife, 34 years of age, had Hunner ulcers of the bladder, chronic pyelonephritis with mixed infection which was resistant to all forms of therapy This condition had existed for 3 years The symptoms were frequency every hour, day and night, dull aching pain on bladder distention, severe paroxysms of spasmodic pain on urination, and voids of 60 to 90 cubic centimeters The cystoscopic examination, made with spinal anesthesia, revealed a bladder capacity of 90 cubic centimeters, diffuse inflammation of the bladder mucosa, and several typical Hunner ulcers which bled on overdistention of the bladder Pyelograms showed typical changes of chronic pyelonephritis with clubbing of calyces and definite narrowing of the infundibula A presacral neurectomy and exeresis of the lateral sacral sympathetics

Fig. 1 Schematic view of nerve supply of the bladder After Mueller *Lebensnerv und Lebensstricke*

simple presacral neurectomy Learmonth concluded that relief of pain was obtained as effectively by the simpler procedure as by the more extensive one. Our own experience has borne out this observation.

tion, made with spinal anesthesia, showed a bladder capacity of 150 cubic centimeters, several typical Hunner ulcer lesions in the bladder, and hemorrhage on overdistention Pyelograms revealed the right side to be normal and on the left side a slight hydronephrosis A presacral neurectomy and exeresis of the lateral sacral sympathetics were performed Immediately after the operation there was urinary retention with severe pain This was relieved by an indwelling catheter drainage for 10 days followed by frequency every 15 to 30 minutes with severe burning in the urethra which subsided in 1 week The patient was discharged on the forty-second day, voiding amounts from 100 to 150 cubic centimeters with complete comfort Four months later voids continued to amount to 100 to 150 cubic centimeters with complete comfort There was slight bladder pain on overdistention but urine was normal Cystoscopic examination still showed active lesions of the Hunner ulcers, but there were normal sensations throughout the bladder to various stimuli Ten months

after operation he voided normally, without pain, and output amounted to 150 to 175 cubic centimeters The patient wrote "Am riding tractor every day and am grateful to be relieved of those awful spasms I used to have"

CASE 3 A S, No 413118, a housewife, 34 years of age, had Hunner ulcers of the bladder, chronic pyelonephritis with mixed infection which was resistant to all forms of therapy This condition had existed for 3 years The symptoms were frequency every hour, day and night, dull aching pain on bladder distention, severe paroxysms of spasmodic pain on urination, and voids of 60 to 90 cubic centimeters The cystoscopic examination, made with spinal anesthesia, revealed a bladder capacity of 90 cubic centimeters, diffuse inflammation of the bladder mucosa, and several typical Hunner ulcers which bled on overdistention of the bladder. Pyelograms showed typical changes of chronic pyelonephritis with clubbing of calyces and definite narrowing of the infundibula A presacral neurectomy and exeresis of the lateral sacral sympathetics

were performed. The patient voided normally without incontinence immediately after the operation and was free from bladder spasm or pain. Voids amounted to 100 and 150 cubic centimeters. She was discharged on the seventeenth postoperative day. Four months later the patient voided up to 150 cubic centimeters once an hour during the day and 4 or 5 times during the night. There was no spasmodic pain on urination and no incontinence but she had mild dull pain in bladder on distention. A cystoscopic examination with local anesthesia revealed the Hunner ulcers to be unchanged. Eleven months after operation the patient had been free from severe pain, there was some bladder discomfort consisting of dull burning pain when bladder was distended or when she was fatigued. Frequency of urination without incontinence was each hour by day and 3 to 5 times during the night, voided 30 to 120 cubic centimeters. The patient stated that her bladder capacity was clearly limited by the discomfort of distention. The cystoscope revealed the Hunner ulcers to be unchanged. Severe pain on distention of the bladder but normal sensations throughout the bladder to various stimuli.

With this patient there was complete relief from severe spasmodic pain, no improvement in frequency or discomfort on distention of bladder, slight increase in bladder capacity, and no change or improvement in Hunner ulcers, but she was completely satisfied and grateful for her operative result.

CASE 4 B B No 413883 a housewife 26 years of age had Hunner ulcers of the bladder with moderate intractable staphylococcal infection of both kidneys resisting all forms of therapy for 1 year. Urination had occurred every 15 to 30 minutes for 3 to 4 months. The patient slept on a bed pan and had intolerable bladder spasms on moving about and on urination. Spinal anesthesia was administered for the cystoscopic examination which revealed a bladder capacity of 60 cubic centimeters and a bladder highly inflamed throughout with several areas of ulceration. The pyelograms showed bilateral hydronephrosis and a one plus hydroureter. A presacral neurectomy with exeresis of the lateral sacral sympathetic chains was performed. Immediately after the operation the patient voided normally without any discomfort, amounts ranging from 50 to 60 cubic centimeters for the first week. The capacity for the second week increased from 150 to 300 cubic centimeters with freedom from pain. She was discharged on the twenty first day voiding from 180 to 200 cubic centimeters without discomfort. Two months later she voided from 100 to 250 cubic centimeters with complete absence of bladder spasm but had slight burning in the urethra and had pain on overdistention of the bladder. A cystoscopic examination made with local anesthesia showed 3 typical Hunner ulcer lesions in the bladder but urine was normal. Eleven months after operation she voided every 2 or 3 hours with slight terminal burning in the urethra, she had no spasm and no pain in the bladder. She had slight urinary incontinence at times with loss of a few drops of urine and wore a napkin to prevent soiling her clothes. A cystoscopic examination revealed a bladder capacity of 180 cubic centimeters, overdistention produced severe pain, the bladder was normal throughout except for the Hunner ulcer areas which showed no change, bladder sensations were entirely normal.

With this case there was improvement but no cure of frequency, there was complete relief of

spasmodic pain which incapacitated the patient. She still had Hunner ulcers and had acquired a slight urinary incontinence, but was completely satisfied with the operative result.

CASE 5 M S No 399155 a housewife 25 years of age had tuberculous cystitis persisting for 1 year without relief following nephrectomy for renal tuberculosis. The symptoms were frequent urination every 30 to 60 minutes by day and 5 to 8 times at night with burning and severe bladder spasms and pain on each urination. General anesthesia was administered for the cystoscopic examination which revealed a diffusely inflamed bladder, a bladder capacity of 75 cubic centimeters, left kidney urine normal, pyelogram normal, but bladder urine contained pus and tubercle bacilli. A presacral sympathectomy and lateral sacral sympathetics exeresis were performed. Immediately the patient was the normal desire to void and complete continence with no pain. By the tenth postoperative day the patient was voiding 100 to 150 cubic centimeters. She was discharged on the sixteenth day having no pain but moderate urethral burning on urination. During the night she voided about 1 or 2 times. Three months later she returned for a check up. She had been asymptomatic till a few days before when she developed increased frequency and urethral burning but no pain. The urine was found to contain many Bacillus coli. The patient was given a course of sulfanilamide with a regression of the frequency. Four months after operation the patient reported that she had continued free from her symptoms.

This patient had been relieved materially of her urinary frequency. Her capacity had considerably increased and she had remained entirely free from her spasmodic bladder pain.

CASE 6 C W No 374641 male a 45 year old laborer had tuberculous cystitis for 2 years following nephrectomy for right renal tuberculosis. He had had bladder irritation for 7 years prior to nephrectomy. He had a frequency of 1 to 2 hours during the day and night with spasms of pain on urination. Tubercle bacilli were found in the urine. Cystoscopic examination was made with general anesthesia revealing a diffuse ulcerative cystitis and a bladder capacity of 110 cubic centimeters. A presacral neurectomy was performed. Immediately afterwards he voided normally without incontinence. Frequency and capacity remained unchanged over pre operative state. There was no pain on urination. Four months later there was no increase in bladder capacity or frequency, patient voiding with complete absence of bladder pain or spasms but there was some burning in the urethra. Seven months after operation his general condition was excellent. He was continent, his urine was a plus pus and tubercle bacilli and he voided every 2 hours day and night with complete comfort.

This patient had not been relieved of his urinary frequency but has been made completely comfortable.

Analysis of these cases reveals certain constant factors. Prior to operation all had severe spasmodic bladder pain, all had some degree of difficulty in voiding although none had residual urine, all patients required general anesthesia for cystoscopic examination and cystometric examinations, in all instances revealed definite hypertonicity of the detrusor mechanism.

Following operation all patients were completely relieved of bladder spasm with its associated excruciating pain. In no instance has this spasmodic pain returned. All patients voided with ease following operation and 1 of the 4 female patients had slight urinary incontinence. Postoperative cystoscopic examinations were made in all cases under local anesthesia. All patients showed some residual bladder lesion and complained of pain on forcible distention of the bladder. Whether or not vascular spasm existed prior to operation and was relieved by it, was not discernible in this series. All patients showed an increase in bladder capacity immediately following operation. This increase in bladder capacity had persisted in 2 patients, while in 4 it had reverted toward the pre-operative level. None of these patients had been relieved of abnormal urinary frequency. None of the 3 patients with Hunner ulcers showed improvement of that lesion or relief from the discomfort usually associated with bladder distention in that disease.

All of the patients here reported are satisfied and grateful for the relief of their intolerable pain in spite of the fact that none can be considered as cured by the operation.

SUMMARY AND CONCLUSION

From the facts here presented it seems evident that sympathectomy relieves bladder pain, not by removing the essential afferent pathways from that viscus but by relieving spasm of the internal sphincter and perhaps other parts of the bladder musculature. Certainly the one constant and predominating feature of all the cases of this series was vesical spasm prior to operation. Likewise the one constant postoperative result was relief from intolerable spasm and ease of urination. These observations and conclusions completely bear out those of Douglas and the theories expressed by others.

It further appears evident that sectioning of the hypogastric nerves alone, without the more extensive and hazardous division of the lateral sacral sympathetics provides adequate relaxation of the sphincter to relieve bladder spasm.

Since normal afferent components exist in the bladder following sympathectomy, it appears illogical to suppose that bladder pain resulting from malignancy should be relieved by this operation. In conclusion we would repeat.

1 The parasympathetic (sacral) pathways carry the essential afferent components of the bladder.

2 The sympathetic (presacral, or hypogastric nerves) pathways may or may not carry afferent pain components of the bladder.

3 Division of the presacral nerves provides relief of vesical spasm and pain resulting from intractable bladder infections.

4 Division of the lateral sacral sympathetics in addition to the presacral nerves accomplishes this same end but does not appear to be necessary or desirable.

5 Sympathectomy brings about the relief of spasmodic pain by relaxation of the vesical outlet and the detrusor mechanism, it does not render the bladder insensitive to pain of other origin.

6 Sympathectomy for the relief of bladder pain should be resorted to in only those patients in whom that pain is clearly demonstrated to result from spasm of the vesical outlet.

7 Sympathectomy was not shown to cure the lesions of Hunner ulcer in the cases here reported.

were performed. The patient voided normally without incontinence immediately after the operation and was free from bladder spasms or pain. Urine amounted to 100 and 150 cubic centimeters. She was discharged on the seventeenth postoperative day. Four months later the patient voided up to 150 cubic centimeters once an hour during the day and 4 or 5 times during the night. There was no spasmodic pain on urination and no incontinence, but she had mild dull pain in bladder on distention. A cystoscopic examination with local anesthesia revealed the Hunner ulcers to be unchanged. Eleven months after operation the patient had been free from severe pain; there was some bladder discomfort consisting of dull burning pain when bladder was distended or when she voided. Frequency of urination without incontinence was each hour by day and 3 to 5 times during the night, voided 30 to 100 cubic centimeters. The patient stated that her bladder capacity was clearly limited by the discomfort of distention. The cystoscope revealed the Hunner ulcers to be unchanged. Severe pain on distention of the bladder but normal sensations throughout the bladder to various stimuli.

With this patient there was complete relief from severe spasmodic pain, no improvement in frequency or discomfort on distention of bladder, slight increase in bladder capacity, and no change or improvement in Hunner ulcers, but she was completely satisfied and grateful for her operative result.

CASE 4. B. B. No. 41383, a housewife, 26 years of age, had Hunner ulcers of the bladder with moderate intracystic staphylococcal infection of both kidneys requiring all forms of therapy for 1 year. Urination had occurred every 15 to 30 minutes for 3 to 4 months. The patient slept on a bed pan and had intolerable bladder spasms on moving about and on urination. Spinal anesthesia was administered for the cystoscopic examination which revealed a bladder capacity of 60 cubic centimeters and a bladder highly inflamed throughout with several areas of ulceration. The pyelograms showed bilateral hydronephrosis and a one plus hydroureter. A presacral neurectomy with excision of the lateral sacral sympathetic chains was performed. Immediately after the operation the patient voided normally without any discomfort, amounts ranging from 50 to 60 cubic centimeters for the first week. The capacity for the second week increased from 150 to 300 cubic centimeters with freedom from pain. She was discharged on the twenty-first day voiding from 180 to 200 cubic centimeters without discomfort. Two months later she voided from 100 to 250 cubic centimeters with complete absence of bladder spasm but had slight burning in the urethra and had pain on overdistention of the bladder. A cystoscopic examination made with local anesthesia showed 3 typical Hunner ulcer lesions in the bladder but urine was normal. Eleven months after operation she voided every 2 or 3 hours with slight terminal burning in the urethra. She had no spasm and no pain in the bladder. She had slight urinary incontinence at times with loss of a few drops of urine and wore a napkin to prevent soiling her clothes. A cystoscopic examination revealed a bladder capacity of 180 cubic centimeters, overdistention produced severe pain. The bladder was normal throughout except for the Hunner ulcer areas which showed no change. Bladder sensations were entirely normal.

With this case there was improvement but no cure of frequency; there was complete relief of

spasmodic pain which incapacitated the patient. She still had Hunner ulcers and had acquired a slight urinary incontinence, but was completely satisfied with the operative result.

CASE 5. M. B. No. 39955, a housewife, 25 years of age, had tuberculous cystitis persisting for 1 year without relief following nephrectomy for renal tuberculosis. The symptoms were frequent urination every 10 to 20 minutes by day and 5 to 8 times at night with burning and severe bladder spasms and pain on each urination. General anesthesia was administered for the cystoscopic examination which revealed a diffusely inflamed bladder, a bladder capacity of 75 cubic centimeters, left kidney urine normal, pyelogram normal but bladder urine contained pus and tubercle bacilli. A presacral sympathectomy and lateral sacral sympathetics were performed. Immediately there was the normal desire to void and complete continence with no pain. By the tenth postoperative day the patient was voiding 100 to 150 cubic centimeters. She was discharged on the sixteenth day having no pain but moderate urethral burning on urination. During the night she voided about 1 or 2 times. Three months later she returned for a check-up. She had been asymptomatic till a few days before when she developed increased frequency and urethral burning but no pain. The urine was found to contain many *Bacillus coli*. The patient was given a course of sulfanilamide with a regression of the frequency. Four months after operation the patient reported that she had continued free from her symptoms.

This patient had been relieved materially of her urinary frequency. Her capacity had considerably increased and she had remained entirely free from her spasmodic bladder pain.

CASE 6. C. V. No. 37641, male, 41 years old, laborer, had tuberculous cystitis for 1 year following nephrectomy for right renal tuberculosis. He had had bladder irritation for 3 years prior to nephrectomy. He had a frequency of 1 to 2 hours during the day and night with spasms of pain on urination. Tubercle bacilli were found in the urine. Cystoscopic examination was made with general anesthesia revealing a diffuse ulcerative cystitis and a bladder capacity of 110 cubic centimeters. A presacral neurectomy was performed. Immediately afterwards he voided normally without incontinence. Frequency and capacity remained unchanged over pre-operative state. There was no pain on urination. Four months later there was no increase in bladder capacity or frequency, patient voiding with complete absence of bladder pain or spasms but there was some burning in the urethra. Seven months after operation his general condition was excellent. He was continent, his urine was a plus pus and tubercle bacilli and he voided every 2 hours day and night with complete comfort.

This patient had not been relieved of his urinary frequency but has been made completely comfortable.

Analysis of these cases reveals certain constant factors. Prior to operation all had severe spasmodic bladder pain, all had some degree of difficulty in voiding although none had residual urine, all patients required general anesthesia for cystoscopic examination and cystometric examinations in all instances revealed definite hypertonicity of the detrusor mechanism.

tion there first occurs hypotony and hyperkinesis. With the continuation of a chronic, partial obstruction this compensating stage of urinary tract function passes shortly into the decompensating stage of hypotony with hypokinesis, which may finally end in complete atony. These stages may be diagnosed by intravenous urography.

So much for the dynamics of urinary transportation. What about renal function? In acute, complete obstruction, in which the urinary tract is hypertonic and hyperkinetic, there may be a reflex cessation of renal function. In these cases all our diagnostic functional methods would reveal no renal function, yet, if such obstruction be of short duration, renal function returns to normal. In chronic, long standing, partial obstructions, in which the urinary tract is in the decompensating stage of hypotony and hypokinesis, renal function is impaired; but no test has yet been devised to tell us the degree of permanent impairment. All functional tests merely measure renal function at the time the test is done. However, we know clinically how many times supposedly functionless kidneys have shown permanent improvement of function, sometimes to a very great degree, when the obstruction has been removed. We believe that there will always be some restoration of renal function if the renal parenchyma has not been entirely destroyed, provided there is not complete atony of the urinary tract. This can be determined by the response of the pelvis and ureter to faradic or other stimulation at the time of operation.

From the standpoint of renal function it is important to know whether the renal pelvis is intraparenchymal or extraparenchymal, for intraparenchymal dilatation will cause much greater pressure death of functioning renal tissue than if it is possible for the pelvis to dilate extraparenchymally. We will discuss later the rôle such intraparenchymal pelvic dilatation might play in hypertension. However, the extent to which an obstructive uropathy may be evaluated in terms of impaired urinary tract function depends upon an inherent system reserve, the factors of which are primarily (1) The ability of the kinetic factor to maintain normal emptying rate in hypotonic dilatation of the urinary tract, (2) the ability of kinetic recovery in cases of hypotony and hypokinesis after the mechanical obstruction is removed, or after the cause of an adynamic obstruction (infection) is eliminated, and (3) the ability of the renal pelvis to dilate extraparenchymally, in which case pressure destruction of the renal parenchyma will be minimized.

All are familiar with the various pathological processes which may cause obstruction in the upper urinary tract. If we consider the etiology of obstructive uropathies, we may classify all these processes into 2 main groups. The first group is that of *mechanical obstructions*, which is further subdivided into the intrinsic obstructions, such as stone, congenital stricture, etc., and the extrinsic obstructions, such as periureteritis, accessory blood vessels, ureteral kink, renal ptosis, etc. The second main group we have called the *adynamic obstructions*, which include congenital atonies, infectious atonies, usually due to lymphatic extension of infection from the adnexa, and idiopathic neuromuscular dysfunction.

The symptomatology of obstructive uropathy is indefinite. In the adynamic obstructions pain never occurs. In the mechanical obstructions typical colic-like pain occurs only if the renal pelvis or the ureter be suddenly distended. In the gradually acquired pathological states, however, there seems to be a decided tendency for sensory symptoms to be referred to the gastrointestinal tract, and to be given naturally a gastrointestinal interpretation.

Much could be written concerning the rôle of infection in obstructive uropathy. Extension of an infection from the adnexa through the periureteral lymphatics may produce an adynamic disturbance of urinary transportation. Infection within the urinary tract itself always hastens renal destruction. Most important, however, is that the persistence of infection is almost proof of existing obstruction to the free transportation of urine, whether this obstruction be of the mechanical or of the adynamic type. It is almost impossible to infect experimentally a normal urinary tract. Conversely, it is almost impossible to disinfect a poorly emptying urinary tract. One of our therapeutic axioms states that a urinary infection cannot be eradicated in cases of urinary stasis, even if renal function allows sufficient concentration of our urinary antiseptic at the site of the infection.

In closing, let us see what relation obstructive uropathy might have to hypertension. Goldblatt and his co-workers have shown that experimental hypertension in dogs may be produced by partially constricting one renal artery. Leadbetter and Burkland have recently reported a case of hypertension in a boy $5\frac{1}{2}$ years of age, which was cured by removing a functionless kidney, the main artery of which was found to be almost completely occluded by a smooth muscle plug which reduced the lumen to a mere crescentic slit. Butler records 2 cases of hypertension associated

OBSTRUCTIVE UROPATHIES

ALEXANDER RANDALL, M D F A C S, and P BOLAND HUGHES M D

Philadelphia Pennsylvania

IN 1926 the term, obstructive uropathy was introduced into medicine by Young with the following definition 'Under this heading are grouped all the changes in the kidney, pelvis, ureter, bladder, and urethra resulting from obstruction to the free outflow of urine from the urinary tract.' This definition epitomizes the urological interpretation of disease prior to the introduction of intravenous urography when we thought only in terms of organopathology and organphysiology. We were by then becoming familiar with the usual gross lesions of the urinary organs and as is always the case we were striving for a similar familiarity with the evidences of earlier pathological changes. But we still thought in terms of individual organopathology.

Since the advent of intravenous urography in 1930 we have learned to evaluate all urinary tract disease except renal neoplasms in terms of urinary tract function rather than in terms of the pathological end picture and for the first time we have been able to visualize competently the normal and the perverted physiological function and to picture and study the entire urinary system uninfluenced by any extraneous artifact. We should, therefore, revise our previous conception

of an obstructive uropathy by realizing that we are not interested so much in the static changes in the urinary organs 'resulting from obstruction to the free outflow of urine' as in the *real changes*—changes in urinary tract function—which can be determined only through a physiological interpretation of the intravenous urogram. If urinary tract function has been affected by an obstructive uropathy we must differentiate between a derangement due principally to impaired renal function and a derangement due to deficient urinary transportation. These two factors though interdependent must be distinctly separated and individually analyzed.

In this paper we will confine ourselves entirely to the upper urinary tract. A brief consideration of the dynamics of the upper urinary tract will serve as an introduction.

When an obstructing lesion produces disturbance of urinary tract function resulting dilatation of the urinary tract is just an anatomical compensating factor. Important however is the kinetic or emptying factor. Renal function and urine transportation will not be impaired in the cases of dilatation if the kinetic function maintains a normal emptying rate. Any sudden mechanical obstruction, such as the impaction of a small stone in the ureter, results immediately in pelvic and ureteral hypertony and hyperkinesis i.e. a renal colic. In any chronic partial obstruct

SYMPOSIUM: TREATMENT OF FRACTURES

CONSERVATIVE TREATMENT OF FRACTURES

E. L. ELIASON, M.D., Sc D., F A.C.S., Philadelphia, Pennsylvania

EXAMINATION of the records of several local hospitals shows that from 10 to 15 per cent of patient visits are made for fracture treatment. Such a common condition probably exists uniformly in other communities and must of necessity be met and treated by a great number of physicians, not all surgeons by any means.

Fractures are, however, the pet aversion not only of the general practitioner but of many surgeons. The reason is twofold. The average physician will not take the time to equip himself with a thorough knowledge of fractures nor will he exercise the patience and the painstaking, time-consuming care necessary for a favorable outcome. Consequently the ultimate results in broken bones are not all that could be expected nor that we could desire. The same discontent is experienced by the patient and hence the frequency of suits for malpractice which is the second reason for the unpopularity of fracture cases in the eyes of the physician.

Thus dislike of fractures is made even greater by reason of the fact that we have run wild with invention and production of costly, strange, wondrous, and complicated gadgets with a multiplicity of levers, nuts, screws, weights, springs, etc., designed to fit fracture treatment into the machine age. Many of these puzzling contraptions are expensive and most of them are cumbersome and require a mechanic or engineer to assemble them. Our hospital storage spaces contain hundreds of dollars worth, bought for one surgeon, for one patient, employed once, often unsuccessfully, and discarded thereafter. In the hands of the originator a complicated apparatus may work wonders, but may cause only confusion and defeat in another. The man and not the splint is responsible for the result. Hippocrates said that the man who presumes to treat fractures must be equipped to do so under any conditions. Special splints for special fractures are desirable and often

necessary, yet the simpler methods of reduction and fixation that have stood the test of time will in the long run, in the greatest number of hands, in the greatest number of patients, produce the greatest number of good results.

Information on fracture treatment should, therefore, be conservative and simple enough in its application to be useful to the general practitioner, reserving the more complicated methods for the unusually difficult cases in the hands of men trained for such work.

Most of the principles of fracture treatment have come down to us from the centuries and a brief historical paragraph may be of interest. Magnuson, of Chicago, wrote a most interesting historical article upon this subject and I will not hesitate to quote some of his facts. Records of fracture treatment come to us from 4,500 years ago. Braestead and Smith, after examining about 5,000 mummies, found that about 5 per cent had fractures, many with splints in place. These fractures had been treated logically and gave excellent results even under our standards of today. Principles enumerated 2,500 years ago are sound to-day. These ancients spoke of "traction and counter traction, position of muscle balance, alinement regulated according to nature, early reduction, traction in the long axis, prevention of pressure points, elevation for swelling, and suiting the splint to the patient and not the reverse." Warning was given not to remove splints until union was solid and designation was made of the average time required for union in the various fractures. This knowledge was carried to Rome by the Greeks and in the first century A.D. Martial referred to Hermes as the best surgeon for fractures and remarked that there were many specialists, some for enlarged tonsils, some cutters for stones, some bone setters, blood letters, and some for removing brands from slaves.

Old as these tenets are, have we respected them as we should? Do we remember and practise them? Do we make use of our x-ray always as a blessing or do we make it into a curse and treat the film evidence rather than the broken bone in the patient? Has simplicity been replaced with

Presented in the Symposium on Fractures, before the Clinical Congress of the American College of Surgeons, New York, October 17-21, 1938

with unilateral pyelonephritis in children whose blood pressure returned to normal after nephrectomy. Arterolar changes were found in the removed kidneys. Freeman and Hartley have recently added another interesting case of hypertension associated with renal ischemia. We recently obtained a similar clinical result by removing a hypoplastic kidney with hypoplastic renal vessels from a young man 28 years of age. There is clinical evidence, therefore, that renal ischemia in one kidney may produce hypertension in man just as it does experimentally in dogs.

But renal ischemia does not necessarily have to be caused by partial constriction of the renal artery. Hartwich, and Harrison and his co-workers have produced hypertension in dogs by ligation of one or both ureters. In man, however, hypotension is just as frequently associated with ureteral occlusion as hypertension. The renal pelvis in dogs is principally intraparenchymal, and dilatation can readily cause renal ischemia by parenchymal pressure. In man, due to the anatomical relationship of the pelvis to the parenchyma, dilatation is frequently almost entirely extraparenchymal. In these cases of course ureteral occlusion would not be as liable to produce renal ischemia. What percentage of cases of hypertension in obstructive uropathy

can be explained by a dilating intraparenchymal pelvis remains to be determined by further clinical investigation.

In conclusion, it may be stated that the rôle of obstructive uropathy broadens as we begin to appreciate and to interpret the finer and earlier diagnostic criteria and to correlate with this study a growing appreciation of the normal and the perverted physiology of urine transportation. The value of intravenous urography is without parallel and is indispensable in attaining this end.

imum amount of trauma incident to the reduction. We are taught that certain muscles act to produce certain physiological movements and positions of parts. Additional observation under the fluoroscope, together with the aid of a conscious patient and local anesthesia, aids greatly in determining the full extent of these muscular actions. A fracture of the shaft of the forearm bones is the best example of this. Experience has shown that here the best position for reduction is with the elbow acutely flexed, and the forearm acutely supinated with traction exerted from over the shoulder of the affected side.

Trauma means destruction and increased hemorrhage, devitalization, and added difficulty due to muscle spasm and pain. Many times roughness has defeated the purpose.

Thoroughness If success is to be our reward, thoroughness is essential and yet it must not be overemphasized. A cabinet-maker's or perfect reduction does not insure a perfect function nor does the absence of perfect reduction necessarily indicate diminished function. It is here that individuality and judgment play such an important rôle. In the past there were only two parties concerned in a fracture result, the patient and the surgeon. A fair anatomical result, with fair or good function, satisfied both. When the roentgen-ray entered the field at once there was born the desire to obtain the so called roentgen or a cabinet-maker's reduction. This resulted in an associated increase in the number of open reductions. Next, a third party entered the field, namely, the insurance companies and our results are now scrutinized by this third party with an impartial eye.

In some respects this has been advantageous to the patient but in other respects it has led to the desire to obtain the so called perfect reduction. Why? It is due to the fact that a jury is more than likely to judge the result by the roentgenographic evidence and not by the degree of function obtained. Hence, we actually find that more open reductions are resorted to in an endeavor to meet this demand. Then, too, if the patient or his family view the film, which should always be insisted upon, they ask for open reduction thinking it necessary for a good result.

Individuality Life, limb, and function for each individual is necessary. Restoration of contour is desirable if compatible with these. A fracture is not only a broken bone but injured soft parts in addition. In fact the soft tissue damage, separately and collectively, may be, and often is, more important at the time of the accident and later when considered in the light of functional results. Perfect alignment, perfect reduction, minimum

deformity, etc., are desirable but not always necessary for restoration of function. It must be the aim of the surgeon to evaluate the numerous factors with relation to required results for the individual case and so conduct treatment. So varied may be the injuries associated with a broken bone, so numerous the constitutional factors incident to age, disease, site of fracture, function desired, economic conditions, etc., required for each particular case, that individuality rather than generality in treatment must obtain. Principles are comprehensive and abstract, but practice must be individual and concrete. Each patient and treatment must click. Fit the treatment to the patient and not the patient to the treatment.

A young person will obtain a better result than will an adult with the same original deformity, by reason of growth factors. A young tennis player will require better function in his forearm than will the retired banker of 70 years. A bad cardiac case might rather have malunion than an open reduction. A badly comminuted fracture of the femur merely requires length and alinement, not perfect reposition. An athlete will require length and alinement for a fracture of his leg. An elderly night watchman could put up with a limp. It is astonishing what vicious deformities may accompany excellent functional results in fractures in the upper extremity of the humerus for example when treated conservatively. Epiphyseal separations do not often require perfect reposition at the expense of an open reduction. Again our statistics show that open reduction in these latter cases is necessary in less than 3 per cent.

A surgeon treating fractures must be practical and must have a mechanical sense. He must be willing individually to at least supervise the treatment throughout the case. Treatment should be absolutely, entirely, and constantly under the guidance of one man.

The initial attempt at a reduction should be accompanied by every factor that could be desired to insure success, proper and sufficient assistance, complete relaxation anesthesia, fluoroscopic control, and the necessary armamentarium for traction and fixation as required. Repeated attempts at reduction militate against the best results, often terminating in open reduction. Our statistics show this relationship very definitely. At certain sites such repeated trauma may terminate in non-union. Ashhurst stated years ago that malunion of moderate degree is less evil than non-union.

When may accurate reduction be imperative? Although not always necessary the best restoration of contour may be required in fractures near or into a joint, in the mid shaft of the humerus,

complexity and multiplicity and the desire to do open reduction for a cabinet maker's reposition? And have we forgotten that the aim of all fracture treatment is the restoration of function with or without restoration of contour? Reported figures show that only 65 to 66 per cent of fractures with good reposition gave good function whereas 45 per cent with poor reposition gave good function. Evidently factors other than the position of the fragments are concerned. It is better to have a deformity with function than a perfect union with dysfunction that results in a reduction of the individual's earning power. The patient must have at least the function necessary for his livelihood.

The 4 factors of most importance in the treatment of any and all fractures are promptness, gentleness, thoroughness, and individuality, as stated by Dr. William Darrach many years ago.

Promptness. No patient suffering with a fracture of a long bone shaft should be moved until the best available fixation has been applied. The trauma of injudicious first aid treatment is often responsible for the bad results. Such careless and injudicious treatment is not always limited to the aid given by the laity, but is all too often met with after the patient reaches the hospital. A patient with a fracture of the shaft of a long bone transported without adequate splinting will have added vessel, muscle, and nerve injury. The limb should be placed as nearly as possible in the position of muscle equilibrium. In the case of the lower extremity, traction as nearly as possible in the direction of the long axis of the uncontrollable fragment is really a necessity. In the humerus the weight of the limb slung at the wrist together with chest binder will suffice if the patient is transported in the upright position. In fact, actual lengthening of the part is sometimes thus obtained. Needless to say if shock exists the appropriate treatment together with morphia should be instituted. Figures indicate that proper transportation splinting, together with large doses of morphia, reduced the mortality in compound fractures of the femur in the World War from 75 to 15 per cent.

The actual or definite treatment of the fracture should be undertaken just as soon as possible, the condition of the patient permitting. A very careful examination should be made with reference to possible visceral nerve or vascular injury before any manipulation is attempted. The original trauma causes nerve injuries quite often in certain fractures. 4 to 8 per cent in cases of fracture of the humerus, of 211 nerve injuries with fractures quoted by Lewis and Miller, 24 per cent were pri-

mary and 42 per cent secondary and incident to treatment. Such knowledge should serve to indicate the need for observation and prevention. Should such injuries be found the patient or members of his family should be informed of their serious nature. The earlier the reduction is attempted the easier its accomplishment. A properly reduced fracture becomes increasingly more comfortable. Persisting pain requires investigation.

It has been the writer's privilege to be present on the field and see many fractures occur in athletic pursuits. Immediate gentle traction and manipulation within a few seconds while the tissues were numb and the muscles relaxed resulted in a very high percentage of reductions sufficiently perfect as to require no further adjustment. Delay permits coagulation, fibrin formation, and cellular exudation with consequent loss of tissue elasticity. The blood at the fracture site soon loses its liquid state and becomes a fibrinous, gum-like clotted mass, interfering with bone reposition and making it more difficult or even impossible. Such are the effects of delay. It is only fair to state that there are some who advocate delay for varying periods of time (days) before reduction is attempted. These advocates report good results. Adequate assistants, satisfactory anesthesia, local spinal or ether and, when possible, the fluoroscope are very desirable. It may be stated here that in acute fractures only a few hours old, novocain injected around the fractured surfaces is most satisfactory in preventing pain and producing muscle relaxation during the reduction. Furthermore, the patient being conscious very often can cooperate splendidly.

Today as soon as a fracture patient is admitted to the University of Pennsylvania Hospital the interne on service examines him thoroughly for associated injuries, meanwhile notifying the chief or his assistant on service and they and the patient meet in the fluoroscopic room where the reduction is conducted. The interne is active in the reduction, being aided and supervised by his seniors. Only when he fails does the more experienced man take hold. This practice has increased the number of successful primary reductions from 45 to 80 per cent in a few years.

Gentleness. No fracture should be traumatized any more than necessary. Eliciting of crepitus is not necessary for diagnosis. It may be harmful. All movements affecting the fractured bone should be undertaken slowly and gently, gradually increasing traction in the direction of muscle equilibrium or balance. If care is exercised in obtaining this position of muscle equilibrium, not only will the reduction be simple but there will be a mini-

imum amount of trauma incident to the reduction. We are taught that certain muscles act to produce certain physiological movements and positions of parts. Additional observation under the fluoroscope, together with the aid of a conscious patient and local anesthesia, aids greatly in determining the full extent of these muscular actions. A fracture of the shaft of the forearm bones is the best example of this. Experience has shown that here the best position for reduction is with the elbow acutely flexed, and the forearm acutely supinated with traction exerted from over the shoulder of the affected side.

Trauma means destruction and increased hemorrhage, devitalization, and added difficulty due to muscle spasm and pain. Many times roughness has defeated the purpose.

Thoroughness If success is to be our reward, thoroughness is essential and yet it must not be overemphasized. A cabinet-maker's or perfect reduction does not insure a perfect function nor does the absence of perfect reduction necessarily indicate diminished function. It is here that individuality and judgment play such an important rôle. In the past there were only two parties concerned in a fracture result, the patient and the surgeon. A fair anatomical result, with fair or good function, satisfied both. When the roentgen-ray entered the field at once there was born the desire to obtain the so called roentgen or a cabinet-maker's reduction. This resulted in an associated increase in the number of open reductions. Next, a third party entered the field, namely, the insurance companies and our results are now scrutinized by this third party with an impartial eye.

In some respects this has been advantageous to the patient but in other respects it has led to the desire to obtain the so called perfect reduction. Why? It is due to the fact that a jury is more than likely to judge the result by the roentgenographic evidence and not by the degree of function obtained. Hence, we actually find that more open reductions are resorted to in an endeavor to meet this demand. Then, too, if the patient or his family view the film, which should always be insisted upon, they ask for open reduction thinking it necessary for a good result.

Individuality Life, limb, and function for each individual is necessary. Restoration of contour is desirable if compatible with these. A fracture is not only a broken bone but injured soft parts in addition. In fact the soft tissue damage, separately and collectively, may be, and often is, more important at the time of the accident and later when considered in the light of functional results. Perfect alignment, perfect reduction, minimum

deformity, etc., are desirable but not always necessary for restoration of function. It must be the aim of the surgeon to evaluate the numerous factors with relation to required results for the individual case and so conduct treatment. So varied may be the injuries associated with a broken bone, so numerous the constitutional factors incident to age, disease, site of fracture, function desired, economic conditions, etc., required for each particular case, that individuality rather than generality in treatment must obtain. Principles are comprehensive and abstract, but practice must be individual and concrete. Each patient and treatment must click. Fit the treatment to the patient and not the patient to the treatment.

A young person will obtain a better result than will an adult with the same original deformity, by reason of growth factors. A young tennis player will require better function in his forearm than will the retired banker of 70 years. A bad cardiac case might rather have malunion than an open reduction. A badly comminuted fracture of the femur merely requires length and alignment, not perfect reposition. An athlete will require length and alignment for a fracture of his leg. An elderly night watchman could put up with a lump. It is astonishing what vicious deformities may accompany excellent functional results in fractures in the upper extremity of the humerus for example when treated conservatively. Epiphyseal separations do not often require perfect reposition at the expense of an open reduction. Again our statistics show that open reduction in these latter cases is necessary in less than 3 per cent.

A surgeon treating fractures must be practical and must have a mechanical sense. He must be willing individually to at least supervise the treatment throughout the case. Treatment should be absolutely, entirely, and constantly under the guidance of one man.

The initial attempt at a reduction should be accompanied by every factor that could be desired to insure success, proper and sufficient assistance, complete relaxation anesthesia, fluoroscopic control, and the necessary armamentarium for traction and fixation as required. Repeated attempts at reduction militate against the best results, often terminating in open reduction. Our statistics show this relationship very definitely. At certain sites such repeated trauma may terminate in non-union. Ashhurst stated years ago that malunion of moderate degree is less evil than non-union.

When may accurate reduction be imperative? Although not always necessary the best restoration of contour may be required in fractures near or into a joint, in the mid shaft of the humerus,

and in the forearm. Length and alignment is very essential in all lower limb fractures.

Open reduction. Open reduction may be fraught with great danger of loss of function, limb, or even life. To teach the promiscuous employment of this method will bring sorrow to many in its application. This refinement should be resorted to only after much deliberation. If experience has shown that the type of fracture under consideration will heal with good function despite its displacement, let sleeping dogs lie and treat the fracture by the closed method.

There are 3 indications for open reduction in an acute fracture, namely: failure to obtain a satisfactory reduction by the closed method; failure to maintain a satisfactory reduction; and lastly, and probably the most important, the surgeon's ability to obtain a satisfactory result if he resorts to an open reduction. In order to have a clear understanding we must explain what the term, satisfactory, should mean in each of the 3 instances. Here, again, individuality enters the field.

The assurance of a satisfactory result if open reduction is to be undertaken is almost imperative. We must base this assurance on the experience we have had in fracture surgery, the bone or bones involved and the level of the fractures in the same, the condition of the patient's health, his age, the age of the fracture, and whether our efforts can accomplish a better functional, not necessarily a better anatomical result. Extensive comminution as a rule should be a deterrent to open reduction.

It is not the purpose of the writer to discuss the surgical technique of open reduction but I would like to emphasize one point. Throughout the literature on the subject, emphasis is placed on keeping the gloved hands out of the wound. Too much emphasis upon this detail has hampered many an operator to the detriment of the patient. In reality there seems to be no reason why a fresh glove previously untouched should enter the wound with any more danger than an instrument. The gloved finger inserted at the fracture site will inform the surgeon at once concerning the character and condition of the fractured area and the direction for extension of the incision if desirable and hence minimize the trauma that must of necessity follow, due to tissue injury by needlessly large misplaced incisions and retractions required to permit visualization.

Here a word may well be added with regard to internal fixation in open reductions in general. It has been the writer's practice in the past to use internal fixation (plate and screws preferably) only

when the fragments will not remain in their proper relationship with the limb placed in the muscle balanced position. Adherence to this principle is responsible for the need for internal fixation in only 18.3 per cent of cases in which patients have been operated upon.

The age of the fracture in poor position or with vicious union needs individual judgment, neither, invariably will mean poor function. To attempt to break up a vicious position with $2\frac{1}{2}$ inch shortening in a 14 weeks old fracture may be justified in a youngster but not in a hemiplegic or a patient with Buerger's disease.

Roentgenograms. Films showing 2 views should when feasible, be taken of every suspected fracture before an attempt is made to reduce it. This both lessens the possibility of trauma and protects the surgeon against the accusation of injury influenced by his manipulation. After the reduction of a fracture under an anesthetic the roentgenogram should not be taken until the anesthetic has ceased to act. Many times a fracture will remain reduced with the muscles still under the anesthetic but the fragments will slip when the muscle tension has returned. We had best be satisfied with the fluoroscopic evidence for that day and take a film 24 hours later. A third film showing 2 views should be taken 2 weeks later.

Physical therapy. A fracture recovers best when the nutrition of the bone and those structures associated with it most nearly approach normal. Physical therapy aids in restoration of blood supply. It should begin if feasible, when the treatment of the fracture begins, not after union has occurred.

Return to full function of weight bearing, etc. must be withheld until solid clinical union is found to be present. The roentgenographic evidence with regard to the rigidity of callus cannot be depended upon.

It has been our experience that the patient himself is his best physical therapist. It should be explained to him that return to function is his job and that only by exercise supplemented by massage and heat, can he get well. He should be carefully instructed in how to use all of these measures. Aided active motion should be explained to him. Pain is nature's warning of trouble. He will not injure himself but a physical therapist might. If a therapist is on the case at once, the patient transfers all responsibility to his shoulders, feeling that he only a patient does not know enough to conduct his own treatments. The individual is his best physical therapist even without the various baths, electrical rays, lights, currents and other such measures.

It is not within the scope of this presentation to describe in detail the various efficient and yet simple dressings described by every treatise on this subject, but rather to call attention to the fact that the meticulous attention to the application of the simple fundamental principles of treatment will give the most satisfactory results, for the most patients, and the most physicians. Special intricate apparatus has its place in special conditions and in special hands.

RESULTS OBTAINED

Following the above principles of treatment our results have improved year by year. There has been an increase in the number of successful primary fluoroscopic reductions. Open reduction was necessary in only 7.3 per cent in the last 3 years of those cases serious enough to be admitted to the hospital. Metal, internal fixation material was necessary in only 18.3 per cent of cases. This reduction from the former figures of 33 per cent occurred very largely in forearm fractures, and open reduction results were good in 69.9 per cent, fair in 20.6 per cent, and poor in only 9.5 per cent.

CONCLUSIONS

1 A fracture implies soft tissue injury as well as a broken bone, and a fracture requires emergency treatment. Promptness is essential, the earlier reduction is attempted the easier reduction is accomplished.

2 Swelling should indicate action rather than delay, and the best way to reduce swelling is to reduce the fracture. Fluoroscopic control with local or spinal anesthesia is desirable. Position of muscle equilibrium reduces trauma and facilitates reduction.

3 Gentleness is indicated, thoroughness is essential but a cabinet-maker's reposition is not necessary to good function, and individuality is essential for best results. It is not the splint but the man behind it that produces results. Fit the treatment to the patient and not the patient to the treatment.

4 Deformity does not mean dysfunction, deformity with function is preferable to perfect restoration, but with loss of earning power. Function, necessary to the individual's livelihood, should be the goal.

THE CINEPLASTIC AMPUTATION

HENRY H. KESSLER M.D., Ph.D., F.A.C.S. Newark, New Jersey

AMONG the large group of the disabled who seek the services of rehabilitation agencies, the amputation case is one that requires careful consideration. On the basis of the Cleveland survey, Faries has estimated the number of persons with arm amputations in the United States to be in the neighborhood of 33,000. While this appears to be a rather high estimate, it nevertheless calls attention to one serious type of handicapped patient whose rehabilitation becomes an important concern of all public agencies.

Many may rehabilitate themselves through educational or vocational aptitudes that are not affected by their handicap. Some have well adjusted personalities that make their social adjustment comparatively easy. The larger number, however, are unable to help themselves and therefore seek our aid. Employment is facilitated by providing these individuals with artificial appliances. The prosthesis serves to remove the psychological aversion toward the crippled by replacing the missing member. It likewise offsets the

economic prejudice of the employer through the increase in industrial efficiency displayed by the amputee.

A man who wears an artificial leg is the least disabled of all cripples. Such a device not only substitutes for the weight bearing function of the natural leg but also eliminates the repellent attitude caused by the defect. Fitting an artificial leg is not a difficult task except in unusual situations.

On the other hand, the problems which face us in the fitting of an appliance to an arm stump are extremely difficult. In the case of an amputation of the arm or hand, the complete restoration of function by any mechanical means is quite beyond human invention. While it has been possible to imitate some of the simpler prehensile actions of the hand by jointed fingers, which can be flexed at will, this should not lead to an enthusiasm which is not warranted in fact and which raises only false hopes in the minds of the armless. The perfection of a mechanical hand with delicate selectivity has baffled inventive genius.

Only a small proportion of those supplied with artificial arms wears them and a still smaller proportion actually uses them. During the World

Presented in the Fracture Symposium before the Clinical Congress of the American College of Surgeons, New York, October 17-21, 1933.

War our government permitted the armless veterans to choose any artificial arm on the market Many chose complicated mechanical hands and arms which they soon laid aside as too cumbersome In England the results were also disappointing In 1918 the Ministry of Pensions made an inquiry into the use of arms furnished by the government and found that considerably less than half were using them In Germany a survey made over a long period of years among a group

of 7,000 arm amputations showed only 129, or 1.8 per cent, wore a mechanical arm (4) In a personal series of 1,500 arm amputations, 230 were observed over a period of 6 years At the end of this period only 12 per cent of this group were wearing their artificial arms and 6 per cent were using them for work and in the routine pursuits of life

The principal problem is that of making the stump play a supporting rôle in daily life and

Fig 14 Congenital amputation with biceps motor a at right with triceps motor

work. The expectations of persons with amputations are frequently too great. They hope to be capable of doing absolutely independent work through the artificial appliance. The use of the prosthesis, however clever it may be, is a limited one, since the safety factors retained by the body in its capacity for compensation may be more valuable than the best mechanical construction. For example, one armed persons learn very rapidly to dress, undress, wash, shave and comb their hair, as well as to write with the remaining arm. The left hand gradually becomes the right hand and assumes all the tasks previously fulfilled by the right.

Because of the unsatisfactory experience with the ordinary mechanical arm, attention has been directed toward the development of a substitute

Fig 15 Traumatic disarticulation of the elbow joint showing biceps motor, a, at center, showing both motors, b, at right, with prosthesis

arm in which the control can be achieved by natural muscular action. This development is marked by the names of Vanghetti, Sauerbruch, Ceci, Putti, Pellegrini, and Bosch-Arana. Jottkowitz, in a survey of 729 cineplastic amputations, found 37 per cent of this group wearing their arms from 1 to 13 years after operation (5).

In the cineplastic amputation the remaining muscles in the amputated stump are utilized to activate the prosthesis. By means of pegs passed through canals in the muscles and attached to levers operating the artificial-hand mechanism, the physiological action of the stump muscles is restored. The biceps and triceps muscles in the upper arm and the flexors and extensors of the lower arm control the grasp and release of the fingers of the artificial hand. Thus, the stump retains its real task of guiding the hand without other problems added to it, such as leverage, in the case of a mechanical arm. Though the fingers of the artificial hand have no feeling, natural control is, nevertheless, exerted by the muscles in the act of grasping, thereby permitting a close approximation to natural hand function.

This report represents a preliminary analysis of the results of cineplasty in a group of 78 cases. While this series is too small for statistical treatment, it furnishes some basis for a discussion of advantages and disadvantages of this procedure.

Age group. The youngest case in the series was a 6 year old boy with a double arm amputation (Fig 1). The oldest person in the series was an individual 61 years of age (Fig 2). There would seem to be some advantage in performing this operation at an early age, while the wide variation in age range would seem to indicate that age in itself does not constitute any contraindication to the procedure.

Type of amputation and stump. The series included all types of amputations such as those due to public, street, and industrial accidents (Figs 3, 4, 5), disease and congenital deformity. In none

of the cases was any attempt made to revise the stump by secondary amputation. The stump was utilized even in the presence of scars and other deformities (Figs 6, 7). Short congenital stumps of the forearm were unsatisfactory for muscle canalization. A single fixation canal permitted attachment of the entire stump as a unit to the activating lever of the hand. Flexion and extension of the stump at the elbow produced opening and closing of the hand (Fig 13).

Site of amputation. This has varied from a disarticulation of the wrist to a very short or high upper arm amputation (Figs 8 to 22c). At this juncture it would seem pertinent to make a plea for consideration of a site for an amputation of the forearm. There is nothing to be gained by disarticulating or amputating at the wrist. Too long a stump is neither applicable for cineplasty nor for ordinary mechanical arms since the receiving extremity becomes much longer than the remaining extremity. Furthermore, the stumps are usually cyanotic and cold and have a tendency to break down because of poor circulation. From

work The expectations of persons with amputations are frequently too great They hope to be capable of doing absolutely independent work through the artificial appliance The use of the prosthesis however clever it may be is a limited one since the safety factors retained by the body in its capacity for compensation may be more valuable than the best mechanical construction For example one armed persons learn very rapidly to dress undress wash shave and comb their hair as well as to write with the remaining arm The left hand gradually becomes the right hand and assumes all the tasks previously fulfilled by the right

Because of the unsatisfactory experience with the ordinary mechanical arm attention has been directed toward the development of a substitute

utilizing his cineplastic arm effectively (Fig 24). In a third case the dorsal motor in a forearm amputation became infected, sloughed out, and the patient is now using a single motor cineplastic arm (Fig 25). In still another case, that of a colleague referred to me for a prosthesis, the dorsal motor was made too deep, became ulcerated and was finally allowed to close. A spring is now utilized in place of the dorsal motor.

Fittings of prosthesis In this entire series, the fitting of the prosthesis has been very satisfactory with the exception of 1 case. Only minor adjustments were necessary in a few cases to permit the amputee to utilize the apparatus immediately. With respect to repairs, the hand is exceedingly light, is made of wood and from time to time

Fig 21 High amputation with double motor, a, at right, posterolateral view

Fig. 20 High amputation of upper arm with both motors. Showing the feasibility of still utilizing the remaining musculature for reciprocal motors a at right posterior view

the standpoint of cineplasty it is important to utilize the bellies of the muscle rather than the tendons and so an amputation at the junction of the middle and distal thirds of the forearm is most suited for this procedure.

Time interval. In 2 cases cineplasty was performed at the same time as the original amputation. The longest time interval between the initial amputation and the time of cineplasty was 30 years. This would indicate that these muscles can be retrained even after prolonged periods.

Re-adaptation. In this series of 78 cases 44 are now employed in remunerative work at such jobs as clerks, lithographer, painter, truck driver, in-

spector of transmission lines, watchman, track foreman, bookkeeper, leather embosser, machinist, elevator operator, fur sorter, laborer, accountant, inspector, helper in storeroom, needle board repair man (Fig. 21), commercial letterer and stereotype operator.

COMPLICATIONS

Infection. In this entire series there were 3 cases of infection. In 1 case of congenital amputation both canals became infected, sloughed out, and were lost. In another case of infection the canal sloughed out but this case was reoperated on, another motor was made and the patient is

Fig 24 Volar aspect showing canal intact, a, at center, dorsal aspect showing two canals. The proximal canal has been lost by infection, sufficient room remained for making a distal canal, b, at right, the hand in use with prosthesis

The results of this cineplastic amputation in a series of 78 cases are distinctly encouraging. Of this group, 44 may be classified as highly successful. These individuals are consistently using the prosthesis at work and in the routine pursuits of life over a period of from 2 to 6 years.

Of the 34 remaining, 19 enjoy partial utility of their prosthesis. Unusual work requirements may render it impractical even to wear the arm at work, as in the case of 1 worker in a chemical

plant who must immerse both arms in a solution as part of work operation.

Of the 15 that can be classified as failures, 5 have been due to surgical complications. Infection of the skin tube, necrosis due to previous x-ray dermatitis, improper placement of canals, too short a stump for utilization of leverage of muscle motors, and improper fit of prosthesis account for these failures. The remainder found it difficult to adjust themselves because of personality factors.

CONCLUSION

The use of the cineplastic amputation in selected cases is of distinct advantage in the rehabilitation of the armless. Through the natural control obtained by this procedure the individual is able to utilize the assistance of the amputated arm in the performance of his daily tasks. By increasing his efficiency, he restores his confidence in himself and his ability to compete with others. He is thus equipped to partake of a fuller life without asking for any special considerations.

fingers are knocked off but can be glued back again. Where the work requirements are such as to indicate need for an arm of heavy construction, this can be supplied by substituting a metal hand or wooden hand reinforced with metal.

Unsatisfactory results The difficulties that do arise can be ascribed to 3 factors: the patient, the operative procedure itself, and the prosthesis.

The patient Unless the patient is co-operative, the best surgical result and the best type of prosthesis will be useless. The expectations of the amputee are frequently too great. He expects to duplicate the physiological act of prehension with all its infinite variations. Even with ordinary mechanical arms, the individual is deceived by the unusual skill of the salesman. The latter, by dint of years of practice and adaptation, has achieved an almost artistic perfection, one which the new amputee cannot accomplish in a short time. Discouraged by his lack of success, the limb is soon discarded. The cineplastic arm has the advantage of depending on a natural physiological process. The re-education occurs in a simple manner in a short space of time.

OPERATIVE PROCEDURE

The site of the motor is selected and a 3 sided flap of the skin and subcutaneous tissue turned up each side being $1\frac{1}{2}$ inches long. The skin tube or loop is prepared by reversing the flap and securing the end of the tube with a silk suture. The rest of the tube is approximated with subcuticular sutures of fine gut closely placed in order to insure perfect apposition. The tube is retracted and the muscle prepared for canalization. Two parallel incisions are made in the muscle belly and an instrument passed through the muscle to form a canal.

The skin tube is then passed through the canal holding the traction suture in the most superficial position in order to avoid distortion of the tube. The edge of the tube is sutured to the adjacent skin. This leaves a skin defect which must be closed. In young children in the upper arm in adults and in those cases in which there is a redundancy of skin in the amputation stump of the forearm it is possible to close the defect by direct approximation of the skin edge. More frequently this cannot be accomplished without danger of skin necrosis. In this event the wound defect is covered with a Thiersch graft. Zeroform gauze wicks are then inserted in the canals. The first dressing is done in about 10 days, the pegs are inserted in about 3 weeks and the stump is ready for prosthesis in about 6 weeks.

There are only a few points that need emphasis to avoid failure. It is most important to select

Fig. 23. Forearm and upper arm amputation in use in factory where needle board is being repaired.

the proper muscle or muscle group for canalization. It is impossible to tell beforehand just which muscles remain after the amputation. We depend therefore on the clinical test of visualizing the contraction of the muscles to be selected in response to the psychophysiological act of opening and closing the hand at the site of amputation. The patient must therefore, be awake and the muscles outlined with a skin dye just before the operation is undertaken.

The second important step, neglect of which has been responsible for many failures in the past is to canalize the muscle and not the tendon. The latter has no contractility. The activation of the artificial hand mechanism depends on the movement of the peg which passes through the tube. This movement varies from $\frac{1}{4}$ to $\frac{1}{2}$ inch and is due to the alternate shortening and lengthening when the muscle contracts or relaxes.

The prosthesis It is not difficult to manufacture the cineplastic arm. It is important that the weight of the apparatus be kept to a minimum. Furthermore, the mechanism should be as simple as possible. The more complicated the prosthesis the less useful the arm. Theoretical advantages should be sacrificed for practical utility. For example, there is no need for incorporating a rotation mechanism at the wrist in forearm cases since pronation and supination of the stump are still retained. However, in upper arm amputation, this rotation mechanism is of distinct value.

The arm can be designed for heavy as well as light duty, depending on the indications in the specific case. In the forearm amputation no straps or apparatus are required above the elbow. In the upper arm amputation a strap to the opposite shoulder is necessary to secure flexion of the elbow.

Fig 24 Volar aspect showing canal intact, a, at center, dorsal aspect showing two canals The proximal canal has been lost by infection, sufficient room remained for making a distal canal, b, at right, the hand in use with prosthesis

The results of this cineplastic amputation in a series of 78 cases are distinctly encouraging. Of this group, 44 may be classified as highly successful. These individuals are consistently using the prosthesis at work and in the routine pursuits of life over a period of from 2 to 6 years.

Of the 34 remaining, 19 enjoy partial utility of their prosthesis. Unusual work requirements may render it impractical even to wear the arm at work, as in the case of 1 worker in a chemical

plant who must immerse both arms in a solution as part of work operation.

Of the 15 that can be classified as failures, 5 have been due to surgical complications. Infection of the skin tube, necrosis due to previous x-ray dermatitis, improper placement of canals, too short a stump for utilization of leverage of muscle motors, and improper fit of prosthesis account for these failures. The remainder found it difficult to adjust themselves because of personality factors.

CONCLUSION

The use of the cineplastic amputation in selected cases is of distinct advantage in the rehabilitation of the armless. Through the natural control obtained by this procedure the individual is able to utilize the assistance of the amputated arm in the performance of his daily tasks. By increasing his efficiency, he restores his confidence in himself and his ability to compete with others. He is thus equipped to partake of a fuller life without asking for any special considerations.

fingers are knocked off but can be glued back again. Where the work requirements are such as to indicate need for an arm of heavy construction, this can be supplied by substituting a metal hand or wooden hand reinforced with metal.

Unsatisfactory results. The difficulties that do arise can be ascribed to 3 factors: the patient, the operative procedure itself and the prosthesis.

The patient. Unless the patient is co-operative, the best surgical result and the best type of prosthesis will be useless. The expectations of the amputee are frequently too great. He expects to duplicate the physiological act of prehension with all its infinite variations. Even with ordinary mechanical arms the individual is deceived by the unusual skill of the salesman. The latter by dint of years of practice and adaptation has achieved an almost artistic perfection, one which the new amputee cannot accomplish in a short time. Discouraged by his lack of success the limb is soon discarded. The cineplastic arm has the advantage of depending on a natural physiological process. The re-education occurs in a simple manner in a short space of time.

OPERATIVE PROCEDURE

The site of the motor is selected and a 3 sided flap of the skin and subcutaneous tissue turned up each side being $1\frac{1}{2}$ inches long. The skin tube or loop is prepared by reversing the flap and securing the end of the tube with a silk suture. The rest of the tube is approximated with subcuticular sutures of fine gut closely placed in order to insure perfect apposition. The tube is retracted and the muscle prepared for canalization. Two parallel incisions are made in the muscle belly and an instrument passed through the muscle to form a canal.

The skin tube is then passed through the canal holding the traction suture in the most superficial position in order to avoid distortion of the tube. The edge of the tube is sutured to the adjacent skin. This leaves a skin defect which must be closed. In young children in the upper arm in adults and in those cases in which there is a redundancy of skin in the amputation stump of the forearm it is possible to close the defect by direct approximation of the skin edge. More frequently this cannot be accomplished without danger of skin necrosis. In this event the wound defect is covered with a Thiersch graft. Zeroform gauze wicks are then inserted in the canals. The first dressing is done in about 10 days the pegs are inserted in about 3 weeks and the stump is ready for prosthesis in about 6 weeks.

FRACTURES OF THE BONES OF THE FACE

JAMES BARRETT BROWN, M D F A C S, St Louis Missouri

FACTORS of importance in extensive facial injuries may be listed as follows: (1) When a patient is examined following a severe blow about the face it is best to suspect a fracture and work from that point. If it is assumed that the possibility of fracture can be considered when the swelling has gone down, or, if soft tissue repairs are carried out with disregard for displaced bone fragments the best chance for correct bone replacement has been missed. (2) Possibilities of good repair are present in almost all instances but must be met promptly and adequately. (3) Simple procedures of accurate replacement and holding of bone and soft parts drainage and bandaging should suffice and, with relatively simple equipment sound care usually can be afforded these patients. (4) The reverse is true if the full picture is not clear to those in charge and restorative measures are lax. (5) Although the lesions may be multiple complicated splints and traction are seldom required and may actually be detrimental in some instances. It is important, however, to have available some one cognizant of the dental requirements and means of fixation because one of the most important functions to be preserved is that of mastication and this requires that the teeth come to gether in normal occlusion. (6) The problems presented by fractures about the upper part of the face require careful evaluation and diagnosis. If tissue has been completely lost this point is of extreme importance in the final outcome, and the extent of loss should be recorded either in the original examination or at the time of operation. (7) Skull fracture and brain injury are so frequent that neurological examination including x ray films, often must be made and local repair delayed if there is any lesion that requires treatment or complete rest. Patients who receive 'snap' blows about the head may have damage to the cervical spine and on the slightest indication this region also should be checked with the x ray. (8) Ocular damage is very frequent and is often the main indication for treatment. (9) Although good position and function may be obtained final bony union may never occur in many

instances. This may be due to the very thin edges of bone, that simply do not unite and also to prolonged infection. In the lower jaw there may be solid union but with persistence of the fracture line on x ray.

ASSOCIATION OF BONE AND SOFT TISSUE DAMAGE IN COMPOUND INJURIES OF THE FACE

The lacerations, avulsions and tears of the soft parts, and the fractures and displacements of the bones may be so numerous that it may be difficult to list all the diagnoses, and the term "compound injury of the face" could be used as a rough classification. Although widespread soft tissue damage often occurs without fracture, and very extensive comminuted fractures result from blunt force which may not even break the skin the two occur together so frequently that it is not possible to separate completely the repair work of bone and soft tissue.

X RAY EXAMINATION

It is not necessary to rush these patients to the x ray room, because most operative procedures can be done without the pictures and the necessary manipulation in the x ray room might be contra indicated if there were skull or cervical spine damage. However when safe for the patient complete views of all involved regions should be taken.

In roentgenograms of the upper jaw the bony ridges of bone show quite well in antral and in verticosubmental positions but there may be many comminutions of the maxilla ethmoid nasal, and other thin bones that are entirely missed on the x ray plate and therefore the condition has to be searched for at the time of operation. Complete skull and cervical spine series should be taken as indicated before. For the lower jaw complete views of both sides including both condyles, should always be taken because multiple fractures may be missed even at operation. The laminograph developed by Dr Sherwood Moore and designated as body section radiography gives the most accurate information of the joint area.

PRIMARY REPAIR TO BE DONE EARLY IF POSSIBLE

These wounds and fractures should be cared for in the first 20 hours if possible before excessive

been scratched in for clearness Separation of the zygomatic-frontal suture lines on both sides, crumpling of the zygomatic arches, and comminution about the orbital borders and antrum

Fig. 3 Representative patient with complete facial separation. a. Patient who had suffered multiple comminuted fractures of practically all the bones of the face shown 3 weeks after operation which was done under basal and deep block anesthesia 1 week after the accident. The nose was completely loose and shattered and as a result of swelling was just on a level with the cheeks. An air way was established through both nostrils with a long speculum and maintained with rubber tubes. The palatal processes had cut through the palate in 2 places and these were forced back into place at the same time. The dorsum of the nose was elevated and held with a double ling of silver wire from side to side put through the fracture lines along the frontal processes with large cutting needles and held on the side of the nose over lead plates as shown. The inner canthi were widely separated by an actual chiseling open of the face as the nose was driven backward. The canthi were replaced at the same time the nose was elevated and the fixation of the nose has helped to assure correct position and direction of the inner canthi. The orbital borders, zygoma and antrum are considered together because as the zygoma is loosened the border goes down and the antrum crumples under it. If the zygoma is driven backward the

zygomatic process of the temporal bone is crumpled either in or out. Restoration is done by making a small incision in the upper buccal fornix entering the antrum through the fracture line and then replacing the orbital border the frontal process and the bulk of the zygoma and if necessary packing the part in place by filling the antrum carefully with an iodoform gauze pack. The fragmented zygomatic process may be carried inward by external pressure or lifted out with a small hook under it placed either from the outside through the mouth or down from the temporal region as suggested by Gillies. The upper alveolus was broken in all the way on the left and was carried back into position and held with direct wires on the teeth across the fracture line and finally with fixation to the lower jaw. The lower jaw was broken through the symphysis and was held with the type of fixation shown in Figure 5b. The upper jaws were used to support the lower and vice versa although both were broken. b and c. Shows complete restoration of contour with normal expression, normal position of the inner canthi, no diplopia, normal vision and normal occlusion. The most prominent feature of the profile the dorsum of the nose is restored. 1 operation.

there would be the necessity of manipulation through contaminated clots and edematous tissue the replacement of bone might be delayed until there is subsidence of the swelling although the soft parts might still be approximated. The replacement of bone fragments should not be delayed longer than 7 to 10 days under nearly all circumstances because the fixation of small comminuted chips after this time may make impossible their correct alignment.

Shock and neurological damage may necessitate delay in early repair and if a patient is intubated the jaws should not be wired together.

GENERAL CONSIDERATIONS OF THE OPERATIVE PROCEDURE

It may be best to wait until the patient is in the operating room before any manipulation is done, so that there will be the least discomfort. Then a complete analysis should be made of what is nec-

Fig 4. a, b, Simple type of splint for elevating dental arch and face. Made by Dr J A Brown for use in patient shown in d and e. The tray is filled with dental compound before it is used, and is held with a simple elastic sling from the top of the head. d, Patient with blindness in left eye, complete transverse and multiple facial fractures with

almost total loss of the left upper jaw. e, Restoration of occlusion, nasal position, and of the cheek prominence with a free costal cartilage transplant. The right inner canthus is still somewhat displaced, as evidenced by the sharp curve of the tarsal border.

essary in order to carry the repair, in definite steps, to completion. For example, the patient in Figure 1 was so uncomfortable because of a symphysis fracture that this was fastened together first, by drilling and direct fixation of the fragments. He was immediately more comfortable, and then the repair of the floor of the mouth, chin and lip was completed. Next, the upper part of the face, nose, ear, eyelid, and scalp were repaired, and by using clean instruments, gloves, and drapes throughout, there was no further mouth contamination.

Anesthesia is usually obtained with novocain, locally, or by deep block of the second and third division of the fifth nerve. A basal drug can also be given, but general anesthesia should be avoided, except that it is necessary when dealing with children.

DÉBRIDEMENT AND PRESERVATION OF TISSUE

Cleaning of these facial wounds is extremely important and should be done with soap and water followed by ether and saline irrigations so that local antiseptics are seldom necessary, anesthesia may have to be given before the cleaning is completed because of pain. Oil ground into the face should be scrubbed and dissolved out completely. Bits of glass from rear vision mirrors or from completely broken shatterproof glass are especially

apt to be overlooked, and for this reason it is well, if possible, to find out whether or not any glass was broken at the time of the accident so that search may be made accordingly.

Débridement should be done very sparingly both of soft parts and bone. If the usual idea of wide excision of torn edges were applied, many parts of features would be needlessly sacrificed. In dealing with loose bone chips extreme conservatism should be adhered to, and it is probably better to leave in some bone fragments that might die rather than adopt the policy of removing all loose fragments and thereby possibly discard many good supporting fragments that might live.

SUTURE OF SOFT TISSUE

As stated, the repair of jaw fractures cannot be totally separated from the repair of the soft parts and, therefore, a brief summary is included here.

In complicated tears such as shown in Figure 1, a correct replacement may be difficult, but a start is made at some known point such as the nostril border, or the edge of the eyebrow. If none can be figured out, closure may be started in the center of a wound and the remaining segments bisected with sutures until there is complete closure. If flaps are torn loose in a trap-door or triangular manner, their correct re-approximation is extremely important if involving a feature. In this

Fig. 3 Representative patient with complete facial separation. a Patient who had suffered multiple comminuted fracture of practically all the bones of the face shown 3 weeks after operation which was done under basal and deep block anesthesia 1 week after the accident. The nose was completely loose and shattered and as a result of swelling was just on a level with the cheeks. An air way was established through both nostrils with a long speculum and maintained with rubber tubes the palatal processes had cut through the palate in 2 places and these were forced back into place at the same time. The dorsum of the nose was elevated and held with a double sling of silver wire from side to side put through the fracture lines along the frontal processes with large cutting needles and held on the side of the nose over lead plates as shown. The inner canthi were widely separated by an actual chiseling open of the face as the nose was driven backward. The canthi were replaced at the same time the nose was elevated and the fixation of the nose has helped to assure correct position and direction of the inner canthi. The orbital borders, zygoma and antrum are considered together because as the zygoma is loosened the border goes down and the antrum crumples under it. If the zygoma is driven backward the

zygomatic process of the temporal bone is trampled either in or out. Restoration is done by making a small incision in the upper buccal foramen entering the antrum through the fracture line and then replacing the orbital border, the frontal process and the bulk of the zygoma and if necessary packing the parts in place by filling the antrum carefully with an iodoform gauze pack. The fragmented zygomatic process may be carried inward by external pressure or lifted out with a small hook under it placed either from the outside through the mouth or down from the temporal region as suggested by Gillies. The upper olecranon was broken in all the way on the left and was carried back into position and held with direct wires on the teeth across the fracture line and finally with fixation to the lower jaw. The lower jaw was broken through the symphysis and was held with the type of fixation shown in figure 3b the upper jaws were used to support the lower and vice versa although both were broken. b and c Shows complete restoration of contour with normal expression, normal position of the inner canthi, no diplopia, normal vision, and normal occlusion. The most prominent feature of the profile, the dorsum of the nose is restored. 1 operation

there would be the necessity of manipulation through contaminated clots and edematous tissue, the replacement of bone might be delayed until there is subsidence of the swelling although the soft parts might still be approximated. The replacement of bone fragments should not be delayed longer than 7 to 10 days under nearly all circumstances because the fixation of small comminuted chips after this time may make impossible their correct alignment.

Shock and neurological damage may necessitate delay in early repair and if a patient is intubated the jaws should not be wired together.

GENERAL CONSIDERATIONS OF THE OPERATIVE PROCEDURES

It may be best to wait until the patient is in the operating room before any manipulation is done so that there will be the least discomfort. Then a complete analysis should be made of what is nec-

Fig 6 a, Comminution of the facial and frontal bones with involvement of the frontal sinuses, displacement of the inner canthi, and flattening of the nose b, Patient seen a few hours after the accident and restoration done immediately, that is, replacement of the comminuted fragments, rubber tube left in frontal sinus to drain into the nose, fragments of nose held up and inner canthi replaced by through-and-through silver wire sutures, placed through the fracture lines of the frontal processes and held over lateral lead plates on the outside of the nose c, d, Restoration of the nasal bridge and normal direction and situation of the inner canthi (one operation)

much that binocular vision is impaired (Figs 3, 4, 7, 8, 9, 11) Blindness may result from section of the nerve by a loose, thin piece of bone and from intra-ocular or direct ocular damage The extra-ocular muscles and nerves may also be torn (Fig 4) The lacrymal apparatus may be impinged on if the frontal process of the maxilla is driven in

Inner canthus displacement occurs if the nose with the frontal processes of the maxilla is crushed backward, there being an actual chiseling open of the front of the face This deformity is as important as any other in which to accomplish an early repair, because, if left until fixation occurs, the canthi probably never will be sunken in normally again (Figs 3, 4, 6, 11)

Nasal flatness goes along with the canthus displacement and the two are corrected together by withdrawing the depressed tissues and bones, molding them into their normal positions, and

frequently holding them there with through and through silver wire sutures inserted under the separated frontal processes and held on the outside of the nose over lead plates (Figs 3, 6, 10)

The general rule for repair is simply to replace these fragments and maintain them in position with the least manipulation possible This replacement amounts to an open reduction, and access to the orbital border can be gained by a short incision in the buccal fornix, then into the antrum through the fracture line that is almost always present The depressed border can then be elevated into position with a Kelly clamp This bone may be locked in place, but, if there is much comminution, the whole number of fragments, including the anterior and lateral walls of the antrum, may be "mulched" in position and held with an iodoform pack in the antrum, with the end left just through the opening in the fornix

Fig 5 a Permanent loss of occlusion in upper jaw fracture which might have been prevented by using the lower jaw for a splint by simply wiring the 2 jaws in occlusion. b Method of Risdon in applying an anterior arch by putting long wires on the posterior teeth bringing them around in front, fastening them together and then anchoring individual teeth to this arch with finer wires. Besides this sup-

port which is used mainly for symphysis fractures fixation to the upper jaw with the teeth in normal occlusion is done and support applied from the chin to the vertex if necessary. c Functional result obtained in a patient with a fracture at the symphysis and through both condyles as well as a separation in the left upper jaw by using the fixation shown in b.

patient (Fig 1), the entire eyelid was closed in a position too far advanced on the forehead and the lid had to be opened completely and resutured before the patient left the operating room.

Close attention should be paid to the wound edges to see that they are in apposition and of course very ragged edges should be cleanly excised. The first sutures may have to be deep but should never be placed far from the wound edge because wide suture marks can never be completely obliterated. Many times widely placed sutures may be put in however but left open until the entire wound is closed then they are tied over a gauze pad to bind the wound closely together and to avoid the surface cutting of the suture.

It is best to effect complete closure of the wound with deep fine No. 000 white silk sutures so that when the final skin sutures are inserted they are merely to support the edges and adjust them. If possible stay sutures may be put in from the inside of the cheek or nose.

Small drains may be placed advantageously and firm pressure dressings of mechanics' waste or marine sponges can be applied finally to control hemorrhage and swelling and thereby infection.

DISPLACEMENT OF THE BONES OF THE UPPER JAW

Transverse facial fractures occur usually from heavy blows dispersed over the face. There may be a level of separation at the frontal zygomatic suture line and at the glabella on both sides there

may be one through the wall of the antrum that may extend all the way around and involve the pterygoid region and frequently there is a complete separation entirely around just above the dental arch. The whole face may sag down and become noticeably elongated and the dental arch may be completely loose to the patient's own sensation and on moving it with the examining fingers (Figs 2 3 4 5, 6).

Nasal, septal, and palate fractures frequently occur along with the above separation and these small thin bones may be comminuted into multiple pieces. The nasal structure including the cartilages may be completely crumbled and there may be one or more complete lacerations through the palate caused by the disrupted bone cutting through the nasal passages may be completely occluded also (Figs 3 6 10).

The zygomatic bone and orbit. The zygomatic bone (malar or cheek bone) frequently receives the blow but is itself seldom broken. Instead it is torn loose from its moorings at the frontal zygomatic process of the temporal bone and the maxilla. The main displacement will be according to the direction of the force if from the front the zygomatic process will be crumpled back and broken by the zygoma itself if from the side the ascending ramus of the zygoma may be tipped in and impinge on the orbital space. In nearly all loosening of this bone the antral wall crumples and should it sag down too much the orbit becomes elongated and the globe may descend so

a

b

Fig 8 a, Marked displacement of entire zygoma after 2 weeks with no hope of holding it in position from the inside of the antrum, because it is broken so far away laterally from any support b, Zygoma replaced and held by direct

wiring from ascending ramus to frontal bone, access to bone gained by opening a scar of accident This elevation is usually not successful if fragment becomes firmly fixed out of position, then globe has to be elevated within orbit (see Fig 9)

a

c

Fig 9 a, Loss of lateral wall and floor of orbit so that no elevation is possible b, Patient whose x-ray film is shown in a The main object of restoration is for eye function, as there is marked depression of the bony orbit, complete ptosis of the lid, and paralysis of the frontalis c, Globe

both condyles This illustrates the use of the lower jaw to splint the upper

Fractures through the frontal and ethmoid sinuses; inner canthus displacement. Sinus involvement is shown in Figure 6 with the fracture through the wall of the frontal, and with wide separation of the inner canthi and complete flattening of the nose, repaired so that practically normal position of the canthi and of the nasal dorsum results with a simple fixation as shown in Figure 3c

With involvement of the frontals and ethmoids there is some possibility of direct dural contamination, and the added precaution must be taken to maintain drainage into the nose without irrigation or manipulation that might carry infection up to the dura If the sinuses are already infected, the chance of spread is greater

Elevation of orbital border through buccal fornic, incision and antral fracture line In Figure 7 the inner part of the orbital ridge is down in a and is back in place in b, supported with an iodoform pack in the antrum In c and d the normal profile and, from the front, the normal position of the globes and the inner canthi are shown

elevated with 1 block of free costal cartilage and held medially with another With this replacement of the globe there was subjective improvement in the ease of ocular movements Binocular vision does not always return after this procedure because of the delicate balance necessary for this function Elevation of the lid was obtained by a fascial loop to the forehead and a second long one from the temporal fascia through the tarsus to the opposite frontalis The upper orbital border was restored with a costal cartilage transplant put in a periosteal sling to give good fixation of the graft All 3 pieces of cartilage were fresh homografts from the mother

a

b

c

d

Fig 7 a Depressed orbital border b Orbital border has been raised by going through the buccal foramen into the antrum through the fracture line in the anterior wall, and then elevating the fragment with a Kelly forceps. The border and orbital floor are held up in place with an iodiform pack if it is thought that they will not stay up without it. c d Result of patient whose x ray films are shown in a and b obtained by a single but early operation with good position resulting in both the globe and the inner canthus. There had also been extensive tearing of the ear and nose.

If there is derangement of occlusion, the lower jaw can be used to splint the upper by fixation of the teeth followed by the application of a bandage from the chin to the top of the head. Frequently the closing power of the muscles attached to the lower jaw will suffice for this and the overhead pull can be omitted (Figs 4 5).

ILLUSTRATIONS OF GENERAL TYPES OF LESIONS

The most frequent lesions are described by the following representative patients and the legends of illustrations may be followed as part of the text.

Restoration of contour after complete facial fractures without special splints. Diagrams and roentgenograms of typical complete facial separations are shown in Figure 2 and a patient completely restored after the most extensive facial fractures of this type is shown in Figure 3 with the operative procedures outlined in the legend.

Elevation of sagged upper jaws with dental splint. In Figure 4 a simple type of apparatus for elevat-

ing upper jaws is shown, made by Dr J A Brown for use in the patient shown in Figure 4 d and e. This does not insure normal occlusion and when it is removed, if there is any tipping of the upper alveolus, the teeth should be forced into their normal occlusion and held there by interdental wiring to the lower jaw and, if necessary, support should be applied from the chin to the head.

Blindness in compound facial injury. The patient in Figure 4, d and e illustrates the loss of vision frequently seen and shows fairly normal replacement of the soft parts, re-establishment of occlusion and the bulging out of the depressed left cheek with costal cartilage.

Loss of occlusion in upper jaw fracture is shown in Figure 5a where interdental fixation with the teeth in occlusion had been omitted.

Anterior dental arch plus jaw to jaw fixation is shown in Figure 5b the type used in the patient in Figure 3 and also in the patient in Figure 5c who had a symphysis separation and fractures of

Direct fixation of a completely loose zygoma is shown in Figure 8 by drilling the frontal bone and the ascending ramus of the zygoma and anchoring them together. It was done in this instance because the very loose bone could not be supported from inside the antrum.

Consideration of late deformities If the late deformities are studied, the requirements of early care may be made more clear, and, since many secondary corrections have to be made, some responsible person or the patient himself should be told of this possibility in all severe injuries.

Elongation of the orbit because of depression and loss of zygoma is shown in Figure 9. Restoration of eye level has been obtained by elevation of the globe with costal cartilage transplants along the floor and in the lateral region.

Late restoration of nasal bridge and profile, using the tissues that have been crumpled in, is shown in Figure 10, a, b and c. The depressed bone and cartilage dorsum was literally dug out of its en-

folded position and then held forward on silver wire slings from side to side.

Late restoration of profile with costal cartilage transplant is shown in Figure 10, d and e, where it has been recognized that tissue has been lost at the time of the accident or from infection. Elevation is effected with transplanted costal cartilage cut in one large piece to replace the entire loss of the septum and give support to the tip through the columella.

Filling in of skull defects, secondary soft tissue correction, and correction of traumatic ptosis, is shown in Figure 11. The lid has been brought down so that closure can occur, by "backing" some of the forehead tissue down into the lid in the form of a V-Y operation and going only through the old scars. The depression of the forehead has been filled with a free fascia lata transplant. Cartilage may also be used for this. The residual ptosis has been corrected with a free fascial loop from the tarsus to the frontalis muscle.

DOUBLE PIN SKELETAL FIXATION IN FRACTURES OF THE LEG

R. ARNOLD GRISWOLD, M.D., F.A.C.S., and GEORGE W. HOLMES, M.D.,
Louisville, Kentucky

CHANGES in automobile design a few years ago had a profound effect on the treatment of fractures of the leg. The most important factor was the increase of power, speed, and force of impact, which caused great damage to both soft and osseous tissues and resulted in a larger percentage of compound injuries. Four-wheeled brakes and smaller wheels changed the usual point of impact on the pedestrian from the knees to the mid-third of the leg. The result has been severe crushing injuries to the leg, with extensive damage to the bones and soft parts. The injuries to muscles, blood vessels, and nerves contribute greatly to the difficulties of treatment and to the time required for healing and restoration of function. These fractures are often bilateral and are frequently accompanied by injuries to other parts of the body.

From the Louisville City Hospital and University of Louisville School of Medicine.
Presented in the Fracture Symposium before the Clinical Congress of the American College of Surgeons, New York, October 17-21, 1935.

The flow of large numbers of these seriously injured patients into our hospitals has had a greater effect on the treatment of fractures in this country than anything since the World War. One of the outstanding developments in this field has been the introduction of numerous methods for skeletal control and fixation of fragments, by the insertion of steel pins in both proximal and distal fragments, and the incorporation of these pins in plaster encasement. This method was adopted at the Louisville City Hospital in 1933, and has been used since that time to the exclusion of all other operative measures. It is not indicated when adequate manual reduction and plaster fixation are possible. It is used only in those cases which we would have treated formerly by continuous traction or direct open reduction and internal fixation. In our city hospital service, which includes a disproportionate number of severe and complicated injuries, the double pin method is used in about half the cases. In private practice the proportion is smaller on account of

Fig 10 a Complete depression of the nasal dorsum from injury without loss of tissue b c Complete restoration of dorsum by chiseling free the depressed bone and

cartilage and holding it forward on a mattress wire sling d e Depression following injury plus loss of tissue so that free cartilage transplant is necessary for elevation as in e

Zygomatic bone versus zygomatic process fractures Some confusion has arisen in relation to these two fractures both of which are illustrated in Figure 7 a and b The zygomatic arch is part of the temporal bone and is broken only occasionally

by itself but is often crumpled in or out by fractures of the zygoma The various maneuvers recommended to lift out zygomatic process fractures do not usually apply to true displacements of the zygoma itself

Fig 11 a Depression of frontal area deformity of lid and inner canthus b Pulling lid and backing tissue down into lid from forehead in V-Y procedure through old scars

c Result of fastening tarsal border to frontalis muscle for elevation of lid and filling the bony depression with free fascia

Direct fixation of a completely loose zygoma is shown in Figure 8 by drilling the frontal bone and the ascending ramus of the zygoma and anchoring them together. It was done in this instance because the very loose bone could not be supported from inside the antrum.

Consideration of late deformities If the late deformities are studied, the requirements of early care may be made more clear, and, since many secondary corrections have to be made, some responsible person or the patient himself should be told of this possibility in all severe injuries.

Elongation of the orbit because of depression and loss of zygoma is shown in Figure 9. Restoration of eye level has been obtained by elevation of the globe with costal cartilage transplants along the floor and in the lateral region.

Late restoration of nasal bridge and profile, using the tissues that have been crumpled in, is shown in Figure 10, a, b and c. The depressed bone and cartilage dorsum was literally dug out of its en-

folded position and then held forward on silver wire slings from side to side.

Late restoration of profile with costal cartilage transplant is shown in Figure 10, d and e, where it has been recognized that tissue has been lost at the time of the accident or from infection. Elevation is effected with transplanted costal cartilage cut in one large piece to replace the entire loss of the septum and give support to the tip through the columella.

Filling in of skull defects, secondary soft tissue correction, and correction of traumatic ptosis, is shown in Figure 11. The lid has been brought down so that closure can occur, by "backing" some of the forehead tissue down into the lid in the form of a V-Y operation and going only through the old scars. The depression of the forehead has been filled with a free fascia lata transplant. Cartilage may also be used for this. The residual ptosis has been corrected with a free fascial loop from the tarsus to the frontalis muscle.

DOUBLE PIN SKELETAL FIXATION IN FRACTURES OF THE LEG

Louisville, Kentucky

CHANGES in automobile design a few years ago had a profound effect on the treatment of fractures of the leg. The most important factor was the increase of power, speed, and force of impact, which caused great damage to both soft and osseous tissues and resulted in a larger percentage of compound injuries. Four-wheeled brakes and smaller wheels changed the usual point of impact on the pedestrian from the knees to the mid-third of the leg. The result has been severe crushing injuries to the leg, with extensive damage to the bones and soft parts. The injuries to muscles, blood vessels, and nerves contribute greatly to the difficulties of treatment and to the time required for healing and restoration of function. These fractures are often bilateral and are frequently accompanied by injuries to other parts of the body.

From the Louisville City Hospital and University of Louisville School of Medicine.
Presented in the Fracture Symposium, before the Clinical Congress of the American College of Surgeons, New York, October 17-21, 1938.

The flow of large numbers of these seriously injured patients into our hospitals has had a greater effect on the treatment of fractures in this country than anything since the World War. One of the outstanding developments in this field has been the introduction of numerous methods for skeletal control and fixation of fragments, by the insertion of steel pins in both proximal and distal fragments, and the incorporation of these pins in plaster encasement. This method was adopted at the Louisville City Hospital in 1933, and has been used since that time to the exclusion of all other operative measures. It is not indicated when adequate manual reduction and plaster fixation are possible. It is used only in those cases which we would have treated formerly by continuous traction or direct open reduction and internal fixation. In our city hospital service, which includes a disproportionate number of severe and complicated injuries, the double pin method is used in about half the cases. In private practice the proportion is smaller on account of

the generally less severe damage. The apparatus which we use is a simplified version of the ones previously described (1, 2), and has recently been modified by Dr. Edward B. Mersch of the Louisville City Hospital staff. This apparatus provides adequate control and fixation of proximal and distal fragments, and gives adequate room for operation or fluoroscopic examination.

ROUTINE PROCEDURE

1. After careful clinical and x-ray examination and recovery from shock, local or spinal anesthesia is administered.

2. One-eighth inch steel pins are driven through the os calcis and through the tibia at the level of the tibial tubercle. If the fracture involves the upper end of the tibia, the proximal pin is inserted through the lower femur. Pins are inserted directly through the skin without incision and are driven through the bone with a hammer rather than drilled. The tight grip of the bone on the driven pin prevents motion which may lead to infection. It is important that the pins be driven only through the cancellous extremities of the bone, since driving pins through the hard cortical bone in the shaft may split the bone.

3. The limb is placed in the apparatus and the pins fixed in place. Traction is applied and reduction completed by mechanical manipulation under visual control with a right angle hand fluoroscope. This fluoroscope, which contains a 45 degree angle mirror, can be used in small spaces and at angles where a straight fluoroscope would be impractical. It also protects the operator from direct radiation.

4. After reduction, traction is reduced to allow firm end-to-end contact of fragments. Overtraction by such powerful mechanical devices may contribute to delayed union.

5. A non-padded plaster cast is applied from toes to groin as soon as the condition of the soft tissue warrants. This cast firmly incorporates both pins.

6. Ambulatory treatment is started after application of the cast. The cast and pins are removed at the end of about 8 weeks. A new cast may be applied at this time as high as the tibial tubercle or the upper thigh according to the site of fracture and the progress of union. This cast takes the place of a convalescent brace until unprotected weight bearing is safe.

7. Compound fractures are treated by thorough debridement after fixation in the apparatus. Those debrided within 8 hours of the time of injury are usually closed primarily. Closure in layers is avoided and the skin only is closed. In

interrupted sutures allow oozing of blood and serum from the wound. No drains are used. The wound is left exposed to air without dressings. Older wounds are packed open with vaseline gauze after debridement. A prophylactic dose of gas and tetanus antitoxin is administered in all compound injuries. The extremity is left in the apparatus for observation and treatment of the wound until its condition permits the application of plaster.

From July 1, 1933 to June 1, 1938, 576 patients with fractures of 1 or both legs were admitted to Louisville City Hospital. Three hundred and eleven of these were recorded as due to automobile accidents. 55 died within 48 hours of shock and associated injuries such as intracranial damage. Two of these deaths were attributed to fat embolus. Thirty six were transferred elsewhere after first aid treatment. The 485 remaining patients had 512 fractured legs. Three primary amputations were carried out for severe crushing injuries. Our reluctance to perform primary amputation may explain 3 amputations subsequently found necessary and may have been a factor in the 5 subsequent deaths from gas infection. Of the 509 extremities treated, double pins were considered necessary in 259. The 250 remaining cases with less severe injuries were treated by traction and manipulative reduction followed by the application of non-padded casts and walking irons. The treatment of these cases was carried out almost entirely by the resident staff of the Louisville City Hospital under only moderately close supervision. Four hundred and sixty patients were followed for a long enough period to judge the results of treatment.

RESULTS

Of 171 simple fractures not requiring pins, 153 healed within 2½ months and 16 healed within 6 months. Of 16 simple fractures into joints not requiring pins, 12 healed in 4 months and 4 within 6 months.

In a group of 21 compound fractures not requiring pins, 20 healed within 6 months. One case of delayed union was treated by subcutaneous drilling and had good union at the end of 12 months. Four of 5 compound fractures into joints not requiring pins were healed in 5½ months. One developed osteomyelitis and required 2 years for recovery.

We had 101 simple fractures requiring pins, 93 of which healed within 4 months. There was 1 amputation in this group due to arterial thrombosis. Too early application of a cast to a poorly nourished extremity probably caused this thrombosis. Five cases showed no union at the end of

6 months All were treated by subcutaneous drilling, which resulted in union in all cases In a group of 16 simple fractures into joints requiring pins, 12 healed in $4\frac{1}{2}$ months, while 4 required 7 months for restoration

There were 130 compound fractures requiring pins One hundred and five of these healed within $6\frac{1}{2}$ months, 8 healed following persistent ambulatory treatment, 6 cases of delayed union, which were submitted to drilling, healed within 18 months One other did not respond to drilling but healed following a sliding bone graft There were 7 deaths in this group, 5 due to gas infection and 2 to late shock There were 3 secondary amputations, 2 for defective blood supply and 1 for gas infection.

Double pins were used in a total of 259 fractures, that is, 518 pins were inserted Complications due to these pins, which were noted or severe enough to require treatment, were as follows: There were one mild and one severe osteomyelitis, 8 infections of soft tissue, 2 of which had persistent draining sinuses

COMPOUND FRACTURES

Recapitulation of the 156 compound fractures treated shows that débridement and vaseline gauze pack were used in 25 Thirteen of these wounds healed well. There were 2 gas infections with death and 1 amputation for defective blood supply Osteomyelitis of mild degree occurred in 7 There were 2 deaths due to late shock

Primary closure after débridement was carried out in 131 cases Primary healing was obtained

in 102 There were 11 mild and 4 severe soft tissue infections Three of these patients developed gas infections which resulted in death. There were 8 cases of osteomyelitis Three amputations were carried out, 1 for gas infection and 2 for sepsis with impaired circulation

CONCLUSIONS

1 Double pin skeletal fixation was carried out in 259 of 509 fractures of the leg, to the exclusion of all other operative measures

2 These cases were from a City Hospital service with a large proportion of severe bumper fractures, and treatment was carried out by the resident staff

3 Complications due to the treatment, i.e., pin infections, have been lower than would have been expected in a similar series treated by direct operative reduction and internal fixation

4 Thorough débridement and copious irrigation have been applied to compound fractures Orr treatment has been reserved for old wounds, recent wounds have been closed primarily without drainage, with interrupted sutures to the skin only, avoiding the introduction of ties or sutures below the skin This has proved to be a satisfactory procedure

5 Subcutaneous drilling of fragments has been effective in cases of delayed union

REPORT OF SYMPOSIUM ON METALLIC FIXATION IN FRACTURES

BOWMAN C CROWELL M.D. Chicago, Illinois

THE question of the open reduction of fractures with the use of metallic fixation was discussed at the meeting of the Fracture Committee of the American College of Surgeons held in New York 1938

In opening the meeting the chairman Dr Frederic W Bancroft, stated that he felt that the Committee had the opportunity to do something constructive in the matter of operative fixation, with particular reference to the metals used for fixation. The paper for discussion was presented by Dr Charles S Venable of San Antonio Texas and dealt with the electrolytic action of various metals in the tissues and its relation to osteosynthesis. Dr Venable viewed this electrolytic action as being the controlling factor in osteosynthesis when metals were used. He stressed the fact that there had been a great deal of difficulty encountered in osteosynthesis by metallic fixation, with many serious complications and many inconsistencies in results. In keeping with this he felt that there was a wide difference of opinion on the part of the various investigators. He felt that many of the analyses of the studies had been defective because of the absence of biochemical examinations and felt that use of metallic fixation was essentially to be considered in terms of metal corrosion concomitant with electrolytic action.

Dr Venable then detailed a series of experimental findings. He showed definitely by these experimental findings that when different metals were placed in bone and immersed in Ringer's solution, metallic corrosion due to electrolytic action occurred. He also stressed the fact that in a single piece of metal alloy of the type in which the components of the alloy acted as independent units in the compound similar electrolysis between the various units with resulting corrosion occurred. He stated that such corrosion evidenced an electrolytic action which disturbed bone cells and bone growth and resulted in the loosening of both the plates and the screws.

Dr Venable showed that vanadium steel silver plated steel, nickel plated steel and chromium

plated steel all showed some degree of corrosion in this set up. He stated that when 2 different metals were used such corrosion invariably took place and the existence of difference of potential could always be shown evidencing electrolytic activity. Chromium alloy steel in his experiments showed a similar action. Vitallium was the only metal in his series which remained practically inert under the same conditions as existed when the preceding metals were used. He followed these experiments by similar ones in the living animal in which actual contact with the metals was made with a wire connection through an outside galvanometer, demonstrating the existence of a current passing from one to the other except when vitallium was used. He demonstrated perfectly that of all the metals tested vitallium alone proved practically inert under the conditions of the experiment. He then showed a number of clinical cases in which vitallium was used with no evidence of interference of bone formation or of loosening of the structures and also a case in which a Parham band was used in conjunction with vitallium fixation with resultant bone absorption in the vicinity of the Parham band.

His conclusions were (1) That it is impossible for macroscopic histological or roentgenological studies to determine the reaction of bone to metal (2) that such reaction can be demonstrated only by biochemical studies (3) that when different metals are used the amount of electrical action depends upon the difference of potential of the metals used (4) that in mixed metals or alloys in which the units of the alloy enjoy independent action a similar difference of potential with the creation of a battery action exists (5) that appliances containing chromium are particularly troublesome by reason of concentration of electrolytically freed chromium in the (6) alloys which are non magnetic entirely resistant to corrosion and which possess sufficient tensile strength should be used for bone fixation (7) experimentally the alloy vitallium made of cobalt chromium and molybdenum is not magnetic and is the only metal known at this time which can be used with consistent results and (8) electrical phenomena are the controlling factors in osteosynthesis with metals.

Presented before the annual meeting of the Fracture Committee of the American College of Surgeons New York February 18 1938

Following Dr Venable's presentation Dr. Colin G Fink, professor of electrometallurgy, Columbia University, discussed the presentation. He stated that as a lay person he assumed that the problem was divided into 2 parts, that of getting mechanically rigid fixation, and that of the behavior and nature of the metal itself. He emphasized the fact that there is always some solubility when metal is in contact with body fluids over a period of time. He felt that Dr Venable's demonstration of vitallium showed that there was not enough solution of vitallium in contact with tissue fluids to create any appreciable electrolytic potential. He stated that his only hesitancy about the alloy was the fact that it was composed of 3 constituents and that under such circumstances it was difficult to reproduce the exact composition at will. Dr Fink stated that if perfectly pure silver could be secured there should be no corrosion in the tissues, and felt that a silver coated steel might be an interesting possibility.

Dr Fink's discussion was followed by the presentation of Mr. Frank, who represented the manufacturers of vitallium. He stated that vitallium had primarily been developed for use in dentistry, and had proved to be electrically inert in the mouth, and had been able to meet all the severe stresses put upon dental prosthesis. He stated that it had absolute resistance to corrosive influences. He also stated that the vitallium alloy used was a single phase alloy in which the fear of interreaction between the components was reduced to a minimum. He compared the corrosive resistance of various metals with that of vitallium and drew the same general conclusions that Dr. Venable had drawn. He stated that vitallium had a high degree of rigidity measured as the modulus of elasticity.

Dr Philip Wilson introduced Captain Daniel J Martin, of West Point, who 2 years previously had tested metals for this committee when they had been attempting to work out a suitable plate. He stated that he believed too much stress was being placed on the point of corrosion inside the body. He did not think that the problem of corrosion should be considered a problem of importance, but that the mechanical properties of the alloy used were much more important. He felt that the chromium-vanadium steel failed not because it was not suitable material to put into the body, but because the heat treatment given before use made it too hard, and sometimes it was cracked in the quenching operation, which accounted for both the corrosive activities and the breaking of plates and screws after insertion into the body. He stated that the stampings on

the plates similarly introduced mechanical faults, and he felt that no pure metal would have the physical properties necessary, and that some kind of alloy was indicated.

Dr Clay Ray Murray next discussed the problem. He stated that the service at the Presbyterian Hospital had investigated the whole question of plates and screws from the standpoint of clinical application. He believed that it was important to consider the purpose for which metallic fixation of the bones was used. If used merely to fix fragments of bone together, to be followed by fixation in plaster, the necessary physical qualities of the metal would be quite different from those required for patients in whom rigid fixation of the fragments sufficient to stand the strain of early, active mobilization without plaster fixation was the object.

He felt that there was no question about the existence of electrolytic action in the tissues. As a matter of fact the mere trauma of operation is sufficient to set up a difference in potential of as high as 100 millivolts between the injured tissue and the adjacent normal tissue. One of the problems for consideration is whether the plate intensifies or prolongs that reaction. In the studies at the Presbyterian Hospital, in which was used a system employing Corning glass Quin-Hydrone electrodes inserted directly into the tissues, he had become convinced that the degree of calcium deposition at the site of fracture was dependent upon the extent of ionization present in the tissues at the fracture site. So long as an acid hydrogen ion concentration existed at the fracture site no calcium deposition occurred. It was of interest that lack of rigid fixation produced acidity at the fracture site due to a mechanical inflammatory reaction regardless of the type of fixation. He had discontinued the use of vanadium steel not because of any reaction in the tissues sufficient to interfere with bone formation, although unquestionably reaction did occur, but because in his experiments vanadium steel was too hard to stand the stresses and strains placed upon it when used as the sole means of fixation under normal body strains. A bone in a living individual is to be considered as under constant vibratory stress due to alternations in muscle tone and to intermittent bending, and torsional and shearing strains due to normal muscle efforts. No tests, which depend upon the ability to bend a metal numerous times at right angles, reproduce the strain the metal is subject to when placed rigidly fixed across a fracture site. Dr. Murray with Captain Martin believed that within reasonable limits the mechanical factors implied

REPORT OF SYMPOSIUM ON METALLIC FIXATION IN FRACTURES

BOWMAN C CROWELL M D Chicago Illinois

THE question of the open reduction of fractures with the use of metallic fixation was discussed at the meeting of the Fracture Committee of the American College of Surgeons held in New York 1938

In opening the meeting the chairman Dr Frederic W Bancroft, stated that he felt that the Committee had the opportunity to do something constructive in the matter of operative fixation, with particular reference to the metals used for fixation. CONFERENCE ON TRAUMATIC SURGERY

THE MEDICAL CONTROL OF SILICOSIS AND TUBERCULO-SILICOSIS

LEROY U GARDNER, M D , Saranac Lake, New York

MEDICAL control of silicosis in the United States today is largely in the hands of industrial physicians experienced in the diagnosis of the particular forms of the disease produced in their respective plants. By means of pre-employment examinations these physicians have an accurate knowledge of the physical condition of each new workman entering the plant; from frequently repeated, periodic examinations they have an opportunity to observe the evolution of at least the early phases of reaction to inhaled dust. By studying the older employees, who worked in these same plants before the introduction of programs of dust prevention, these doctors have become familiar with the more advanced stages of these diseases, and they also have at their command accurate data upon the degree and character of atmospheric pollution in different parts of their plants. By correlating these data with their medical findings, they have drawn reasonably reliable conclusions as to the hazard from breathing dusts of varying silica content. Some of these conclusions are still tentative and may be altered in the light of subsequent experience and the introduction of improved methods of examination.

As a result of their individual observation in different plants certain principles have been formulated which now govern the medical control of silicosis and related conditions. Although variations in the anatomical form of the disease and in the degree of associated disability may be created by inhaling silica in various combinations with other mineral dusts, and by the diversity of processes producing dust in different plants, these general principles seem to be applicable to all industries.

Three of these observations are of fundamental importance. (1) The diagnosis of silicosis is based upon 3 factors: (a) evidence of disease in the lungs demonstrated in roentgenograms, (b) a history of

exposure to silica dust, *adequate to produce such disease*; (c) a physical examination to determine the presence of infection and disability. (2) The major cause of disability is not the tissue reaction produced primarily by the inhaled dust, but pulmonary infection which so frequently accompanies such reaction. (3) The degree of disability is not proportional to the extent and severity of the anatomical changes observed in the roentgenogram. Disability can be measured only by observation and physical examination of the workman.

TYPES OF LESIONS

The pathological lesions of silicosis in pure form and silicosis with infection have been divided into 4 major categories. Since each type presents a different clinical picture and requires different administrative treatment, these 4 types will be discussed individually.

1. A pulmonary reaction characterized anatomically by accumulations of dust-filled phagocytes and proliferation of cellular connective tissue in the larger septa and trunks, and roentgenographically by exaggeration of the linear shadows chiefly cast by the blood vessels, may be due to a variety of causes. Such appearances may be a manifestation of beginning silicosis, in which case they may later progress to the stage of parenchymatous nodulation, but they may also be due to the inhalation of non-silicious dusts which produce only linear reactions without further progression. Furthermore, the roentgenographic appearances of certain chronic infections of the lungs and the pulmonary changes associated with cardiovascular disease of certain types may closely simulate the picture produced by dust. Only a thorough study of the individual and his occupational history can possibly reveal the cause in a particular case. The roentgenographic appearance of linear exaggeration is rarely associated with disability. When it is, other causes must be carefully excluded before attributing the clinical findings to the pulmonary condition. Since linear exaggeration in the pulmonary roentgenogram may be due

From the Saranac Laboratory for the Study of Tuberculosis Presented in the Symposium on Industrial Medicine and Traumatic Surgery, before the Clinical Congress of the American College of Surgeons, New York, October 17-21, 1938

in the rigidity of fixation and the ability of the metals used to stand normal physiological strains were of far more importance than the possible electrolytic potential established by the metal in the tissues. This did not, of course, apply to the use of metals which produced marked electrolytic changes, or to the use of 2 different metals in the tissue. A vanadium steel plate, subjected to continuous vibratory stress of very small amplitudes for the period of a week, became so brittle that the steel could be snapped in the fingers. Clinically similar action had been evidenced by plates which had broken in the bone even after healing of the fracture by callus had been accomplished. Tests made with an 18 per cent chromium and 8 per cent stainless steel specially prepared had convinced him that the metal had, when properly treated, not sufficient electrical activity in the tissues to cause damage, nor did it have the proper physical characteristics to warrant its use under the conditions of resumption of active motion within a few days of operation without plaster fixation. To him this seemed important since he found that the cutting down of disability time by the early restoration of active function represented the chief advantage in most cases of the operative reduction of fractures.

He asked Dr Hudack who had carried out some experimental procedures, to present his evidence. Dr Hudack stated that the metal used should have resistance to surface corrosion and resistance to fatigue failure. Vanadium steel under the vibratory stresses described had suffered intermolecular corrosion as the result of fatigue strain, making it liable to fracture. The same thing did not happen when a solid solution of the 3 phase high chromium low nickel steel was used. It was also found that stamping and casting both impaired the necessary physical qualities of the metal. In addition it was found that a non abrasive polishing of the surface was necessary. He also stated that a minimum degree of corrosion was much less important than these physical qualities. Preceding the non abrasive polishing of the surface a passivating of the surface by the use of an acid bath was indicated. Microscopic section of the tissues a year after the

insertion of plates and screws constructed for him, *mechanically perfect, inserted so that rigid fixation was a fact*, showed bone trabeculae still occupying the thread of the screw without evidence of decalcification or histological change.

A representative of the stainless steel (18 per cent chromium—8 per cent nickel) manufacturers stressed the buffering and passivating of the metal before insertion into tissues. She also stressed the fact that evidence of corrosion in specific solutions outside the body could hardly be considered as indicative of the extent of such action in the complicated tissue fluid set up at the fracture site.

At the invitation of Dr Philip Wilson Dr George W. Hawley presented a tantalum plate based on the angle iron used in steel buildings, one surface being attached to the bone and the other resting in a longitudinal slot previously cut in the bone at the site of the application of the plate. He stressed the fact that this type of plate might be of great benefit in getting rigid fixation.

Dr William O'Neill Sherman, of Pittsburgh stressed the point that he did not believe that animal experiments were of much value. He felt that the vanadium steel plate as used by him was effective mechanically if rigidly fixed and could be depended upon to stand the strains to which it would be subject physiologically. He believed that no metal was capable of standing the vibration test which had been imposed on the vanadium steel by Dr Murray and Dr Hudack, and that although the specific stainless steel mentioned had done so in the experimental test, it could not be consistently expected to do so.

The results of the whole conference would seem to indicate that the 2 factors first, the composition of the metallic fixation used and second the rigidity and adaptability of the fixation used to physical strains and stresses, probably represent the basis of a possible solution to the question of operative fixation.

It is evident that the question whether or not operative fixation is to be followed by active mobilization or by fixation in plaster has a great bearing on which of the 2 factors mentioned may be the most important consideration in any given case.

CONFERENCE ON TRAUMATIC SURGERY

THE MEDICAL CONTROL OF SILICOSIS AND TUBERCULO-SILICOSIS

LEROY U GARDNER, M D, Saranac Lake, New York

MEDICAL control of silicosis in the United States today is largely in the hands of industrial physicians experienced in the diagnosis of the particular forms of the disease produced in their respective plants. By means of pre-employment examinations these physicians have an accurate knowledge of the physical condition of each new workman entering the plant; from frequently repeated, periodic examinations they have an opportunity to observe the evolution of at least the early phases of reaction to inhaled dust. By studying the older employees, who worked in these same plants before the introduction of programs of dust prevention, these doctors have become familiar with the more advanced stages of these diseases, and they also have at their command accurate data upon the degree and character of atmospheric pollution in different parts of their plants. By correlating these data with their medical findings, they have drawn reasonably reliable conclusions as to the hazard from breathing dusts of varying silica content. Some of these conclusions are still tentative and may be altered in the light of subsequent experience and the introduction of improved methods of examination.

As a result of their individual observation in different plants certain principles have been formulated which now govern the medical control of silicosis and related conditions. Although variations in the anatomical form of the disease and in the degree of associated disability may be created by inhaling silica in various combinations with other mineral dusts, and by the diversity of processes producing dust in different plants, these general principles seem to be applicable to all industries.

Three of these observations are of fundamental importance. (1) The diagnosis of silicosis is based upon 3 factors. (a) evidence of disease in the lungs demonstrated in roentgenograms, (b) a history of

Traumatic Surgery, before the Clinical Congress of the American
College of Surgeons, New York, October 17-21, 1938

exposure to silica dust, *adequate to produce such disease*, (c) a physical examination to determine the presence of infection and disability. (2) The major cause of disability is not the tissue reaction produced primarily by the inhaled dust, but pulmonary infection which so frequently accompanies such reaction. (3) The degree of disability is not proportional to the extent and severity of the anatomical changes observed in the roentgenogram. Disability can be measured only by observation and physical examination of the workman.

TYPES OF LESIONS

The pathological lesions of silicosis in pure form and silicosis with infection have been divided into 4 major categories. Since each type presents a different clinical picture and requires different administrative treatment, these 4 types will be discussed individually.

1. A pulmonary reaction characterized anatomically by accumulations of dust-filled phagocytes and proliferation of cellular connective tissue in the larger septa and trunks, and roentgenographically by exaggeration of the linear shadows chiefly cast by the blood vessels, may be due to a variety of causes. Such appearances may be a manifestation of beginning silicosis, in which case they may later progress to the stage of parenchymatous nodulation, but they may also be due to the inhalation of non-silicious dusts which produce only linear reactions without further progression. Furthermore, the roentgenographic appearances of certain chronic infections of the lungs and the pulmonary changes associated with cardiovascular disease of certain types may closely simulate the picture produced by dust. Only a thorough study of the individual and his occupational history can possibly reveal the cause in a particular case. The roentgenographic appearance of linear exaggeration is rarely associated with disability. When it is, other causes must be carefully excluded before attributing the clinical findings to the pulmonary condition. Since linear exaggeration in the pulmonary roentgenogram may be due

in the rigidity of fixation and the ability of the metals used to stand normal physiological strains were of far more importance than the possible electrolytical potential established by the metal in the tissues. This did not, of course, apply to the use of metals which produced marked electrolytic changes or to the use of 2 different metals in the tissue. A vanadium steel plate, subjected to continuous vibratory stress of very small amplitudes for the period of a week, became so brittle that the steel could be snapped in the fingers. Clinically similar action had been evidenced by plates which had broken in the bone even after healing of the fracture by callus had been accomplished. Tests made with an 18 per cent chromium and 8 per cent stainless steel specially prepared had convinced him that the metal had, when properly treated, not sufficient electrical activity in the tissues to cause damage, nor did it have the proper physical characteristics to warrant its use under the conditions of resumption of active motion within a few days of operation without plaster fixation. To him this seemed important since he found that the cutting down of disability time by the early restoration of active function represented the chief advantage in most cases of the operative reduction of fractures.

He asked Dr. Hudack, who had carried out some experimental procedures to present his evidence. Dr. Hudack stated that the metal used should have resistance to surface corrosion and resistance to fatigue failure. Vanadium steel under the vibratory stresses described had suffered intermolecular corrosion as the result of fatigue strain, making it liable to fracture. The same thing did not happen when a solid solution of the 3 phase high chromium low nickel steel was used. It was also found that stamping and casting both impaired the necessary physical qualities of the metal. In addition it was found that a non-abrasive polishing of the surface was necessary. He also stated that a minimum degree of corrosion was much less important than these physical qualities. Preceding the non-abrasive polishing of the surface a passivating of the surface by the use of an acid bath was indicated. Microscopic section of the tissues a year after the

insertion of plates and screws constructed for him, *mechanically perfect inserted so that rigid fixation was a fact* showed bone trabeculae still occupying the thread of the screw without evidence of decalcification or histological change.

A representative of the stainless steel (18 per cent chromium—8 per cent nickel) manufacturers stressed the buffering and passivating of the metal before insertion into tissues. She also stressed the fact that evidence of corrosion in specific solutions outside the body could hardly be considered as indicative of the extent of such action in the complicated tissue fluid set up at the fracture site.

At the invitation of Dr. Philip Wilson Dr. George W. Hawley presented a vitallium plate based on the angle iron used in steel buildings, one surface being attached to the bone and the other resting in a longitudinal slot previously cut in the bone at the site of the application of the plate. He stressed the fact that this type of plate might be of great benefit in getting rigid fixation.

Dr. William O. Neill Sherman, of Pittsburgh stressed the point that he did not believe that animal experiments were of much value. He felt that the vanadium steel plate as used by him was effective mechanically if rigidly fixed and could be depended upon to stand the strains to which it would be subject physiologically. He believed that no metal was capable of standing the vibration test which had been imposed on the vanadium steel by Dr. Murray and Dr. Hudack, and that although the specific stainless steel mentioned had done so in the experimental test, it could not be consistently expected to do so.

The results of the whole conference would seem to indicate that the 2 factors—first the composition of the metallic fixation used, and second the rigidity and adaptability of the fixation used to physical strains and stresses, probably represent the basis of a possible solution to the question of operative fixation.

It is evident that the question whether or not operative fixation is to be followed by active mobilization or by fixation in plaster, has a great bearing on which of the 2 factors mentioned may be the most important consideration in any given case.

infections. Since such lesions are most frequently discovered in persons exposed to mixtures of silica and other minerals, the latter may play an *etiological rôle*. Regardless of their cause all such lesions are complicated by emphysema and this reaction is responsible for the cardinal symptom of dyspnea.

The severity of the dyspnea limits the capacity for work and usually compels retirement. Many old employees, who suffer from this condition are permitted to perform light work about the plant, which they may prefer to retirement on pension. Discharge becomes obligatory only in cases where the massive fibrosis is due to associated tuberculosis, which has become active and is shedding tubercle bacilli in the sputum. The methods of detecting this outcome logically belong in the next category.

4 Tuberculosis is the most important infection of the lungs to be considered in the silicotic subject. Bronchopneumonias of other origin may present difficulties in diagnosis but, as they generally run a chronic course and produce results comparable to those provoked by the tubercle bacillus, they will not be discussed.

Tuberculosis associated with silicosis may manifest itself in typical form in which case it offers no particular problems of diagnosis or administration. The discovery of active or questionably active foci of this infection in pre-employment examination obviously disqualifies an applicant for work in a silica industry. Ample experience indicates that long-continued inhalation of silica dust may reactivate such latent foci and produce chronic disease. Apparently healed foci of tuberculosis offer greater problems. In young applicants, whose foci are more likely to be of recent origin, it is unwise to permit the risk of reactivation. Some authorities apply this dictum not only to apparently healed foci of reinfection in the pulmonary apices but even to the calcified foci of primary infection that generally occur in childhood. While most of the latter lesions are completely healed and sterile by the age of employability, a few cases of reactivation have been observed. In experimental animals reactivation has been proved possible in any focus still containing living tubercle bacilli. A reasonable policy would permit employment of all persons of mature age with roentgenographic evidence of small calcified primary foci. If the subject were young and his primary tubercle were large or exhibited any other suggestion of incomplete healing, he should be rejected, at least temporarily. In the periodic examination the discovery of a new case of typical tuberculosis in a silicotic subject demands

the same procedure as in the general population, i.e. immediate treatment.

Unfortunately the majority of tuberculous complications in silicotic lungs are not typical and present serious problems in diagnosis. Such conditions fall in 2 categories, 1 an acute manifestation and the other characterized by unusual chronicity.

Acute tuberculosis is quite as rare in silicotic groups as it is elsewhere. Since the victims are prostrated by symptoms of intoxication, they would hardly be a problem in the pre-employment examination. If the periodic examination of a workman, whose films previously revealed generalized, discrete nodulation, discloses a marked increase in the size of the nodular shadows with loss of their ordinarily sharp definition, one should suspect infection. If in addition the film presents a new ill-defined but localized shadow, perhaps in the upper portion of the lung, the probability of tuberculous complication is even greater. Usually, if the man himself has not volunteered a complaint, questioning will reveal symptoms and he may even have some fever. Obviously he needs prompt hospitalization with the usual treatment. Such cases tend to run a rapid course and most of them terminate fatally within 6 to 12 months.

The chronic aspects of tuberculosis in the silicotic subject have already been mentioned in connection with the massive types of simple silicosis. The questions raised in section 3 remain to be discussed. If the localized lesion is due to some cause other than an active infection, it is classified as one of simple silicosis. If it results from an infection that is still active but encapsulated and latent, it should be classified as tuberculo-silicosis¹. This is a new condition and not merely a superimposition of an element of infection upon a background of silicotic fibrosis. It apparently results from the simultaneous action of silica and relatively few tubercle bacilli barely able to survive in an environment of avascular scar tissue. It may produce no symptoms of intoxication and no bacilli in the sputum for many years because the investing scar tissue prevents absorption of toxic products and the excretion of tubercle bacilli. Late in life, however, the infectious element usually becomes dominant, symptoms of infection are manifested, bacilli reach the bronchi and are expectorated, and frequently the fibrous area breaks down to form a cavity.

¹The writer has previously employed the term, "silico-tuberculosis," to describe the same condition. At a recent meeting of the Correspondence Committee on Silicosis of the International Labor Office it was urged that in conformity with South African usage the order be reversed. In compliance with this request for international uniformity in terminology the condition in the future will be referred to as "tuberculo-silicosis."

to so many causes, it is impossible to state whether associated tuberculosis or another infection in a particular individual is due to the underlying anatomical change. Among groups of persons employed only in industries creating highly silicious dusts, the incidence of pulmonary infection may be moderately increased in individuals showing linear exaggeration. However, the increase never approximates the percentage observed in persons with specific nodulation of silicosis.

It is generally customary to accept for employment in a dusty industry any applicant whose film reveals slight or moderate degrees of linear exaggeration. Men with very marked changes of this type whose occupational history suggests considerable previous exposure to silica dust will be rejected by many examiners. It is debatable whether this attitude is justified except in the case of young individuals under 30 or perhaps 35 years of age. In applicants over 40 who have already been exposed for 15 or 20 years the condition is much less likely to progress particularly in an industry where the engineering methods of dust control are effectively applied. The discovery of linear exaggeration upon periodic examination of persons already employed demands no action unless the condition is developing rapidly in young individuals. This rather rare occurrence is probably best met by transfer to another department of the plant. Otherwise no change in occupation is indicated, compensation rarely enters the picture owing to the lack of disability and consequent wage loss.

2. Dust reaction characterized anatomically by the formation of discrete fibrous nodules, not over 6 and usually not over 4 millimeters in diameter, uniformly distributed throughout all parts of both lungs and roentgenographically by the picture known as nodulation (discrete shadows of the above size and distribution) is most likely to have been caused by inhaling free silica. A history of adequate exposure to such dust together with a physical examination usually establishes the diagnosis with reasonable certainty. Only a few rare fungus infections, certain tumors and very unusual cases of cardiovascular disease produce similar patterns in the pulmonary roentgenogram. Discrete nodulation is uncommonly associated with sufficient disturbance of pulmonary function to impair the capacity for habitual work. In advanced cases, which are usually complicated by emphysema, dyspnea on exertion is a common symptom. The individual with generalized discrete nodulation is definitely more susceptible to tuberculous infection and to bronchopneumonia of other etiology than a normal subject. The same

is not true for lobar pneumonia. Although this increased susceptibility to infection makes the silicotic workman a potential liability, he is usually capable of productive work until such infection develops.

Pre-employment examination often unjustly prevents persons with simple discrete nodulation but no disability from obtaining work. In periods of labor shortage, however, skilled workmen with such manifestations of silicosis have been accepted and have rendered efficient service. Provision in the compensation laws to relieve employers of full responsibility for any infection which might develop subsequently, would overcome their natural reluctance to hire such men and would permit most silicotics to be self supporting. In the periodic examination of persons already employed in a silica industry the discovery of early, simple, discrete nodulation does not justify discharge. Significant degrees of disability will not be manifested in the absence of infection, and in industries with effective dust prevention programs the silicosis will progress with equal rapidity regardless of continued employment. Only the young individual who has developed silicosis at an early age, need be transferred to another job because his naturally greater susceptibility to tuberculosis might be augmented by further exposure to silica dust. Perhaps the most important function of the periodic examination is the early detection of evidence of pulmonary infection. Such cases must be given the benefit of prompt treatment and removed from positions where they might endanger fellow workmen with silicosis. They will be considered in section 4.

3. Dust reactions characterized anatomically by areas of massive, conglomerate fibrosis with or without an associated discrete nodulation present the greatest problems in diagnosis and administration. The pathological anatomy of such lesions consists of large areas often bilateral composed of great numbers of nodules embedded in a matrix of diffuse fibrosis which more or less completely obliterate the normal pulmonary architecture. Other parts of the lungs usually exhibit small, discrete, isolated nodules but these may be absent. Almost invariably the so called 'conglomerate fibrosis' is associated with well marked emphysema often of the bullous type. The causation of such lesions is not well understood. Some of them are unquestionably due to low grade infections which produce no toxic symptoms for long periods of time. Others in the writer's opinion are the result of excessive accumulations of silica dust in the scars of healed

METHODS OF INVESTIGATION OF OCCUPATIONAL SKIN DISEASES

LOUIS SCHWARTZ, M.D., New York, New York

IN order to investigate intelligently the cause of occupational dermatoses, one must have at least a sufficient knowledge of dermatology to distinguish contact dermatitis from such ordinary skin diseases as psoriasis, impetigo, urticaria, pityriasis rosea, etc. In addition, one should also have a fair knowledge of chemistry. The actual investigations in factories will give one the knowledge of industrial processes which is also an essential requirement.

Before we can hope for success in finding out the cause of a particular outbreak of occupational dermatitis, we must have the experience and knowledge gained by studies of the normal skin hazards and the normal incidence of occupational dermatoses in the basic industries. Such studies not only acquaint us with the irritating properties of various chemicals and compounds, but often lead to the discovery of health hazards not previously reported. It was in the course of such routine studies that we first noted the health hazards connected with the manufacture and use of certain chlorinated hydrocarbons and certain synthetic resins.

The basic industries are selected for routine studies, because they manufacture the chemicals used in all other factories, and their workmen are subject to the hazards of contact with these chemicals. We also make it a practice to scan the reports of occupational dermatoses which are submitted to the Public Health Service by the Compensation Boards of the various states, and we note if there is any unusual occurrence of occupational dermatoses in any one factory. If there is, we investigate its cause.

To gain entrance into factories to make our studies, we first awaken the interest of the owners or management to the importance of our work. This is done by means of letters and interviews in which we assure them that our studies are conducted in such a manner as not to alarm the workers or to inconvenience the routine of the factory, and that the results of our investigations will in no way hurt their business, but, on the contrary, will help to lessen the health hazards among their

workers. After such interviews permission to make the investigations have always been granted.

In proceeding with an investigation, the first step is to discuss with the plant superintendent the occurrence of occupational diseases, especially those of the skin, which to his knowledge had occurred in the factory, to obtain from him a list of the raw materials used in the factory and of the products manufactured. The next step is to consult with the plant physician, if there is one, or with the nurse or first aid attendant, concerning the chief infections or diseases treated in the dispensary, and to obtain from them a little better conception of the incidence of skin diseases than was obtained perhaps from the superintendent. The medical records, if any have been kept, are then examined regarding the number of cases of skin lesions treated, the departments in which the patients worked, and the causes given for their occurrence. This procedure often yields a clue as to what part of the factory has the greatest skin hazards. It is also well at this time to request that such of the workers, who have had occupational skin diseases or who are known to be affected at the present time, be called into the dispensary to be questioned and examined. This enables us to check and evaluate the criteria used by the plant physician in making a diagnosis of occupational dermatitis.

We then request the superintendent to appoint someone familiar with all the industrial processes in the factory to escort us through the plant. In many instances he himself, together with the plant physician, accompanies us in our inspection. We begin at the point where the raw materials come in and follow them through the plant until the finished product is ready for shipment. In each department visited we first interview the foreman, asking him if he knows of any workers who have now, or ever have had skin diseases, and what in his opinion caused these diseases. We then go through the department and have the manufacturing process explained to us. We examine the hands and faces of the workers for skin lesions, at the same time taking note of their work clothes, whether they are clean or dirty, and whether protective clothing in the form of gloves, aprons, boots, respirators, etc., are worn. We

From the United States Public Health Service
Presented in the Symposium on Industrial Medicine and Traumatic Surgery, before the Clinical Congress of the American College of Surgeons, New York, October 27-28, 1938

The industrial physician's problem in diagnosis is difficult. As long as the infection remains dormant the workman is not a menace to his fellows; he may not be seriously incapacitated though more or less short of breath, and he may wish to continue at his job. It is probably just as well that he should for no form of treatment up to the present time has cured such a disease so far advanced. If the employee's temperament is such that he is happier at home, he should be retired on compensation but permitted to perform light jobs.

If he is kept under observation, it is not always easy to determine when his tuberculo-silicotic lesion is about to break down and become a menace to other employees. Systematic records of body weight are kept; a progressive loss suggests the need for further investigation. Repeated roentgenograms may reveal a change in the size or the character of the localized lesion and perhaps evidence of extension in the surrounding lung. Examination of the sputum for tubercle bacilli requires patience as many negative reports must be anticipated; persistence will usually yield positive results. Guinea pig inoculation or culture are preferable to direct methods of examination as the number of organisms is small when they first make their appearance.

At the first indication of clinical or bacteriological activity the workman with tuberculo-silicosis should be removed from contact with other silicotics. In some plants special isolated jobs, involving little or no physical effort, have

been created for them. Hospitalization and any of the forms of treatment applicable to uncomplicated chronic tuberculosis have had little effect upon this condition. Intelligent cooperation with a minimum of physical effort may prolong life but it cannot cure the disease. Since this is usually most difficult to obtain from men of this class there is need for research upon new means of therapy. Today one can only hope that modern programs of dust prevention will preclude the development of tuberculo-silicosis in the new generation of workmen.

From the foregoing discussion it is obvious that uncomplicated silicosis usually produces too little disability to disqualify a workman for his habitual occupation. The supervision of tuberculosis or other infections of the lungs are largely responsible for decreased capacity to work and are the ultimate cause of death in many silicotic subjects. Therefore, it should be the major objective of the industrial physician to protect his silicotic charges from contact with the tubercle bacillus. The methods which he employs inside of the plant have already been indicated but his responsibility does not end here. He must also extend his supervision into the home and the community at large. By cooperation with the public health authorities programs of case findings and education should be encouraged. Every hospitalized case of open tuberculosis in an employee reduces the possibility of a disabling infection in an industrial physician's plant.

While outbreaks of occupational dermatoses usually occur in only one department of a factory, it is necessary to study not only that one department, but the whole process of manufacture, or at least all of the processes which precede the one in which the outbreak occurred. We should study the sickness records of the plant for at least 1 year previous to the outbreak, in order to determine whether the outbreak occurred suddenly, or whether there was a gradual increase in the number of cases of dermatitis, and whether there was any connection between a sudden increase in the incidence and the use of new chemicals, new processes, or changes of old processes in the factory. Detailed inquiries should be made of the superintendent, the foreman, and the workers as to changes in manufacturing processes and the introduction of new chemicals preceding the outbreak of dermatitis.

Patch tests should be performed with all of the materials handled by the affected workers in an effort to track down the offending substance. In some instances the management purchases, under trade names from other concerns, the chemicals which they use and do not know their composition. It is necessary in these cases to trace the chemicals to their original source of manufacture and thus determine what they really are.

By way of illustrating how such outbreaks of dermatitis are studied, I will outline a few actual investigations which we made.

SPECIFIC INVESTIGATIONS

CASE 1 We were requested to investigate an outbreak of dermatitis in a cotton mill. It was found that the lesions occurred only among those workers whose forearms came in contact with new heddle frames in the weaving machines. The skin of the forearms touched by the heddle frames was first affected. The frames were made of spruce and were painted with a yellow, waxy varnish. Patch tests with the varnish scraped off the frames gave positive reactions, while patch tests with the wood itself gave negative results. Removing the varnish from the heddle frames checked the occurrence of dermatitis. This definitely established the fact that the varnish on the new heddle frames was the cause of the dermatitis.

Wanting to ascertain what in the varnish caused the dermatitis, we visited the manufacturer of the frames. There it was found that the varnish on these frames was purchased from a different paint factory than was the varnish which had previously been used and which had caused no dermatitis. The new varnish was introduced because it produced a smoother and a more waxy finish on the heddle frames. It was learned that some of the workers in the heddle frame factory, who were engaged in applying the new varnish, also contracted dermatitis. Letters to the other cotton mills, which had purchased the same new heddle frames, brought out the fact that cases of dermatitis had occurred also among their workers since the installation of the new frames. The makers of the varnish were then visited and the ingredients of the varnish obtained. These were taken back to the first cotton mill, reporting the out-

break, and patch tests were performed with all of the ingredients in the varnish on those workers who had suffered with dermatitis. It was found that chlorinated ceresin, a wax, was the chief irritant. Patch tests performed in other cotton mills confirmed the results obtained in the first mill. The chlorinated ceresin produced a smoother, waxy finish to the varnish, but under the atmospheric conditions, usually prevailing in cotton mills, the workers perspire freely and the perspiration, coming in contact with the wax, caused the formation of hydrochloric acid which was the actual cause of the dermatitis.

While patch tests are a great help in determining the causes of occupational dermatitis, it is not always possible to use them and we must sometimes devise other methods of approach. The following is an example of this:

CASE 2 An outbreak of dermatitis among cable splicers occurred in Chicago and in New York City simultaneously and in no other place, although the process of cable splicing is the same in all parts of the United States. After several unsatisfactory attempts by others at determining the actual cause of this outbreak, the telephone company referred the problem to the Public Health Service.

The workers affected had been patch tested by previous investigators and at first refused to submit to any more such tests. Therefore, we decided to divide the operation of cable splicing into 7 stages and to have the workers, who had been affected and who were now well, work a number of days on each stage then rest a few days before taking up the succeeding stage. In this way, we hoped to find out at what operation in cable splicing the dermatitis actually occurred.

It was found that the dermatitis occurred during the operation of "boiling out" the green and blue, paper-wrapped wires in the cables. The "boiling out" was done with a mixture of paraffin and mineral oil, and was done for the purpose of removing all moisture from the wires. The dyes used on the green and blue papers were malachite green and methyl violet. Although some of the stages of operation consisted of "boiling out" other colored wires with this mixture, no dermatitis occurred from splicing wires dyed any other color, nor did it occur from the "boiling-out" mixture itself. Patch tests performed with strong concentrations of the two dyes produced dermatitis in some of the workers. By the time that we had reached this stage of our study the workers had become so interested that they consented to our patch testing experiments.

Further experiments showed that in the process of "boiling out" the dyes were partially decomposed, and that the decomposition products were dissolved in the "boiling out" compound. The "boiling-out" compound was used over and over again, and in this way it contained a high percentage of decomposition products which were carried off in the fumes and irritated the skin of hypersensitive workers. The reason that the outbreak occurred at that particular time in Chicago was that there was a large amount of cable splicing being done for the Chicago Fair and the workers were unusually exposed to the fumes of the "boiling-out" compounds, while in New York, at about the same time, new cables larger than any that had been laid before were being installed and this entailed an unusual amount of cable splicing. As a result of these experiments new dyes were satisfactorily substituted for the old dyes in the manufacture of telephone cables.

CASE 3 Recently we were requested by an insurance company to investigate dermatitis occurring among workers in a factory manufacturing conduits made of paper

note the cleanliness of the work room, whether there are any safeguards on the apparatus such as ventilating hoods etc., and ask each worker if he now has or ever has had any skin diseases. The names of workers, who are found to be affected with skin lesions or who state that they have been affected at some time or other are taken, and at the end of the day's inspection these workers are summoned to the dispensary and examined further.

The primary inspection of the men at work takes but a short time—not over half a minute for each man. The same procedure is followed in every department, and notes concerning the industrial processes and hazards are taken. At the end of the day's inspection usually an hour or so before the end of the day's shift, we go to the first aid room and send for the workers found during our inspection to be affected with skin diseases. Such workers are examined one at a time with only the plant physician, nurse, or first aid attendant present. The worker is required to disrobe completely and his body is examined for the presence of skin diseases. It is important to strip the patient, because often an important clue to the diagnosis is revealed which might otherwise be overlooked.

A card record is made of the patient noting the name, sex, age, color, and a detailed description of the worker's occupation, giving the chemicals with which he comes in contact. The date of entering on his present occupation is noted as is also a history of his previous occupations. A record is made of previous skin diseases and of any allergic history. A detailed account of the present skin diseases is taken putting down the date of onset and the symptoms, a written description of the skin lesions and their location is made on the card, the patch tests if any are performed are also described, giving the names of the chemicals applied as patches, the length of time they are allowed to remain on the skin and the resultant reactions. Based on this data the diagnosis is made and the actual skin irritant if found is named. Under the heading Remarks we record complicating skin lesions and the treatment advised.

CRITERIA FOR DIAGNOSIS

The following criteria are used in making a diagnosis of occupational dermatoses.

1 History This should bring out the fact that the dermatitis was not present before the patient entered on his present occupation and that it developed during a period of industrial exposure or after a lapse of a reasonable period since the cessation of exposure.

2 Site of eruption The eruptions must have begun first on the exposed parts, usually the hands, fingers and forearms, if the offending material is a solid, or a liquid and on the face and neck, if the offending material is a vapor. However, in the case of irritant dusts, which may penetrate the clothing the covered parts of the body may be affected first, especially if the clothing is not frequently changed. Sometimes the points of friction, such as the wrists where the ends of the gloves and sleeves rub, or the belt line where the belt or the top of the trousers cause friction, are the first affected.

3 Characteristic appearance of lesions An acute industrial dermatitis begins as an erythema followed by papules, vesicles, and crusts no matter what the irritant may be. It must be remembered however that there are a few classes of industrial irritants which produce more or less characteristic lesions on certain parts of the body such as paronychia which is a common lesion among fruit and vegetable canners. Acnes are common lesions caused by chlorinated waxes, petroleum oils, and coal tar folliculitis and boils are often produced by dirty clothes and oil and keratosis and malignant growths are caused by coal tar, certain petroleum, and arsenic.

Patch tests are an important diagnostic procedure but they must be performed by someone familiar with the technique and who will not patch with primary irritants, otherwise they may lead to wrong conclusions. Before patch tests are performed on the workers, the object of performing them must be explained to them and their consent obtained, otherwise legal complications may develop.

Differential diagnosis is often difficult, but a rule that applies in many instances is that dermatitis, due to occupation, tends to get well when the patient is removed from his work, and recurs after the patient goes back to his same job.

When a number of factories manufacturing the same products have been examined a fair idea of skin hazards in that particular industry is obtained. The knowledge and experience gained by routine studies of industrial processes and skin hazards in basic industries prepare us to understand intelligently the investigation of the causes of outbreaks of occupational dermatoses. The requests for such investigations come from insurance companies, the managements of factories and labor unions. Such outbreaks of occupational dermatoses usually occur when new chemicals are introduced or when new manufacturing processes are being installed or when there is some change made in old manufacturing processes.

THE DIAGNOSIS AND THERAPY OF SO CALLED POSTTRAUMATIC NEUROSIS FOLLOWING CRANIOCEREBRAL INJURIES

DONALD MUNRO, M.D., F.A.C.S., Boston, Massachusetts

POSTTRAUMATIC neurosis, posttraumatic state, compensation neurosis, postconcussional state or neurosis, litigation neurosis, traumatic hysteria and malingering are all common and interchangeable terms. They are used to describe a group of symptoms which pester patients, doctors, insurance companies, and law courts and which develop after the patient, who has received any craniocerebral injury, has left the hospital or its equivalent. They imply conscious or unconscious attempts on the part of the victim to prolong unduly his period of invalidism and suggest a non-organic rather than an organic basis for his complaints. There have been, and doubtless always will be individuals, who, after being hurt, give false testimony, and intentionally magnify minor injuries in order to obtain more money or other compensation than they are justly entitled to.

However, it is neither fair nor correct to conclude on that account, that all patients who have had head injuries in the past, and who, at some later date, complain of disabling symptoms, that cannot be shown by ordinary tests to be due to objective changes, should be classified with this unsavory minority. For example, LeFever and Secrest have shown that of 100 patients injured in industry and later proved to have objective signs of brain abnormalities 71 per cent had complained at first chiefly of headaches, 64 per cent of dizziness, and 43 per cent of tinnitus. The usual tendency of the medical profession to avoid the middle ground of reason and to take the attitude that such individuals are either the blackest sinners or the most spotless saints, justifies a consideration of the diagnostic and therapeutic possibilities of this problem. Only those patients, who continue to complain of symptoms referable to the head after they have been active a few weeks, are included.

DIAGNOSIS

When a physician is confronted with the necessity of making a diagnosis of a man who attributes

headaches, inability to work, lassitude, dizziness, and the like to an antecedent accident, it is obviously of the first importance to be sure that he did, in fact, injure his head as he claims. To do this, it is only necessary to demonstrate a period of unconsciousness or its lay equivalent, and/or a period of severe headaches immediately or shortly after the accident. Confirmation may be had by scars on the scalp and, of course, by x-ray evidence of bone damage of appropriate age. The usual and best evidence for or against this claim will be historical, however. In collecting it, the doctor should stay away from the legal or controversial aspects and content himself with obtaining those facts which can be verified by associated objective evidence. He should never accept the patient's own story without such confirmation as is obtainable from a description, or a lack of it, of the details of the periods immediately preceding and following the accident as well as those of the accident itself. These can and should be checked by independent witnesses or by the demonstration of such incontrovertible facts as the state of the weather, the road, the job, and the like.

Having satisfied himself that his patient has actually or probably been the recipient of a craniocerebral injury, the physician is justified in concluding that the symptoms about which the complaint is being made may be due, among other things, to the late effects of this damage. However, this conclusion cannot be final until other possible causes have been ruled out. The patient may, for example, have had an intercurrent disease, the presence of which is unknown to him, and which has no relationship whatever to the head injury, but which is actually producing symptoms that mimic those commonly seen as some of the late results of the previous accident. Even should this be considered a far-fetched possibility, the physician still must learn whether or not there is present evidence of continuing cerebral or cranial pathology. To get all this data, the patient who would learn the cause of his post-traumatic syndrome or who would be relieved of his symptoms must submit to hospitalization.

Presented in the Symposium on Industrial Medicine and Traumatic Surgery, before the Clinical Congress of the American College of Surgeons, New York, October 17-21, 1938

impregnated with coal tar pitch. Men working inside the factory were not affected but those working in the yard where the finished conduits were stored suffered considerably with dermatitis. Previous investigations resulted in no satisfactory explanation. A visit to the factory was made and on examination of the workers brought out the following facts:

All the workers exposed to the fumes and dust of the coal tar pitch, whether in the yard or inside the plant, had a marked melanosis. The workers in the yard suffered with dermatitis especially on bright days similar to a severe sunburn. The workers inside the factory stated that they too suffered more from sunburn on their days off from work than those employed elsewhere. Patch tests performed with coal tar pitch dust gave no reactions upon removal of the patch but upon exposure of the patch area to sunlight there developed a marked sunburn. This showed that exposure to coal tar pitch sensitized the skin to light. Examinations of workers in other factories making conduits where there was an exposure to coal tar products revealed the same conditions. This was the first time that occupational photosensitivity was reported in America. Effective preventive measures were devised.

Because of the experience we have gained in making studies of industrial processes and the skin hazards connected with them we are often called upon to investigate the causes of outbreaks of dermatitis occurring among the users of manufactured goods. The following will illustrate this:

CASE 4. A certain manufacturer of wrist watches decided to use jet black sweat proof straps on his products. He ordered such straps from a leather strapmaker. After about 100,000 of these straps had been sold to stores complaints and law suits began to come in because of dermatitis on the wrists of the wearers of these watches which had been caused by the leather straps. The straps were

sent by the watchmaker to a leather research institute and to a well known dermatologist to determine if they contained a skin irritant. Reports from both were negative. Before contesting the suits for damages however someone in the factory suggested that a number of the workers be asked to wear the straps as an experiment to see if any of them would develop dermatitis. Accordingly, 50 workers volunteered and were given the straps to wear and in a few days 6 of them had developed a dermatitis of the wrists. The Public Health Service was then requested to investigate.

We visited the manufacturer of the straps and learned from him the source of the leather and of the dyes. We obtained samples and patch tested the workers who had worn the wrist watch straps with the undyed leather, the dyed leather, and with each of the chemicals used in the dyes. Positive reactions were obtained only from the dyed leather and from one of the dyes used in the dye mixture. This dye is known as butter yellow and has the chemical name of amido-azo-toluene hydrochloride and had never before been reported as a skin irritant. In fact it was thought to be so innocuous that it had been used to color some edible fats. We found that the yellow dye was mixed with the black dye (nigrosine) in order to give the straps a jet black color instead of the blue black color imparted to the straps if only nigrosine was used. Elimination of butter yellow from the dye mixture stopped the dermatitis caused by the wrist watch straps.

We have had similar experiences with fabrics, paints and cosmetics.

These are in brief the methods of investigation which we adopt in studying the causes of occupational and other forms of contact dermatitis. All of the investigations and problems of contact dermatitis are interesting, instructive, and fascinating, and some of them will tax the ingenuity of clever chemists, allergists and dermatologists.

will deprive him of the use of any alibi for a failure to improve, that is based on the doctor's directions. Such a requirement will also set the stage for his psychological rehabilitation, the chief essential of which is to force him to assume full responsibility for all his actions. Thus, he will govern the speed with which he recovers and is able to return to his normal way of life, insofar as his permanent anatomical disabilities will permit him. Necessary adjuncts to this regimen are that he shall not see his doctor except at infrequent intervals, that his return to work shall, if possible, await his own request, and, that when he does return, he shall be started in on a job that does not require the use of his full physical capacity, even if this means a shift in work or temporary, half, or part-time employment.

Unfortunately, only a minority of patients that have had craniocerebral injuries suffer at this later date from organic abnormalities that have been missed previously and that can be demonstrated objectively. Usually, all objective tests are entirely normal and all symptoms exclusively subjective. All that the doctor has learned from his study of the patient is that at some designated time in the past, he did sustain a head injury and that now he shows no objective evidence of disease or injury. If the patient or those concerned with his welfare want more diagnostic data, he must accept the necessity of undergoing further, more complicated diagnostic procedures. These, because they carry a minimal but inescapable risk, cannot be forced upon him. If he elects not to take this further step, the doctor can do no more than inform him that at that time no objective evidence of disease or injury can be elicited as a cause for his subjective complaints. Hence, his symptoms may be due to neurosis, malingering, a subdural hematoma, cerebral atrophy, or psychotic maladjustment, and, because no certain differentiation can be made without further studies, no reliable advice as to treatment nor statement as to the future can be given. Such an opinion, being based upon demonstrable facts, can be supported in the face of hostile argument where traumatic neurosis and its synonyms will let the doctor down because of its vagueness and the implications of malingering that inevitably accompany it.

SUPPLEMENTARY DIAGNOSTIC PROCEDURES

If the patient or those responsible for him elect to go further in their efforts to rid the patient of his symptomatology, there are 2 supplementary procedures that are open to him. Both have a slight but inescapable risk and, therefore, cannot

be carried out without his specific consent. This permission should be written and should be used only after the doctor has satisfied himself that the patient, his family, and any other interested parties fully understand that this further investigation carries no actual or implied promise of relief and that it is essentially and primarily a diagnostic procedure. As such, it will only indicate what further methods, if any, can be used to promote relief.

The first of these procedures is encephalography. A discussion of its technique and limitations cannot be undertaken here. Suffice it to say that in my clinic encephalography has demonstrated cortical atrophy with a high degree of accuracy, solid subdural hematomas sufficiently often to be a valuable adjunct in their diagnosis, (6) and fluid subdural hematomas and "encysted fluid" not at all. None of these conditions need be accompanied by any objective changes that would necessarily be demonstrable by any of the procedures discussed above. Encephalography has had no value as a method of treating the symptoms of the posttraumatic syndrome. While I have used it at times for this purpose, usually accompanied by suggestion, I do not believe that it is as efficient or reliable as other and more classical varieties of psychotherapy.

The other supplementary diagnostic procedure is exploratory trephination (3, 4, 6). This procedure offers the final opportunity to arrive at the cause of these late symptoms. While its ultimate object is to visualize a part of the cortex of both cerebral hemispheres, its chief and almost exclusive use is to determine whether or not a subdural hematoma is present and acting as the probable cause of the symptoms. This possibility is not so remote as might be imagined. Reference to Figure 1 will demonstrate that subdural hematomas are present in about 1 out of every 5 cases of craniocerebral injury that are hospitalized at the time of the causative accident. The figures are reliable having been verified in each case by operation or autopsy. When it is further borne in mind that the probability of diagnosing and treating subdural hematomas is extremely small, in non-hospitalized patients and in patients that are cared for in the smaller general hospitals during their period of acute illness, it must be apparent that previously unrecognized subdural clots will be even more common among those patients who come in complaining of late symptoms. No figures are available relative to this later occurrence rate, but it may well be that every other one of such patients will eventually prove to be suffering from the more

Requisite information such as here outlined can not be obtained in an office under any conditions and a physician will do much better if he refuse to give any opinion, whether to patient, insurance company, or lawyer, until he is permitted to acquire the facts he needs in the proper way. Indeed, he should refuse to have anything to do with the case under any other circumstances.

Preparatory to a more intelligent estimation of the data that is to be acquired, and after the patient has been hospitalized, it is well to get what details one can relative to the treatment given at the time of the accident. This must, of necessity, have considerable bearing on the occurrence of late symptoms. If we predicate, for example, 2 individuals neither 1 of whom had any significant demonstrable symptoms during the acute stages but who had been hurt in exactly the same way and to the same degree, and in whom a mild contusion and edema of the brain represented the underlying pathology, it should be obvious that the patient whose increased intracranial pressure had gone untreated would and should have greater permanent cellular destruction in his brain. If both these men happened to be compensation cases and complained of an inability to work 3 months after the injury or had "post-traumatic" or "compensation neurosis" or were accused of "malingering" an organic lesion which was compensable could unquestionably be ascribed to the 1 who received improper or no treatment while the other who had received proper and adequate therapy, should be regarded with suspicion. Yet, the late symptoms are present in the first patient in part at least, because of his doctor's failure to base his diagnosis on demonstrated pathology and because of his belief that a lumbar puncture was unnecessary since the patient didn't complain. It is this same fundamental inexactitude which leads to a diagnosis later of "postconcussional neurosis" when the patient's original injury was a lacerated brain, and despite the fact that concussion by definition is a self-limited disease and can have no aftermath. Thus there should be available in every late case of craniocerebral injury, data as to earlier increased or decreased intracranial pressure as to the presence of blood in the cerebrospinal fluid reports of ordinary x-ray studies a description of the pathology found in the course of any exploratory operation that was done records of blood pressure changes an enumeration of the number and notation as to the extent of any scalp wounds and the involvement of air sinuses or arterial grooves in fracture lines. These facts will confirm or deny the probability of a head injury as deduced from

the history, and will serve to annotate and help in the interpretation of the physical signs collected during this later hospitalization.

At this late date after the accident the doctor's further aim should be to get a complete picture of the patient's present physical condition. The picture should be based chiefly, however, on an objective demonstration of facts. A physical examination repeated neurological examinations, necessary mental tests, tests of the special senses study of the blood and urine and an estimation of the efficiency of the kidneys, must all be included. Lumbar puncture with a demonstration of the intracranial pressure and chemical, serological and cytological examinations of the cerebrospinal fluid are absolutely essential. An adequate x-ray examination should visualize the bony structures that come under suspicion. Such a procedure is the minimum that permits an inferential opinion as to the physical relationship between the accident in the past and the subject's symptomatology of the present. If the general studies are negative it can be concluded that no intercurrent disease, previously unrecognized, is causing the symptoms which bring the patient to the doctor at that time. The special examinations should eliminate associated mental disease, arteriosclerosis, syphilis, multiple sclerosis, syringomyelia, pernicious anemia, and the like. The lumbar puncture and cerebrospinal fluid studies will rule out an expanding intracranial lesion and the x-ray a previously unnoticed bone injury.

TREATMENT

If by these diagnostic methods the surgeon can show that the patient did in fact, sustain a craniocerebral injury as he alleges and that at the time of this later examination there is objective evidence of craniocerebral pathology, the indicated therapy should be provided without further delay. If there is objective evidence of cranial or intracranial abnormality, such treatment will of necessity be operative. A decompression will be required for a high intracranial pressure depressed fractures should be elevated cortical abscesses must be drained and appropriate steps taken to correct such unusual conditions as traumatic arteriovenous aneurysm the presence of bilateral subtemporal decompressions and the like. In addition measures to improve the patient's general condition and psychological reactions should be initiated. For the first a program of graduated increasingly severe exercise interspersed with judicious periods of rest will be found most useful. The patient should be made the sole judge of the rate of increase. This

operation Despite this obvious lack, however, my experience has satisfied me that this exploratory procedure is amply justified in any patient who is known to have sustained a craniocerebral injury, and who either asks to have it done or accepts it after having been told that it is quite as likely to be a useless as it is to be a useful procedure from his point of view.

CONCLUSIONS

1 In patients who complain of symptoms which persist for a month or more after their discharge from medical care following an acute craniocerebral injury, it should be possible, provided the patient is hospitalized, to make (a) a probable diagnosis of head injury from the history, (b) an estimate of the efficiency of the earlier treatment and the probability of resultant late symptoms, and (c) a positive diagnosis of

previously unknown intercurrent disease and of residual objective signs of the previous injury.

2 The resultant diagnoses should be phrased as follows. "No present evidence of organic disease", "no present evidence of organic disease but a probable earlier craniocerebral injury"; or "present evidence of organic disease due to the residual effect of an old craniocerebral injury," or "to unconnected intercurrent disease"

3 These diagnoses should replace such meaningless and inaccurate terms as "posttraumatic and postconcussional neurosis" and should be made only after hospitalization of the patient

4 They do not rule out the presence of such conditions as a subdural hematoma, cortical atrophy or scars, or psychotic maladjustments as the cause of the symptomatology

5 Further investigative and diagnostic procedures include encephalography and transtemporal trephination

6 In a group of 47 patients who subjected themselves to diagnostic transtemporal trephination for symptoms that persisted for 1 month to

chronic forms of this condition. My experience leads me to this conclusion because in dealing with 330 hospitalized subdural hematoma suspects there were only 62 or a little under 2 per cent of the explorations that were negative. Patients who have subjective symptoms long after their injury and who also harbor subdural hematomas, have the fluid rather than the solid variety (5). Except as a guess it is impossible to diagnose this type of clot by any means other than exploratory trephination. This is well illustrated by the following characteristic case.

A twenty year old college student was knocked unconscious playing football while a freshman. During the following 2 years he was removed from college, sent back to school, had a diagnosis of and was bled for polycythemia was next considered to be a brain tumor suspect after which he moved to Chicago and was told he was hysterical. He then returned to New York where he had a negative encephalogram made and was sent to a well known sanatorium. It was decided at this latter place that he had neither hysteria nor a psychosis. Following this he was given pituitary extract as a possible pituitary tumor case had another encephalogram made in Chicago and then had his appendix removed. Despite all this he still had his headaches. He returned to college for 3 months but had to leave. I saw him at that time. He had no objective signs of central nervous system disease but was offered exploration and accepted. A fluid subdural hematoma was found and drained. His headaches and other symptoms were relieved by the time of his discharge from the hospital. He returned to college in 2 months and rejoined his original class. During the 4 succeeding years he graduated with honors, started in business and had no return of any symptoms whatsoever.

Since it is primarily diagnostic, the exploratory trephination need not be limited to subdural hematoma suspects. It may be legitimately used to verify other diagnoses such as cortical atrophy or scars or widespread arachnoidal adhesions. It will have a negative value also. This was well illustrated within my own experience by 2 instances.

In one a patient was suspected of having been the victim of an automobile accident but proved at exploration to have no appropriate cerebral pathology. Further investigation initiated as the result of this operation demon-

strated that he was suffering from acute bromidism and had never been in an accident. In the other case compensation was about to be paid for a hemiplegia alleged to have been induced while the patient was at work and as the result of an admitted injury that he had sustained 1 week previous to the onset of the paralysis. Exploration to verify the presence of a subdural clot demonstrated that he had had an arteriosclerotic thrombosis of one middle cerebral artery and that that was the cause of the hemiplegia which was entirely unconnected with the injury.

When a subdural hematoma is found by this means this same exploratory procedure can be used as a therapeutic measure. If the hematoma is, as usual, fluid it can be adequately drained and removed through only one transtemporal trephination. With this in mind the diagnostic operation should be started by trephining on the side opposite to the speech cortex. If this should prove negative the other side can be done.

Although invariably initiated as an exploratory diagnostic procedure, I have been able to make therapeutic use of this operation in 47 instances. All the patients had fluid subdural hematomas, all except 2 have been followed to date for periods varying from 1 month to 6 years (Table II) and all came under my observation for relief of symptoms that had persisted a month or more after they had been discharged from medical care administered for their original injury. Thirty three of these 45 cases were relieved of all symptoms and enabled to return to their normal life and occupations following the drainage of their hematomas. A study of Tables II and III will give the details of the successes and failures.

In general it can be said that in such patients (1) The type of occupation, kind of accident and length of the follow up after the first 2 postoperative years are of little significance in making the diagnosis or the prognosis. (2) The successful cases averaged 4 years younger than the failures. (3) The large majority of failures will be apparent after the first postoperative year. (4) The shorter the interval between the receipt of the blow and the removal of the hematoma, the better the result. In this series the number of failures was approximately 20 per cent greater than the successes at the end of the first postoperative year, 12 per cent at the end of the third and 19 per cent at the end of the sixth year. (5) Finally, and most important of all only 33½ per cent of the successes as opposed to 83 per cent of the failures showed objective evidence of the presence of central nervous system disease previous to operation and in addition to the subjective symptoms.

Unfortunately no figures are available as to the number of patients studied on account of the same complaints but who refused exploratory

MULTIPLE PRIMARY MALIGNANT LESIONS

LEONARD K STALKER, M.D., RICHARD B PHILLIPS, M.D., and
JOHN deJ PEMBERTON, M.D., F.A.C.S., Rochester, Minnesota

MULTIPLE primary malignant lesions occur more frequently than one would suspect before reviewing the literature of the past 20 years. We were stimulated in making such a review by the rather frequent occurrence of multiple primary malignant lesions in cases seen on the surgical service of one of us (Pemberton) in the year 1937. As a result, we reviewed all cases, approximately 2,500, in which operation was performed and a diagnosis of malignancy was made by a surgeon and pathologist at the Mayo Clinic in 1937.

The true significance of multiple primary malignant tumors has not yet been clearly established. It is hoped that studies of this kind, apart from their interest, may add to the genetic background of cancer. Billroth, in 1869, first reported cases of multiple malignant tumors. Rather comprehensive reviews have been made by Major (1918), Owen (1921), Hanlon (1931), Warren and Gates (1932), Hurt and Broders (1933), Schreiner and Wehr (1934), Bugher (1934), and Burke (1936).

Billroth, in 1869, proposed 3 postulates for the authenticity of multiple cancer: (1) Each tumor must have an independent histological appearance, (2) the tumors must arise in different situations, and (3) each tumor must

produce its own metastasis. Inasmuch as these conditions, especially the third one, are not usually fulfilled in cases in which operation is performed, we have used the criteria that have been proposed by Goetze, namely: The macroscopic and microscopic appearance of the tumors must be that of the usual carcinomas of the organs involved; exclusion of metastasis must be certain; diagnosis may be confirmed by the character of the metastasis in each case. Multiple primary neoplasms were found in 113, 4.52 per cent, of our series of approximately 2,500 cases of malignancy.

In 1931 Hanlon reviewed the reports of 3,000 consecutive necropsies performed at the Mayo Clinic. In 950 cases death was attributable to malignant tumors, in 710 of these cases the tumors were carcinomas. In 18, or 2.5 per cent, of the 710 cases of carcinoma multiple primary neoplasms were found.

Warren and Gates, in 1932, reported the results of necropsy in 1,078 cases of cancer, multiple primary neoplasms were found in 3.7 per cent of the cases. They also found reports of more than 1,200 cases of multiple primary malignant tumors in a review of the work of more than 430 authors. They said that on the basis of all statistics the incidence of multiple primary malignant tumors is 1.84 per cent in all cases of cancer, but that on the basis of the American figures alone the incidence is 3.9 per cent. They also expressed the

From the Division of Surgery, the Mayo Clinic and The Mayo Foundation

opinion that the occurrence of multiple malignant lesions is more frequent than can be explained on the basis of chance.

In 1933 Hurt and Broders reviewed a series of 2,124 cases of malignancy that were observed at The Mayo Clinic in 1929. The diagnosis was made by microscopic examination in all of the cases. Multiple primary malignant tumors were found in 71, or 3.3 per cent of the cases. The authors concluded that the factors which cause the development of the tumors also express themselves in the grade of malignancy, according to the classification of Broders. They expressed the opinion that the incidence of multiple primary malignant lesions was greater than would be expected if the occurrence was accidental.

Schreiner and Wehr, in 1934, reported a series of 11,212 cases of malignancy seen at the State Hospital, in Buffalo, New York, in 20 years. Multiple primary malignant lesions were found in 307, or 2.7 per cent of the cases.

Bugher, in 1934, reported the results of a series of 4,394 necropsies in 1933, or 22.3 per cent of the cases, deaths were due to cancer and in 30, or 3.1 per cent of the 1,083 cases there were multiple primary malignant tumors. He computed the expected occurrence of coincidental multiple primary malignant neoplasms from the mortality statistics in cases of cancer in the United States and found that it was exceeded by the actual occurrence.

Burke, in 1936, reported the results of a series of 2,033 necropsies performed at the Wisconsin General Hospital, at Madison. Cancer was found in 583, or 28.6 per cent of the cases. True multiple primary cancers were found in 46 or 7.8 per cent of the 583 cases.

The European figures for the most part have been derived from reports of a series of necropsies and, as a rule, indicate a lower incidence of multiple primary malignant tumors than do the American figures. Bilello and Montanini reviewed 8,024 cases in which necropsy was performed in Italy. Malignant tumors were found in 1,154 of the cases, but multiple primary malignant tumors were found in only 7 or 0.6 per cent, of the 1,154 cases. Gornaiowa and Schabad, of Leningrad, made a similar review of 6,652 cases in which necropsy was performed. They found 1,238 cases of malignancy, multiple malignant tumors were present in 23, or 1.8 per cent of the 1,238 cases.

There were 327 separate neoplasms in our series of 113 cases. In 51, or 45.1 per cent of the cases, multiple primary malignant lesions occurred simultaneously, in 62 or 54.9 per cent of the cases, the neoplasms appeared at different and varying intervals of time. In each case, however, the patient was operated on and the diagnosis of malignancy was confirmed by microscopic examination in 1937. In 30 or 26.5 per cent of the cases, an interval

Fig. 1. Primary malignant lesions found in Case 1.
a adenocarcinoma grade 1 of the descending colon ($\times 29$). b adenocarcinoma grade 1 of the uterus ($\times 29$).

c intracystic papillary adenocarcinoma grade 1 of right ovary ($\times 33$). d papillary adenocarcinoma grade 1 of the left fallopian tube ($\times 40$).

of 5 years or more had elapsed between the development of individual lesions. In one case malignant tumors had occurred at varying intervals for 43 years. In the 30 cases the average interval had been 12.3 years, in 21 of the 30 cases, 10 or more years had elapsed between the development of individual neoplasms.

Sixty-three of the patients were females and 50 were males. The average age of the 113 patients was 59.7 years. Seventy-three of the patients were between 50 and 70 years of age.

In this series of 113 cases the distribution of the malignant lesions was similar to the usual distribution of such neoplasms. More than 2 primary malignant lesions were encountered in several of the cases. As many as 12 neoplasms of the skin were found in 1 case.

In 35 of the 113 cases the multiple primary malignant lesions involved only the skin. In the classification of the situation of the neoplasms those that involved the lips were included as lesions of the skin. Excluding the cases in which the neoplasms involved the skin, including the lips, there were 64 cases in which 2 or more primary malignant lesions were found. Two lesions were found in each of 50 cases, 3 lesions were found in each of 11 cases, 4 lesions were found in each of 2 cases, and 5 lesions were found in 1 case. In each of 14 other cases 1 or more primary malignant lesions of the skin were associated with a primary malignant lesion of some other organ.

Of the 327 lesions, 167 involved the skin and lip, 97 of these were basal cell epitheliomas, 69 were squamous cell epitheliomas, and 1 was a melano-epithelioma. The 167 skin neoplasms were distributed over the entire body but were chiefly confined to the skin of the face and neck. A skin lesion was found in 54 cases, in 35 of these cases the patients had multiple skin neoplasms only, with no evidence of other malignancy. In 19 cases the malignant lesion of the skin was associated with a malignant lesion in another part of the body. Twenty malignant lesions of the lip were found in a group of 18 cases, in 13 of these there also was some other malignant lesion of the skin. There were 43 neoplasms of the breast in a group of 28 cases.

Fig. 2. Gross specimen removed in Case 2, a large carcinoma, grade 2, is situated in the ascending colon and a similar lesion is situated in the transverse colon, numerous small polyps are visible.

In this group 9 patients had bilateral mammary carcinomas without evidence of any other malignant lesion. Four patients had carcinoma of both breasts and 15 had carcinoma of one breast, all of these 15 patients also had a primary malignant lesion in some other part of the body. There were 27 malignant lesions of the ovary in a group of 17 cases. Primary malignant lesions of both

Fig 3 Malignant lesions found in Case 3 a at left adenocarcinoma grade 3 of the cecum ($\times 27$), b adenocarcinoma grade 3 of the sigmoid colon ($\times 34$)

Fig 4 Malignant lesions found in Case 5 a at left adenocarcinoma grade 3 of left breast ($\times 54$) b adenocarcinoma grade 4 of right breast ($\times 74$)

ovaries were encountered in 10 cases, in 2 of these cases there were primary malignant lesions in other parts of the body. In 7 cases a primary malignant lesion of the ovary was associated with a primary malignant lesion in another part of the body. There were 14 malignant lesions of the uterus and cervix in a group of 13 cases, 2 separate primary malignant lesions were found in 1 uterus. The neoplasm was primary in the cervix in 5 instances and in the fundus in 9.

Forty seven primary malignant lesions of the gastro intestinal tract were found in a group of 32 cases. Twenty four of the neoplasms were situated in the colon, 13 were in the rectum, 8 were in the stomach, 1 was in the esophagus, and 1 was in the anus.

A miscellaneous group included a variety of primary malignant growths. The tongue was involved in 4 cases, the urinary bladder and prostate gland each were involved in 3 cases, the paranasal sinuses, pharynx, larynx, parotid gland, and thyroid gland each were involved in 2 cases and the brain, bronchus, kidney, mastoid cells and fallopian tube each were involved in 1 case. In this group must also be included 4 sarcomas that were situated in various parts of the body.

REPORT OF CASES

Ten of the cases are of special interest. In the reports of these cases the stated ages of the patients are the ages at the time the patients were observed at the clinic in 1937. Five pri-

mary malignant lesions were found in Case 1. There also was a family history of cancer in this case.

CASE 1. The patient was a woman aged 69 years. Her father, mother and 3 cousins had died of cancer. In 1921 operation elsewhere had disclosed a definite carcinoma of the ascending colon. Two other operations were performed at the clinic. The first of these operations at the clinic was performed because of carcinoma of the descending colon. The second operation disclosed separate neoplasms of the uterus, right ovary and left fallopian tube (Fig 1). The pathologist reported that these neoplasms found in the descending colon, uterus, right ovary and left fallopian tube were primary malignant lesions.

CASE 2. The patient was a woman aged 58 years. Her mother had died at the age of 33 years of an abdominal tumor that probably was malignant. A total abdominal hysterectomy had been performed in 1931 for adenocarcinoma of the uterus. In 1931, a resection of the ascending colon and the right half of the transverse colon was performed for a carcinoma of the cecum and another carcinoma of the transverse colon (Fig 2). There were several small polyps in the segment of the colon that were removed.

The following case has been reported previously by Dr C H Smith. In this case the family history of the same type of carcinoma was rather pronounced.

CASE 3. The patient was a man aged 47 years. His father had died of carcinoma of the stomach and his brother had been a patient at the clinic in 1933 when he had undergone a resection of the cecum for adenocarcinoma grade 4. An exploratory laparotomy which was performed September 4, 1935 disclosed a carcinoma of the sigmoid colon.

Fig 5 Malignant lesions found in Case 6, a, at left, adenocarcinoma, grade 3, of breast ($\times 77$), b, adenocarcinoma, grade 4, of lymph node of stomach ($\times 100$)

Fig 6 Malignant lesions, Case 9, a, at left, adenocarcinoma, grade 3, of left breast ($\times 51$), b, endothelial sarcoma of lymph node obtained from right axilla ($\times 255$)

and a large carcinoma of the cecum. The cecum and a portion of the large and small intestine were resected. The neoplasm in the cecum was an adenocarcinoma, grade 3 (Fig 3a). On September 25, 1935, the sigmoid colon was resected, the lesion in this segment of the intestine was a carcinoma, grade 3 (Fig 3b). The patient returned to the clinic on November 8, 1937, examination at that time disclosed a carcinoma of the descending colon, which proved to be an adenocarcinoma, grade 3.

It is of interest to note that the brother of the patient in Case 3 returned to the clinic in February, 1938. Examination disclosed a carcinoma of the rectum, grade 2.

CASE 4 The patient was a woman, aged 36 years. A radical amputation of the left breast had been performed in 1935, because of carcinoma. In December, 1935, a resection of the descending colon was performed at the clinic, because of adenocarcinoma, grade 2. A radical amputation of the right breast was performed in 1937, because of adenocarcinoma, grade 3.

In the following case an interval of 15 years elapsed between the development of malignant lesions of the breasts.

CASE 5 The patient was a woman, aged 63 years. Her mother had died of carcinoma of the liver and her father had died of carcinoma of the stomach. Her first visit to the clinic was in 1922, when an operation was performed for adenocarcinoma, grade 3, of the left breast (Fig 4a). She returned to the clinic in 1937 and underwent an operation for adenocarcinoma, grade 4, of the right breast (Fig 4b). In the course of this operation 4 rather discrete basal cell epitheliomas were removed from the skin of the trunk.

CASE 6 The patient was a woman, aged 67 years. She first came to the clinic in 1921. At that time a radical mastectomy was performed because of adenocarcinoma, grade 3 (Fig 5a). In 1936 a resection of a portion of the descending colon was performed elsewhere because of adenocarcinoma, grade 2. The patient returned to the clinic in 1937. At this time she was subjected to operation because of adenocarcinoma, grade 4, of the stomach (Fig 5b).

In Case 6 there was no family history of cancer but the patient had had 2 malignant lesions before the one that was found when she returned to the clinic in 1937. Fifteen years had elapsed between the occurrence of the first 2 malignant lesions.

The next case, which demonstrates the occurrence of identical malignant lesions of bilateral organs of homologous twins, has been reported previously by Phillips and Broders.

CASE 7 The patient was a woman, aged 48 years, she was an identical twin. Her paternal aunt had died of carcinoma of the breast, at the age of 45 years. In 1927 an older sister had undergone an operation for a tumor of the breast. A radical mastectomy had been performed in 1927 because of adenocarcinoma, grade 4, of the right breast. Another radical mastectomy had been performed in 1928 because of a similar neoplasm of the left breast. She first came to the clinic in 1937. At this time she was subjected to operation for papillary adenocarcinoma, grade 3, of both ovaries.

In 1930 her twin sister had undergone a simple mastectomy for early carcinoma, grade 4, of the right breast. This twin came to the clinic in 1932, because of a recurrence of the neoplasm on the right side. Examination also disclosed a growth in the

Fig 3 Malignant lesions found in Case 3 a at left adenocarcinoma grade 3 of the cecum ($\times 27$) b adenocarcinoma grade 3 of the sigmoid colon ($\times 34$)

Fig 4 Malignant lesions found in Case 5 a at left adenocarcinoma grade 3 of left breast ($\times 54$) b adenocarcinoma grade 4 of right breast ($\times 74$)

ovaries were encountered in 10 cases in 2 of these cases there were primary malignant lesions in other parts of the body. In 7 cases a primary malignant lesion of the ovary was associated with a primary malignant lesion in another part of the body. There were 14 malignant lesions of the uterus and cervix in a group of 13 cases, 2 separate primary malignant lesions were found in 1 uterus. The neoplasm was primary in the cervix in 5 instances and in the fundus in 9.

Forty seven primary malignant lesions of the gastro intestinal tract were found in a group of 32 cases. Twenty four of the neoplasms were situated in the colon 13 were in the rectum 8 were in the stomach, 1 was in the esophagus and 1 was in the anus.

A miscellaneous group included a variety of primary malignant growths. The tongue was involved in 4 cases, the urinary bladder and prostate gland each were involved in 3 cases the paranasal sinuses pharynx larynx parotid gland, and thyroid gland each were involved in 2 cases and the brain bronchus kidney, mastoid cell and fallopian tube each were involved in 1 case. In this group must also be included 4 sarcomas that were situated in various parts of the body.

REPORT OF CASES

Ten of the cases are of special interest. In the reports of these cases the stated ages of the patients are the ages at the time the patients were observed at the clinic in 1937. Five pri-

mary malignant lesions were found in Case 1. There also was a family history of cancer in this case.

CASE 1 The patient was a woman aged 69 years. Her father mother and 3 cousins had died of cancer. In 1921 operation elsewhere had disclosed a definite carcinoma of the ascending colon. Two other operations were performed at the clinic. The first of these operations at the clinic was performed because of carcinoma of the descending colon. The second operation disclosed separate neoplasms of the uterus right ovary and left fallopian tube (Fig 1). The pathologist reported that these neoplasms found in the descending colon uterus right ovary and left fallopian tube were primary malignant lesions.

CASE 2 The patient was a woman aged 58 years. Her mother had died at the age of 33 years of an abdominal tumor that probably was malignant. A total abdominal hysterectomy had been performed in 1931 for adenocarcinoma of the uterus. In 1937 a resection of the ascending colon and the right half of the transverse colon was performed for a carcinoma of the cecum and another carcinoma of the transverse colon (Fig 2). There were several small polyps in the segment of the colon that were removed.

The following case has been reported previously by Dr C H Smith. In this case the family history of the same type of carcinoma was rather pronounced.

CASE 3 The patient was a man aged 47 years. His father had died of carcinoma of the stomach and his brother had been a patient at the clinic in 1933 when he had undergone a resection of the cecum for adenocarcinoma grade 4. An exploratory laparotomy which was performed September 4 1935 disclosed a carcinoma of the sigmoid colon.

Fig 5 Malignant lesions found in Case 6, a, at left, adenocarcinoma, grade 3, of breast ($\times 77$), b, adenocarcinoma, grade 4, of lymph node of stomach ($\times 100$)

Fig 6 Malignant lesions, Case 9, a, at left, adenocarcinoma, grade 3, of left breast ($\times 51$), b, endothehal sarcoma of lymph node obtained from right axilla ($\times 255$)

and a large carcinoma of the cecum. The cecum and a portion of the large and small intestine were resected. The neoplasm in the cecum was an adenocarcinoma, grade 3 (Fig 3a). On September 25, 1935, the sigmoid colon was resected, the lesion in this segment of the intestine was a carcinoma, grade 3 (Fig 3b). The patient returned to the clinic on November 8, 1937, examination at that time disclosed a carcinoma of the descending colon, which proved to be an adenocarcinoma, grade 3.

It is of interest to note that the brother of the patient in Case 3 returned to the clinic in February, 1938. Examination disclosed a carcinoma of the rectum, grade 2.

CASE 4 The patient was a woman, aged 36 years. A radical amputation of the left breast had been performed in 1935, because of carcinoma. In December, 1935, a resection of the descending colon was performed at the clinic, because of adenocarcinoma, grade 2. A radical amputation of the right breast was performed in 1937, because of adenocarcinoma, grade 3.

In the following case an interval of 15 years elapsed between the development of malignant lesions of the breasts.

CASE 5 The patient was a woman, aged 63 years. Her mother had died of carcinoma of the liver and her father had died of carcinoma of the stomach. Her first visit to the clinic was in 1922, when an operation was performed for adenocarcinoma, grade 3, of the left breast (Fig 4a). She returned to the clinic in 1937 and underwent an operation for adenocarcinoma, grade 4, of the right breast (Fig 4b). In the course of this operation 4 rather discrete basal cell epitheliomas were removed from the skin of the trunk.

CASE 6 The patient was a woman, aged 67 years. She first came to the clinic in 1921. At that time a radical mastectomy was performed because of adenocarcinoma, grade 3 (Fig 5a). In 1936 a resection of a portion of the descending colon was performed elsewhere because of adenocarcinoma, grade 2. The patient returned to the clinic in 1937. At this time she was subjected to operation because of adenocarcinoma, grade 4, of the stomach (Fig 5b).

In Case 6 there was no family history of cancer but the patient had had 2 malignant lesions before the one that was found when she returned to the clinic in 1937. Fifteen years had elapsed between the occurrence of the first 2 malignant lesions.

The next case, which demonstrates the occurrence of identical malignant lesions of bilateral organs of homologous twins, has been reported previously by Phillips and Broders.

CASE 7 The patient was a woman, aged 48 years, she was an identical twin. Her paternal aunt had died of carcinoma of the breast, at the age of 45 years. In 1927 an older sister had undergone an operation for a tumor of the breast. A radical mastectomy had been performed in 1927 because of adenocarcinoma, grade 4, of the right breast. Another radical mastectomy had been performed in 1928 because of a similar neoplasm of the left breast. She first came to the clinic in 1937. At this time she was subjected to operation for papillary adenocarcinoma, grade 3, of both ovaries.

In 1930 her twin sister had undergone a simple mastectomy for early carcinoma, grade 4, of the right breast. This twin came to the clinic in 1932, because of a recurrence of the neoplasm on the right side. Examination also disclosed a growth in the

Fig 7 Malignant lesions found in Case 10: a at left adenocarcinoma grade 4 of breast ($\times 40$), b adenocarcinoma grade 1 of uterus ($\times 43$)

left breast. Operation disclosed that the lesion of the left breast was an adenocarcinoma grade 4. A radical dissection was performed on the right side; this revealed that the recurrent neoplasm also was an adenocarcinoma grade 4. At the time this was written there was no evidence of a malignant lesion of either ovary of the second twin.

In the following case an unusual combination of neoplasms was encountered.

CASE 8. The patient was a woman aged 51 years. Her uncle had died of carcinoma of the lip. In 1933 a radical mastectomy had been performed for carcinoma of the left breast. The patient came to the clinic in 1937. At this time a total hysterectomy was performed because of sarcoma of the left ovary. In examining the specimen that was removed at the operation the pathologist encountered an endometrial polyp that contained 2 separate malignant lesions: a sarcoma and a carcinoma.

In the following case carcinoma and sarcoma occurred simultaneously.

CASE 9. The patient was a woman aged 55 years. In March 1937 a radical mastectomy was performed because of an adenocarcinoma grade 3 of the left breast (Fig 6a). Two months later a mass of lymph nodes was removed from the right axilla. Examination of this mass disclosed a sarcoma of the endothelial type (Fig 6b).

CASE 10. The patient was a woman aged 53 years. One brother had died of carcinoma of the stomach and another brother had died of carcinoma of the colon. The patient came to the clinic in 1934 at that time her breast was removed because of adenocarcinoma grade 4 (Fig 7a). In 1937 a hysterectomy was performed because of adenocarcinoma grade 1 of the uterus (Fig 7b).

REMARKS

In this series of cases the skin, including the lip, was involved more frequently than was the rest of the body. In the cases in which the skin was involved the incidence of basal cell epithelioma was slightly greater than that of squamous cell epithelioma. A history of a previous dermatitis such as psoriasis or which had followed some kind of chemical irritation, or roentgen therapy was obtained in many cases of neoplasms of the skin.

In 17 cases the only malignant lesions encountered were neoplasms of each of bilateral organs, namely, the breasts and ovaries. Many authors may criticize us for including these neoplasms as multiple primary malignant lesions because the possibility of metastasis from the opposite breast or ovary is considered by some to be strong. It is true that an absolute proof of the true primary nature of a growth such as one of this type is difficult to obtain, but in many instances there was a difference in the grading of the lesion, a difference of many years between the occurrence of the 2 neoplasms, and in some instances there was a difference even in the type of lesion. We believe that neoplasms in each of bilateral organs are more often primary, so have included all bilateral malignant lesions as being primary and feel that their situation relative to one another is immaterial.

The average age of the 113 patients in the year 1937 was 59.7 years. If this figure had been determined on the basis of the age at the time of the occurrence of the first primary malignant lesion the figure would have been somewhat lessened. It would then be less than the average age reported by many other authors, such as 62.6 years reported by Hanlon, 62.1 years reported by Owens, 50.4 years reported by Hurt and Broders, and 55.5 years reported by Warren and Gates. We feel that these ages would represent the average age for the occurrence of single malignant lesions and do not believe that the prevalent impression that multiple malignant lesions occur more often at an advanced age than do single malignant lesions is based on adequate data.

The number of females in comparison to the number of males is slightly increased, but

this increase is not great enough to be of any significance. This has been the usual observation of other authors.

The fact that more than a fourth of our patients had an interval of more than 5 years between the noted occurrence of the first and second lesions is of interest, but we feel that it is of only slight significance. Of course, the longer the interval between the development of the 2 primary malignant lesions, the more certain is the likelihood that the second neoplasm is not a metastasis or recurrence of the first. In the majority of our cases the multiple malignant lesions developed simultaneously. This would suggest that more than one primary focus for the development of cancer may have been present in each of these cases.

A family history of malignancy was noted in 26.6 per cent of the 113 cases. This agrees with the 15 to 30 per cent reported by other authors. It seems that a percentage such as this would in part substantiate the definite views of many authors that there is a hereditary factor in the etiology of cancer. In many of the cases (Cases 1, 2, 3, 5, 7, 8, and 10) several members of the family had had cancer. In one case, Case 6, which previously was reported by Phillips and Broders, simultaneous bilateral carcinomas of the breast occurred in each of homologous twins. McFarland and Meade have collected 20 reports of cases in which identical tumors have occurred simultaneously in the same organs of identical twins. Since homologous twins originate from the same fertilized ovum, it follows that they have identical genetic constitutions. It may be that the study of cases such as these, from the standpoint of genetics, will help to throw some light on the solution of the genesis of cancer. The genetic factors in the development of cancer in human beings eventually will be given greater consideration. The occurrence of cancer among several members of one family should be discussed rather frankly with other members of the family, the discussion should include the known hereditary aspects of cancer. In this way the development of cancer among other members of the family might be prevented or arrested at an early stage. They would be encouraged to co-operate with the physician and undergo

periodic health examinations. They might be prompted to seek early advice regarding painless lumps, or about other signs which ordinarily, to them, might seem insignificant. This procedure might avoid or eliminate sources of irritation, and in some few cases it possibly might restrict reproduction.

Holman and Lockhart-Mummery recently have expressed similar opinions. It is difficult to speculate as to why an individual with one cancer should have another separate and apparently unrelated neoplasm at a later date. Some authors, as for example Bugher, have demonstrated that the incidence of the development of multiple primary neoplasms is greater than one would expect on the basis of chance alone. This implies the presence of a definite predisposition or susceptibility to malignancy, or to the action of some factor favoring the development of malignancy in cases such as we have reported.

SUMMARY

A review was made of 2,500 cases of malignant lesions in which operation was performed at the clinic during the year 1937. One hundred thirteen instances of multiple primary neoplasms were found in this group of cases.

Three hundred twenty-seven separate neoplasms were observed in the 113 cases; 167 involved the skin and lip, 47 of the neoplasms were situated in the gastro-intestinal tract, 43 in the mammary gland, 27 in the ovaries, 14 in the uterus or cervix, and 29 were situated in various regions and, therefore, are classified as miscellaneous.

THE FATE OF LIVING AND DEAD CARTILAGE TRANSPLANTED IN HUMANS

LYNDON A. PEER, M.D., F.A.C.S., Newark, New Jersey

SURGICAL opinion differs widely concerning the fate of various types of cartilage grafts after transplantation in human tissues. Numerous investigators have buried cartilage grafts in animals, and our knowledge of the behavior of human cartilage grafts is based very largely on the conflicting results of this animal experimentation.

Desiring to obtain more definite information concerning the fate of human cartilage grafts in human tissues, I performed the following experiments.

1 Six segments of cadaver cartilage preserved in alcohol were transplanted beneath the skin of 6 other humans (homografts) and removed for examination at intervals from 6 months to 2 years.

2 Eight segments of living autogenous costal cartilage were buried beneath the skin of 8 humans and removed for examination at intervals from 6 months to 6 years. All of these grafts were transplanted without perichondrium.

Cadaver cartilage grafts The use of cartilage preserved in alcohol to fill depressions of the nose, face, and skull, like most surgical procedures, is not new. It was utilized rather extensively a generation ago and was discarded because of the belief that the grafts either suppurated or were absorbed and replaced by fibrous tissue. Recently there has been a revival of the method. Pierce and O'Connor, J. B. Brown, Claire Straith, C. R. Straatsma, and I, among others have used cartilage preserved in alcohol to repair saddle nose and defects of the skull. Successful grafts examined by external palpation appear to retain their size and consistency to periods of over a year.

The advantage of this procedure is obvious, as fresh cartilage from cadavers is easily obtainable in almost any desired quantity, and

a supply of this cartilage preserved in alcohol may be kept on hand in the hospital laboratory for use when needed. It goes without saying that the donor must be proved free from syphilis. The disadvantage of the method lies in the uncertainty as to the ultimate fate of the transplant.

Autogenous rib cartilage grafts Koenig, in 1896, was the first to use cartilage transplants in man, and since that time, living autogenous rib cartilage has been employed widely as a filling substance, and for the structural support of soft tissues.

There is, however, a great difference of opinion concerning the fate of the autogenous cartilage graft following transplantation. In the literature one finds a variety of conflicting reports all based on clinical observation of the grafted area. A single exception is the report of Gillies on one specimen of rib cartilage examined microscopically 18 months after transplantation. A questionnaire sent to 10 surgeons, who frequently use rib cartilage grafts, disclosed a variety of beliefs concerning the fate of the grafts. These opinions were based on clinical evidence and may be summarized as follows: (1) Cartilage tends to survive when transplanted. (2) Cartilage tends to degenerate when transplanted. (3) Cartilage survives when transplanted with its perichondrium, but tends to degenerate and disappear when transplanted without its perichondrium.

PREVIOUS EXPERIMENTAL WORK WITH LIVING CARTILAGE IN ANIMALS

The literature on cartilage during the past 80 years is so extensive that I have attempted to summarize only the most important work and indicate its significance.

Paul Bert was probably the first to transplant cartilage. From his experimental studies with animals he came to the conclusion that a cartilage graft retained its viability and led to

Read before the Society of Plastic and Reconstructive Surgery,
St. Louis, Missouri, October 22, 1937.

Fig 1

Fig 2

Fig 3

Fig 1 Alcohol preserved septal cartilage buried 6 months. The cartilage cells are greatly shrunken but there is no invasion or absorption of the cartilage graft.

Fig 2 Alcohol preserved rib cartilage buried 9 1/2 months. This section shows the earliest invasion of the dead cartilage grafts in my series. The cartilage is represented at A and the dense host connective tissue capsule surrounding the cartilage at B. At C one edge of the cartilage is invaded by ingrowing fibroblasts from the capsule and there is partial absorption in this area.

Fig 3 Alcohol preserved septal cartilage buried 14 months. The cartilage is divided into 2 separate portions by invading host fibrous tissue. There are numerous blood vessels and giant cells in the invading fibrous tissue and the edges of the cartilage show indentations where absorption has taken place. A and B represent the cartilage and C the invading fibrous tissue.

the formation of bone. He experimented probably before 1865, but this is our first reference.

Ollier, in 1867 and Zahn in 1884 assumed a diametrically opposed view of the fate of adult animal cartilage transplants. They both noted degenerative changes in the grafts that led ultimately to their absorption. Zahn concluded that cartilage grafts degenerated whether transplanted into the same animal (autografts) or transplanted into different animals (homografts and heterografts).

Fischer is responsible for the origin of the theory that the survival of a cartilage graft is dependent on the presence of the perichondrium. In his experiments, costal cartilage degenerated after about 8 weeks when transplanted as a homograft without its perichondrium. Cartilage transplanted with its perichondrium showed little alteration in structure over the same period of time.

We find expressed in this early experimental work on animals the 3 viewpoints as to the fate of adult cartilage transplants which still exist today. (1) Cartilage tends to survive when transplanted. (2) Cartilage tends to degenerate when transplanted. (3) Cartilage survives when transplanted with

its perichondrium but tends to degenerate and disappear when transplanted without its perichondrium.

Illustrating the more recent work on cartilage transplants in animals, Leo Loeb in 1920 buried xiphoid cartilage with perichondrium and the fat of guinea pigs in the same guinea pig (autograft) and in different guinea pigs (homograft). He removed the cartilage at intervals of 1 day to 5 months and 19 days. He found that after autotransplantation reaction in the tissues about the transplant was almost entirely lacking.

After homotransplantation lymphocytes collected about the graft and, in places, lymphocytes connective tissue cells, and blood vessels entered necrotic portions of the cartilage. The reaction to the graft began early, reached a maximum in about 3 weeks, and from that time on ceased to a great extent. Both the autograft and the homograft remained up to 5 months and 10 days.

Mannheim and Zypkin performed 50 experiments with guinea pigs transplanting cartilage from one part of the animal to another in the same animal. Their conclusions on sections examined up to one year after

Fig 4

Fig 5

Fig 6

Fig 4 Alcohol preserved rib cartilage buried 18 months. Thin strands of host fibrous tissue are shown invading the cartilage between the letters *A* and *B*. There is a large area indicated by *C* where absorption of cartilage has taken place. This space is occupied by host fibrous tissue containing many blood vessels, giant cells, and endothelial cells.

Fig 5 Alcohol preserved septal cartilage buried 18 months. The cartilage graft is broken up into many small

cartilaginous islands by invading host fibrous tissue. One of these small cartilage islands is indicated by *A* and a larger mass of cartilage by *B*. The host connective tissue just outside of the cartilage graft contains numerous giant cells indicated at *C*.

Fig 6 Alcohol preserved septal cartilage buried 2 years. The cartilage graft is invaded by numerous fibrous tissue ingrowths. Two of these areas are indicated by *A* and *B*. A portion of the cartilage has been changed to bone at *C*.

transplantation were (1) The cartilage retained its specific structure in all cases (2) Both degenerative and regenerative processes occurred (3) The cartilage, after transplantation in soft parts, was better preserved than after transplantation in the skull (4) Cartilage transplanted without its perichondrium was better preserved than cartilage transplanted with its perichondrium (5) Free autotransplanted cartilage grafts form a good material for plastic repair.

PREVIOUS EXPERIMENTAL WORK WITH LIVING CARTILAGE IN HUMANS

Koernig, in 1896, was the first to use cartilage transplants in humans. He buried cartilage segments as wedges for the repair of partial destruction of the laryngeal and tracheal cartilages.

Von Mangoldt, in 1899, successfully transplanted costal cartilage for support of the nose.

Nelaton and Ombredanne, in 1904, buried costal cartilage in forehead flaps which were later swung down to the nose.

Neuhof, in 1923, after an extensive survey of the literature concluded that simple cartilage grafts, after transplantation, remain unaltered in appearance and in staining reaction

for many weeks, only in grafts that are several months old does fibrillation of the cartilage begin. There is a gradual death of the cartilage cells and they disappear ultimately. Vascularization of the graft, and replacement by fibrous tissue or calcification, may occur, depending on the locality in which the graft is transplanted. The outstanding feature in the histological fate of cartilage transplants is the long period of quiescence that precedes the final phase of the degeneration and substitution. In referring to rib cartilage transplants, Neuhof states: "The cartilage is absorbed slowly, allowing adequate time for replacement by dense fibrous tissue that maintains the architecture of the graft." He further says that remnants of cartilage have been found as long as 2 years after transplantation.

In opposition to this viewpoint, the earlier work of Staige Davis, in 1917, gave clinical evidence of the permanence of the rib cartilage transplanted in the nose.

Gillies also, in 1920, stated that no changes other than curvature were found in any of his successful autocartilage grafts, and in only a few of the homografts was the cartilage replaced by fibrous tissue as a late sequel. Three years was the longest that Gillies had a graft under observation. Gillies buried an auto-

cartilage graft and a fresh homocartilage graft beneath the abdominal skin of the same patient. He removed both grafts after 18 months, and on section, found the cartilage alive and active in both cases. The cells in the homograft were more vacuolated and showed more degenerative changes than did those of the autograft. The autograft appeared as normal adult cartilage.

Other important contributions were given by Henle, Lexer, Eiselsberg, Sgambati, Schmieden, Tuffier, Morestin, Gosset, Leriche, Queim, and Bossi.

PREVIOUS EXPERIMENTAL WORK WITH THE TRANSPLANTATION OF DEAD CARTILAGE IN ANIMALS

Even in the literature of over 50 years ago there are instances of the homotransplantation of fixed or dead cartilage with the use of alcohol, heat, and other agencies as the fixing or killing agent.

Prudden in 1881, transplanted cartilage grafts killed by immersion in 95 per cent alcohol. His results showed degeneration and partial absorption of all these grafts.

Nageotte in 1922, buried rabbit cartilage fixed in alcohol, in rabbits' ears. He found that the fixed cartilage lost its basophilic staining and promoted a metaplasia of the fibroblasts which surrounded it into chondroblasts with the consequent new formation of

cartilage and bone. Phagocytes and fibroblasts penetrated only into the open cavities at the periphery of the graft and in the cracks which eventually gave access to the surrounding host tissue cells.

Poletini, in 1922, pursued similar experiments with cartilage fixed in alcohol. His sections showed penetration of fibroblasts and formation of connective tissue fibers within the cartilage where no cavities or cracks previously existed as a point of entry. He also found cartilage and bone formation in the vicinity of the graft.

Nigrisoli in 1927 transplanted calves cartilage fixed in 95 per cent alcohol into the kidney and bone of guinea pigs. He removed his grafts from 6 days to 180 days, and found that the bulk of the graft survived in each case. Connective tissue from the host tended to invade the cartilage and calcifications were found in the grafts. Very rarely did he find reformed bone and cartilage outside of the graft.

Didier and Guyon, in 1928 transplanted killed cartilage grafts in the ear, shoulder and linea alba of rabbits. They observed grafts up to 8½ months, and found calcification and invasion by fibroblasts from the host tissue. One case showed ecchondroses and another case showed ossification with the formation of fatty marrow. Two cases showed a clear histological picture of bone formation.

Fig 10

Fig 10 Autogenous rib cartilage graft buried 18 months. The cartilage is indicated at A and the host connective tissue at B. There is no invasion or absorption of the cartilage.

Fig 11

Fig 11 Autogenous rib cartilage graft buried 2 years. The matrix and cells appear normal and there is no evidence of invasion or absorption.

Fig 12

Fig 12 Autogenous rib cartilage graft buried 4½ years. The section shows a cortex of normal appearing cartilage with a cavity in the center which is partially occupied by strands of bone. I believe that the center of this cartilage graft failed to survive transplantation because of nutritional difficulties and was transformed to bone (see text). A represents the cartilage and B the strands of bone.

The newer literature, while reporting the survival of killed cartilage transplants, emphasizes the reaction of the host tissue and a very gradual modification of the cartilage. The modification included calcification and ossification as progressive changes, and invasion by fibroblasts with degeneration of the matrix as degenerative changes. These changes do not interfere with the survival of the block of cartilage up to periods as long as 1 year.

The work here summarized, with fixed or dead cartilage transplants, was all performed in animals. The following is an account of transplants made in humans.

PREVIOUS EXPERIMENTAL WORK WITH THE TRANSPLANTATION OF DEAD CARTILAGE IN HUMANS

The author (14) buried segments of cadaver septal and rib cartilage preserved in alcohol beneath the chest skin of humans and removed them at intervals of 7 days, 8 days, 32 days, 4 months, and 14 months. All of the grafts up to and including the 4 month specimen remained as tolerated dead foreign bodies. The 14 month section showed invasion by fibrous tissue, partial absorption of the cartilage and in one area calcification or early bone formation. The perichondrium was removed from these grafts before transplantation.

Experimental procedure All this work was performed on human beings. The experimental subjects, as in previous work with dermal grafts (15) were patients who underwent rib graft operations for the repair of saddle nose or skull depressions. In these operations it is customary to hoard excess rib cartilage beneath the chest skin to be used in case the cartilage inserted in the nose or scalp fails to remain in place. When the plastic repair is satisfactory, the excess cartilage beneath the chest skin is removed and discarded. Segments of human costal and septal cartilage preserved in 50 per cent alcohol for one month or more were inserted beneath the chest skin as dead homografts, together with the hoarded rib cartilage and removed for examination at intervals of 6, 9½, 14, 18, and 24 months (Figs 1-6).

The living autogenous rib cartilage grafts were obtained in a like manner with the exception of the 4½ year and 6 year specimens which were removed from the nose. Eight specimens of autogenous rib cartilage grafts are shown removed at intervals of 6, 9, 11, 17, and 18 months, 2, 4½, and 6 years. The perichondrium was removed from all of the cartilage grafts before transplantation (Figs 7-14). The specimens¹ were fixed in Zenkers

¹The sections were prepared and photographed by Mr. David J. McKinnon, of the Newark Eye and Ear Infirmary. Dr. Royce Paddock aided in reviewing the foreign literature.

cartilage graft and a fresh homocartilage graft beneath the abdominal skin of the same patient. He removed both grafts after 18 months, and on section, found the cartilage alive and active in both cases. The cells in the homograft were more vacuolated and showed more degenerative changes than did those of the autograft. The autograft appeared as normal adult cartilage.

Other important contributions were given by Henle, Lever, Eiselsberg, Sgambati, Schmiedt, Tuffier, Morestin, Gosset, Leriche, Queim, and Bossi.

PREVIOUS EXPERIMENTAL WORK WITH THE TRANSPLANTATION OF DEAD CARTILAGE IN ANIMALS

Even in the literature of over 50 years ago there are instances of the homotransplantation of fixed or dead cartilage with the use of alcohol, heat, and other agencies as the fixing or killing agent.

Prudden in 1881, transplanted cartilage grafts killed by immersion in 95 per cent alcohol. His results showed degeneration and partial absorption of all these grafts.

Nageotte, in 1922, buried rabbit cartilage, fixed in alcohol, in rabbits' ears. He found that the fixed cartilage lost its basophilic staining and promoted a metaplasia of the fibroblasts which surrounded it into chondroblasts with the consequent new formation of

cartilage and bone. Phagocytes and fibroblasts penetrated only into the open cavities at the periphery of the graft and in the cracks which eventually gave access to the surrounding host tissue cells.

Poletini in 1922, pursued similar experiments with cartilage fixed in alcohol. His sections showed penetration of fibroblasts and formation of connective tissue fibers within the cartilage where no cavities or cracks previously existed as a point of entry. He also found cartilage and bone formation in the vicinity of the graft.

Nigrisoli in 1927, transplanted calves cartilage fixed in 95 per cent alcohol into the kidney and bone of guinea pigs. He removed his grafts from 6 days to 180 days and found that the bulk of the graft survived in each case. Connective tissue from the host tended to invade the cartilage and calcifications were found in the grafts. Very rarely did he find new formed bone and cartilage outside of the graft.

Didier and Guyon, in 1928, transplanted killed cartilage grafts in the ear, shoulder and linea alba of rabbits. They observed grafts up to 8½ months, and found calcification and invasion by fibroblasts from the host tissue. One case showed ecchondroses, and another case showed ossification with the formation of fatty marrow. Two cases showed a clear histological picture of bone formation.

The specimen, buried $4\frac{1}{2}$ years (Fig 12), shows a large segment of normal appearing cartilage with a free space in its central portion. A part of this central space is occupied by bone which extends lengthwise through the center of the graft, and at one point communicates with the surface at the side of the graft. I believe that this condition occurred the following way; after transplantation of a large block of cartilage, the peripheral portions of the cartilage are able to obtain better nourishment from the surrounding tissues than the more remote central portion. The central portion, therefore, becomes devitalized, or actually dies from lack of nutrition, and is transformed into bone. The bulk and shape of the cartilage graft is not changed, and the peripheral portion of the graft, which obtains adequate nourishment, remains as living cartilage. The bone formation, therefore, represents a degeneration at the core of the graft, where the cartilage failed to survive because of nutritional insufficiency. The specimen of cartilage buried 6 years (Fig 14) appears as normal living cartilage with no evidence of fibrous tissue invasion or absorption. The surrounding connective tissue is in close contact with the cartilage and on one side gives the appearance of slightly penetrating the external surface of the cartilage. This cartilage graft, however, was scraped with a scalpel before insertion in the nose, and I believe that the surrounding host tissue merely occupies the small depressions formed in the cartilage by the scraping of its external surface. The failure of the host connective tissue to penetrate more deeply at these favorable entry points is further evidence of the surviving power of autotransplanted rib cartilage.

SUMMARY OF FINDINGS IN AUTOGENOUS RIB CARTILAGE GRAFTS

The cartilage grafts buried from 6 months to 2 years, showed no evidence of invasion by fibrous tissue or absorption.

The graft, buried $4\frac{1}{2}$ years, appeared in the form of a cylinder of living cartilage, with bone formation in the center. I believe that this bone formation at the core of the graft represents a degeneration of cartilage which

failed to survive transplantation because of nutritional difficulties.

The segment buried 6 years appeared as normal living cartilage. The host connective tissue on one side of the graft slightly penetrated the edge of the cartilage and this may represent beginning invasion. The cartilage graft, however, was scraped with a scalpel before insertion in the nose, and I believe that the surrounding host tissue merely occupies the small depressions formed in the cartilage by the scraping.

CONCLUSIONS

1. The dead cartilage grafts buried from $9\frac{1}{2}$ months to 2 years showed progressive invasion by fibrous tissue and partial absorption. In contrast to these findings autogenous rib cartilage grafts showed no invasion or absorption over the same period of time.
2. Two late autogenous rib cartilage grafts buried $4\frac{1}{2}$ years and 6 years appeared as living cartilage.
3. From the evidence found in these sections one may conclude that autogenous rib cartilage survives after transplantation as living cartilage and, up to periods as long as 6 years, neither increases nor decreases in size.
4. Autogenous rib cartilage is better material for plastic repair than dead, pickled cartilage.

Fig. 13 at left Autogenous rib cartilage graft buried 4 1/2 years. A higher magnification photograph of the 4 1/2 year section shows the bone at A and the cartilage at B. Note the abrupt change from bone to cartilage.

Fig. 14 Autogenous rib cartilage graft buried 6 years. The cartilage cells and matrix appear normal. There is

however, a slight penetration of fibrous tissue into the edge of the cartilage. This cartilage graft was scraped with a scalpel before insertion in the nose and I believe that the fibrous tissue merely occupies the small depressions in the cartilage resulting from this scraping. Surrounding connective tissue is in close contact with cartilage.

solution, sectioned in the usual manner, and stained with hematoxylin and eosin and with Mallory's connective tissue stain.

Presentation of the living and dead cartilage grafts together is advantageous, since the dead grafts which are invaded by fibrous tissue serve as controls for the living cartilage grafts.

Description of cadaver cartilage transplants

The first section buried 6 months shows a septal cartilage graft with shrunken cells and normal staining matrix (Fig. 1). There is no invasion of the cartilage from the surrounding host tissue and the graft is apparently existing as a tolerated dead foreign body. In contrast to this the rib cartilage buried 9 1/2 months shows a beginning invasion of the cartilage by connective tissue and some absorption of cartilage (Fig. 2). This 9 1/2 month specimen represents the earliest section in my series showing fibrous tissue invasion. The septal graft buried 14 months (Fig. 3) is separated into 2 masses by ingrowing fibrous tissue. New blood vessels are present in the invading connective tissue and giant cells are scattered at intervals near eroded edges of cartilage. There is also an area of calcification, or early bone formation in the center of the cartilage graft.

There are 2 specimens buried 18 months (Figs. 4-5). One is rib cartilage and the

other septal cartilage. Both of these grafts show invasion by fibrous tissue and partial absorption. The oldest section (Fig. 6) buried 24 months is septal cartilage and also shows invasion by fibrous tissue and absorption. There is a small area of bone formation along one edge of the graft which probably represents altered cartilage, since lacunae can be demonstrated in the calcified substance. Numerous small cavities are present in the cartilage occupied by giant cells, large endothelial cells, fibroblasts, and blood vessels.

Summary of findings in pickled cartilage grafts. The grafts remain after transplantation as tolerated dead foreign bodies for about 9 1/2 months. From this time on the surrounding host tissues invade the foreign cartilage and very slowly absorb portions of the cartilage. This process, however, is very gradual and the bulk of the graft is still present 2 years after transplantation. The 14 month and 2 year specimens showed areas of calcification or early bone formation.

Description of living autogenous rib cartilage transplants. The 5 sections buried from 6 months to 2 years all appear as normal living cartilage (Figs. 7-11). They are surrounded by a dense connective tissue capsule and there is no evidence of invasion or absorption of the cartilage by the surrounding host tissue.

The specimen, buried $4\frac{1}{2}$ years (Fig. 12), shows a large segment of normal appearing cartilage with a free space in its central portion. A part of this central space is occupied by bone which extends lengthwise through the center of the graft, and at one point communicates with the surface at the side of the graft. I believe that this condition occurred the following way, after transplantation of a large block of cartilage, the peripheral portions of the cartilage are able to obtain better nourishment from the surrounding tissues than the more remote central portion. The central portion, therefore, becomes devitalized, or actually dies from lack of nutrition, and is transformed into bone. The bulk and shape of the cartilage graft is not changed, and the peripheral portion of the graft, which obtains adequate nourishment, remains as living cartilage. The bone formation, therefore, represents a degeneration at the core of the graft, where the cartilage failed to survive because of nutritional insufficiency. The specimen of cartilage buried 6 years (Fig. 14) appears as normal living cartilage with no evidence of fibrous tissue invasion or absorption. The surrounding connective tissue is in close contact with the cartilage and on one side gives the appearance of slightly penetrating the external surface of the cartilage. This cartilage graft, however, was scraped with a scalpel before insertion in the nose, and I believe that the surrounding host tissue merely occupies the small depressions formed in the cartilage by the scraping of its external surface. The failure of the host connective tissue to penetrate more deeply at these favorable entry points is further evidence of the surviving power of autotransplanted rib cartilage.

SUMMARY OF FINDINGS IN AUTOGENOUS RIB CARTILAGE GRAFTS

The cartilage grafts buried from 6 months to 2 years, showed no evidence of invasion by fibrous tissue or absorption.

The graft, buried $4\frac{1}{2}$ years, appeared in the form of a cylinder of living cartilage, with bone formation in the center. I believe that this bone formation at the core of the graft represents a degeneration of cartilage which

failed to survive transplantation because of nutritional difficulties.

The segment buried 6 years appeared as normal living cartilage. The host connective tissue on one side of the graft slightly penetrated the edge of the cartilage and this may represent beginning invasion. The cartilage graft, however, was scraped with a scalpel before insertion in the nose, and I believe that the surrounding host tissue merely occupies the small depressions formed in the cartilage by the scraping.

CONCLUSIONS

1 The dead cartilage grafts buried from $9\frac{1}{2}$ months to 2 years showed progressive invasion by fibrous tissue and partial absorption. In contrast to these findings autogenous rib cartilage grafts showed no invasion or absorption over the same period of time.

2 Two late autogenous rib cartilage grafts buried $4\frac{1}{2}$ years and 6 years appeared as living cartilage.

3 From the evidence found in these sections one may conclude that autogenous rib cartilage survives after transplantation as living cartilage and, up to periods as long as 6 years, neither increases nor decreases in size.

4 Autogenous rib cartilage is better material for plastic repair than dead, pickled cartilage.

Fig. 2 (Case 9) Ureterocele in a diverticulum of the urinary bladder. A Ureterocele seen during the time of ejaculation protruding in a balloon shape with its minute ureteral orifice at the edge and lying in front of the trigone of the bladder. The ureteral orifice on the opposite side of the trigone is normal in shape, size, and position. B The same case showing the diverticulum of the urinary bladder during systolic contractions of the ureter in which the balloon of the ureterocele has been retracted inwardly and the ureterocele hides from its normal protruding position in the bladder.

The Modern Surgical Treatment of Ureterocele — Robert C. Utterre.

THE MODERN SURGICAL TREATMENT OF URETEROCELE

ROBERT GUTIERREZ, A B , M D , F A C S , New York, New York

FOR the practising urologist there is no subject of greater interest and importance than a knowledge of the surgical anomalies of the ureter commonly met with in everyday urological practice. Some of these anomalies may affect function little if at all during the early years of life, yet at a later period may become a source of disease and misery to the patient; their true nature may remain unrecognized by the general surgeon or practitioner, symptoms may mislead in diagnosis, unnecessary and irrelevant operations be performed, and neglect of the true condition even lead to a fatal outcome. It is thus evident that the early recognition and treatment of such an anomaly as a ureterocele is a matter of vital importance.

It cannot be too often repeated that in all cases of urinary disturbance in which the symptoms are obscure, as is frequently the case in attacks of pain in the kidney, bladder or ureter, with urgency, frequency, dysuria, and polyuria of unknown causation, as well as in cases in which urinalysis reveals the presence of pus, blood, or bacteria, a cystoscopic examination with urographic studies is indispensable. The data thus obtained may at once reveal that the cause of the trouble lies in some hitherto unsuspected anomaly of the ureter at the point where it opens into the bladder.

Not the least interesting of the pathological findings that may be brought to light by the cystoscope is the ureterocele, often spoken of as the cystic dilatation of the ureter in its intravesical portion. The discovery of pathological changes at this point may promptly account for symptoms higher up in the urinary tract, such as pain in the kidney region, hemorrhage, suppuration, colic, associated with crises of pyelitis and pyonephritis, with chills and fever. Urographic examination in such cases may disclose urinary stasis with hydro-ureter and hydronephrosis.¹

The picture presented by this so called cystic dilatation is so characteristic that it can seldom be mistaken or confused with any other pathological condition. It thus furnishes the most striking proof of the value of early cystoscopic and urographic diagnosis, since the surgical removal of this obstructive ureteral swelling is now generally accomplished quite easily, if taken early, making it possible to save, by modern conservative treatment, many a kidney that would in the past have been sacrificed through incorrect diagnosis and consequent neglect.

DEFINITION

By the term ureterocele is understood the cyst-like formation that arises when the vesical end of the ureter, usually after an abnormally long course through the mucosa, becomes stretched out into an abnormal dilatation as the result of narrowness of the orifice, or a congenital or acquired stenosis of the orifice has led to such a dilatation of the ureter within the bladder. The outer covering of such a formation is composed of bladder mucosa, which makes it easily distinguishable from the relatively rare and insignificant prolapse of the ureteral mucosa into the bladder, an eversion of ureteral mucosa through the ureteral orifice, in which case the covering membrane is clearly of another character, ureteral, not vesical. In the early cases reported this distinction appears not to have been made.

The form and size of the sac constituted by the dilated end of the ureter may vary widely, the simplest form being that of a balloon that protrudes during ejaculations, with an opening at its tip, which is the orifice of the ureter, herniating forward into the bladder. The various authors report cysts from the size of a hazelnut to that of an orange, or even 5 to 6 centimeters in length; in infants they have sometimes filled the entire bladder. These ureteroceles may be round, elongated, or flat, and may be either open or closed. If small, a

¹Gutierrez, R. In Cabot's Modern Urology, 3d ed., vol. 2, chap. XI, pp. 374-509. Philadelphia: Lea & Febiger, 1936. J. Am. M. Ass., 1936, 106: 183-189.

ureterocele may have no effect upon the passage of urine, or may announce its presence only when the bladder, in contracting, presses the little tumor against the internal ureteral orifice. But if the dilatation of the ureterocele reaches the vesical orifice or the internal urethral orifice, it will act like a valve or an obstruction of a median lobe of the prostate and will cause retention and other definite urinary disturbances. The entire upper urinary tract is then liable to suffer through back pressure and infection due to the hydraulic retention of urine. While in simple cases taken early, treatment may be accomplished by way of the urethra, in the more advanced and neglected cases removal of the entire ureter and kidney by a total ureteronephrectomy may become necessary.

The purpose of this paper, therefore is two fold first to call attention to the importance of this clinico-anatomopathological entity, as well as to the variety of modern surgical problems that have been so greatly misunderstood in the past on account of the mixed symptomatology, the lack of proper diagnosis and the absence of any standardized type of treatment and second, to report, at the same time, a series of 16 cases of ureterocele which the author has had the opportunity to diagnose and treat and which have served as the basis of this study. All of these cases have been observed by the author personally and collected from his office files. 8 of them having been private cases diagnosed and treated by electrofulguration and cystoscopic manipulations at the office, while the other 10 cases were observed and treated by him in the clinics of three New York hospitals.

HISTORY AND LITERATURE

Like other anomalies of the urinary tract the earliest findings of ureteroceles were made at autopsy. Lechler in 1834 was the first author to give a clear account of such a structure which however he and the attending surgeon mistook for a double bladder. This case was in a 3 months old infant who after several attacks of screaming pain one of which was observed to have ceased abruptly when external manipulation caused sudden ejaculation of urine died within a few days

of what was believed by the surgeon to be peritonitis. Autopsy revealed however, no indications of any peritoneal inflammation but showed that within the bladder of the child and filling its whole cavity was a "second bladder," highly inflamed, upon the lower surface of which could be seen, close to the true bladder neck, the orifice of the ureter. "The inner bladder," says Lechler, "was a formation peculiar to itself, for it alone was inflamed and no other organ, not even the mucous membrane of the bladder, took any part in it." It is of interest to note that in this case, as in many other cases of ureterocele since reported, there were other congenital malformations, the left kidney being twice the size of the right, and being drained by 2 ureters, both of which had undergone torsion.

Englisch, in 1898, was the first investigator to delve into the subject and bring to light not only the case of Lechler, which was buried in ancient archives, but also some 14 others to which he added one case of his own. In 6 of the 15 cases that he collected the ureter was blind in 9 it was patent. In practically all of these cases it was reported that other anomalies existed. Among them was the case of Lihenfeld (1856) in a man of 65 in which the dilatation was referred to as 'a second bladder which projected into the lumen of the urethra.' Wrang's case (1870) was in a little girl in whom the left kidney had 3 hilums and 3 ureters, one of which corresponding to a single calyx bulged out into the bladder in a sac the size of a hazelnut. Weigert (1886) reported 2 cases in one of which the subject was a stillborn male infant with a cleft palate and harelip as well as supernumerary fingers on both hands, the right ureter formed the ureterocele while the left emptied into a seminal vesicle. Other early cases in Englisch's collection were those of Bostroem (3 cases) in 1884, Geerds in 1887, Caillé in 1888 and Groschik (1898). Freyer in 1897 found 2 stones in one such ureter, and was the first to suggest, in a report to the Royal Society, that calculus might be the primary cause of such a dilatation.

Lipmann Wulf in 1898 appears to have been the first to observe such a case cystoscopically, but he called it a tumor of the bladder until he found at operation that it

was a cystic dilatation of the ureter Groszlik in 1901 first correctly diagnosed a ureterocele through the cystoscope Cohn in 1904 was the first surgeon to carry out an open operation on the basis of a correct cystoscopic diagnosis

An important thesis on the subject was written in 1913 by Marmier, who in a study of 42 cases found 38 that showed evidence of stenosis of the ureteral orifice Some of these cases, from Albarran, Pasteau, Bazy and others, are discussed in detail

In these radio-urographic days with more modern means of investigation, additional progress has been made in the clinical diagnosis of ureterocele, the presence of which can now easily be discovered in a good intravenous urogram, where the cystic dilatation of the intravesical portion of the ureter may be seen as a filling defect in the cystogram

There is no doubt of the definite progress that has been made in recent years concerning the treatment and prognosis of this clinico-urologic entity, particularly since Edwin Beer in 1910 introduced the use of the Oudin high frequency current for the electrofulguration treatment of vesical tumors In later years this ideal method has been applied with even greater success to the prevention and correction of ureterocele, as well as of other obstructing conditions of the lower urinary tract¹

As regards terminology, we find that bladder cyst or even double bladder was the current expression in the earliest cases It was Englisch who in 1898 introduced the term "cystic dilatation of the vesical end of the ureter," an expression which, however cumbersome, obtained the greatest vogue, especially in Germany and France Certain authors (Fenwick, Blum), however, have pointed out that the name cyst is misleading since the dilatation has not the structure of a true cyst Fenwick (1903) proposed that the term "ballooning of the ureter" be adopted as the most suitable Blum, who reviewed the literature up to 1920, by which time 100 cases had been reported, states that "intravesical prolapse

of the ureter" was a favorite name, the differentiation between such prolapse and a ureterocele not having yet been clearly made The name *ureterocele* was first used by Leshnew in 1912, and that of *intermittent ureterocele* by Ottow in 1914 Kotzenburg (1914) spoke of ureteral cysts, and Pleschner (1917) of "phimosis of the ureter." The superior value, however, of a single word like *ureterocele*, to express so characteristic a formation as this disease entity, is obvious, not to mention the greater descriptive accuracy of this term

CLASSIFICATION

In making a study of ureterocele, we cannot fail to note the number of different types that have been observed and reported in the literature. All these are in reality the expressions of a single disease entity, the difference being that in some the pathological condition is more advanced than in others In other words we must believe that, just as in tumors of the bladder, the growth begins with a small excrescence like a pearl upon the bladder wall, at the orifice of the ureter, and that this minute structure gradually, as the result of infection, exaggerated hydraulic pressure or other pathological condition, progresses to the stage of a dilatation of much larger dimensions and takes on a cystic character This hydraulic and cystic dilatation of the intravesical portion of the ureter is in many cases the result of a congenital malformation or obstruction at the ureteral orifice, which sooner or later will produce a definite interference with the proper drainage of the kidney and ureter. Some of these ureteroceles reported in the literature, as well as some observed by the author himself, have been as large as an orange, occasionally even occupying the whole bladder

We think, therefore, that it may be useful to classify ureteroceles according to these different clinico-pathological stages and to point out the variations which they may exhibit, since not all develop along precisely the same lines, owing to the variety of factors that play a part in their formation Thus, some of them may never result in any hydronephrosis at all Others, in which the lesion is not discovered until a late stage has been reached, may go so

¹Gutierrez, Robert Transurethral treatment of bladder neck obstructions Endoscopic prostatic resection In *History of Urology*, vol II, chapter V, 237-286 Baltimore Williams and Wilkins Company, *Surgery of the seminal vesicles, ampullae and vasa deferentia* In *Oxford Loose-Leaf Surgery*, vol III, Pt 2, pp 301-309 New York Oxford University Press, 1935

Fig 1 Classification of the most common varieties of ureterocele A simple unilateral ureterocele B simple bilateral ureterocele C bilateral ureterocele containing stone and producing complete retention of urine in a female D ureterocele prolapsing through the urethra and protruding beyond the urethral meatus commonly observed in males E ureterocele with minute ureteral orifice producing urinary stasis with marked hydro-ureter and hydronephrosis representing the final stage of the obstructing type of uropathology of the upper urinary tract F ureterocele with reduplication of the ureters and kidney pelvis with hydro-ureter and hydronephrosis

far as to produce functionless hydro ureters and hydronephrosis. In such cases it is too late for any conservative procedure to save the damage resulting in a kidney which might have been restored to usefulness if the condition had been recognized earlier.

I have accordingly collected nine different types which will illustrate some of the more common varieties that I have had occasion to see in the routine course of urological practice and which are met with in the literature. These are shown in Figures 1, 2, 3, and 4.

Fig 3 Drawing from radio-urographic films and cystoscopic data of Case 8, showing a blind left ureterocele, with complete calcification of the corresponding functionless left kidney

Figure 1 comprises 6 of these, as follows A, Simple unilateral ureterocele B, Simple bilateral ureterocele These two forms may be observed at any age and in either sex, and are the commonest of all C, Ureterocele ballooning inside the bladder and containing a stone. This may cause complete retention, as occurred in one of the cases herewith reported D, Ureterocele prolapsing through the urethra, and protruding beyond the meatus—a type that has recently been stressed by Grandineau, Davis and Owens, Campbell, Laffitte, Boeckel and others These last two types are more commonly observed in females, because of the shortness of the urethra E, Ureterocele with hydro-ureter and hydronephrosis—an advanced stage caused by the ureterocele obstructing the mouth of the ureteral orifice and interfering with normal drainage F, Ureterocele in an anomalous condition of the upper urinary tract, in which 2 ureters open at the level of the ureterocele, producing hydro-ureter and hydronephrosis in a case of double ureter and double kidney, thus constituting an anomaly in a twofold sense In cases of this type of anomaly, sometimes one of these double ureters opens normally into the bladder, while the other independently herniates to form a ureterocele.

In addition to this group of six, there are three other types not quite so frequently observed, which are illustrated in Figures 2, 3, and 4 In the first of these, the ureterocele

Fig 4 Ureterocele in a female child who was admitted to the hospital in uremia Postmortem examination showed the enormous size of the ureterocele blocking the entire passage of urine, thus producing hydro-ureter and hydronephrosis This fused type of megaloureterocele gives the impression of having loosened the entire mucosa around the area of the trigone of the bladder, causing this to protrude through the urethra in a ballooned cyst-like shape. This case also illustrates duplication of ureter and kidney pelvis on one side with bilateral pyouretero-hydronephrosis (Modified drawing after Campbell)

opens into a diverticulum of the urinary bladder in such a way that the ureteral orifice debouches within the fundus of the diverticulum, occupying one angle of the trigone (see Fig 2, A and B). Here the ureterocele, clearly showing the ureteral orifice on its tip, balloons from the diverticulum into the bladder during ejaculation or upon rhythmic contractions of the ureter, or during inspiration and expiration, when it can be observed cystoscopically as it alternately appears and disappears. We reported this type of case in 1928 in connection with 55 cases of diverticulum of the urinary bladder and have had the opportunity more recently of seeing another case of the same type. The next type is the blind ureter forming a ureterocele such as has been reported in the literature by Englisch, Kelly, Papin, Dourmashkin, Chivella and others, and of which I have seen one case, in an elderly female patient, in whom there was also

complete calcification of the functionless corresponding kidney (Fig 3) Finally, there is a fused type, or megalo ureterocele, in which the bladder mucosa in the area of the trigone is loosened up and forms a single balloon, like a bladder inside of another bladder, in which the mouths of the anomalous ureters are found, and which has herniated through the lumen of the urethra (Fig 4)

We see, therefore, that although the condition known as ureterocele is anatomopathologically a unit, a single entity, it can, nevertheless be subdivided and classified according to these different clinical types Such a classification will emphasize the importance of a condition which, if left untreated in its earlier stages, may lead even to grave disintegration of the kidney itself and in some instances to fatal uremia

From a histological point of view, it is possible to establish a further classification into a mucous and a muscular type The sac of the ureterocele may be formed simply of vesical and ureteral mucosa and submucosa, in which case we may speak of a mucous type Or there may be present a layer of muscular fibers, sparse or occasionally abundant, in which case we may refer to a muscular type The mucous type is the more commonly observed, in the author's experience

ETIOLOGY

The pathogenesis of ureterocele has been widely discussed, and the most divergent opinions have been expressed with reference to the origin of these cystic dilatations

The theories for a long time turned largely about the question whether they were congenital or acquired, whether the stenosis at the ureteral orifice which characterizes nearly all ureteroceles has its origin in embryonal life and is the result of a malformation arising in the early stages of gestation, or whether it is an acquired condition secondary to some inflammatory condition, or due to calculus formation or infection reaching the ureteral orifice from some other part of the genito-urinary system or even from a distant focus elsewhere in the organism

The classic arguments for a congenital origin are (1) the relative frequency with which

ureterocele has been discovered in the very young, (2) the tendency of the condition to be bilateral, (3) the frequency with which other concomitant anomalies of the urinary tract are observed While most ureteroceles are probably of congenital origin, there is nevertheless complete evidence that they may occasionally be acquired Among grounds for the belief in such acquired origin is the familiar observation that, at any stage of life, cystitis may, by its gradual infiltration of the mucosa of the bladder and lower end of the ureter produce enough scar tissue about the ureteral orifice to provoke stenosis thus creating at least one of the prerequisites for ureterocele formation Many authors hold the view that inflammatory disease of the upper urinary tract, including stone formation and various infections stands in a causal relation to ureterocele It is a moot question today how ever, whether these are the causes or the result of the narrow opening and the ballooning of the ureter into the bladder

Among the works of early writers on the subject we find ureterocele attributed to various causes, among which may be mentioned (1) A gluing together of the walls of the ureteral orifice in fetal life, resulting in stenosis, or, in rare instances in complete closure, a "blind ureter," of which Dourmashkin has found 25 in the literature (2) An adhesion of the ureter under the blind ending in the bladder wall—a view which is supported by the fact that the deformity frequently affects only one side (3) A hypoplasia of the bladder and ureteral mucosa at the orifice of the ureter (4) An abnormally long submucous course of the ureter (5) A vertical course of the ureter through the bladder wall instead of the normal oblique course (6) An abnormal mobility and malformation of the trigone It has been argued by several authors that the increased pressure in such a ureter meets less resistance on the part of the bladder musculature than it would if it entered in the normal oblique direction, that in the latter case the physiological tension of the muscularis is sufficient to withstand the increased pressure and to prevent a dilatation at its lower end In other words the portion of the ureter that passes along immediately under

Fig 5 Theoretical pathogenesis of ureterocele The anatomopathological conception of the different steps in the mechanical formation of the ureterocele A, The ureter with its minute orifice piercing the bladder wall, with the dotted lines representing the first stage of the loosening up of the mucosa of both the ureter and the bladder, during ejaculation B, C, and D, the successive stages by which the ureterocele gains in size and balloons into the bladder D reveals the degree of obstruction and back pressure which ultimately produce hydro-ureter and hydronephrosis

the mucosa for a long distance, or perhaps in the submucosa, would remain outside the sphere of action of the vesical musculature, it would therefore give way more easily to the pressure within the ureter and so become projected with its mucosa into the bladder as a ureterocele (Fig 5) It would then go without saying that the cyst would grow constantly bigger and bigger and extend chiefly in the direction of the trigone, where it meets the least resistance

If we assume with Groslik a blind or nearly blind end to the ureter, due to a gluing together of the epithelium in early life, it is evident that the first result of urinary stasis in the upper segment will be dilatation of the ureter The greatest injury will occur in the portion of the ureter behind the bladder, since this is only loosely connected with its surroundings and offers the least resistance to increased pressure With reference to the effects on the 3 coats of the ureter, the changes occurring in the submucosa will be less than those in the mucosa, and those in the muscularis will be least of all, due to its resistance The result will be a dilatation behind the bladder, a protrusion between the muscularis and mucosa, into the bladder, both of these parts being bound together and running through the muscularis itself Thus, the ureter will assume the form of an hourglass, ballooned behind and before, but contracted at just the place where the muscularis is pierced

by the canal. The greater the resistance of the muscularis, the closer will be the contraction and the narrower the orifice.

Gottlieb, in a comprehensive article based on the careful study of 5 cases of his own and a critical analysis of 100 cases collected from the literature, points out that stenosis or stricture alone could not start a ureterocele; for if this were the only cause, the condition would be very much more common than it is It would appear that there must be a general inferiority (congenital) of the connective tissue, and especially that of Waldeyer's sheath, of the ureter, that an abnormally narrow orifice, *alone*, causes retrograde dilatation; while weakness of Waldeyer's sheath, *alone*, causes herniation of the ureter, but that neither of these factors alone can make a ureterocele Two factors are needed A constitutional inferiority of the muscle fibers would be congenital A stenosis might be either congenital or acquired, as through inflammation, stone, or tumor.

Chwalle studied ureteral buds in 3 month embryos, and described one in particular in which he found indications pointing to a congenital origin of ureterocele Papin is very sure that the condition is always congenital, and states that a ureterocele is only the lower segment of a hydro-ureter for which stenosis at the ostium is necessary Dardanelli regards a ureterocele as a sort of hernia He says that it is not merely a complication of hernia, but

that it is a hernia *sui generis*, with a symptomatology all its own, and that the peritoneum being in some cases very mobile and slippery causes the ureters to take a curved lateral direction toward the end of their course resulting in their displacement into the bladder. In the report of 13 cases Blumer found 10 of true congenital origin, of which 5 died of urinary infection in childhood. O'Connor and Johnson, in a recent study of 19 cases of ureterocele, concluded that this lesion was not due to an obstruction in the extramural portion of the ureter, nor was it due to atony of the ureteral wall, but to a combination of a congenital or developmental narrowing of the ureteral orifice, along with a congenital weakness of the connective tissue and muscular elements surrounding the ureteric meatus. Lavender meets the objection of those who say that if these cysts were congenital they would appear earlier, by the reminder that the wear and tear of life as old age approaches causes congenitally defective organs to show weaknesses that did not appear in earlier years. Caulk is of the opinion that many ureteroceles are acquired, and that they are not infrequently secondary to inflammatory processes, such as those occasioned by the passage of stones or by ulcers in this region or that they develop from ureteritis due to a renal lesion, such for example as tuberculosis. Another cause might be the faulty reimplantation of the ureter after a ureterovesical anastomosis. Pettillo holds the view that adhesions between the seminal vesicles and the ureter or between the broad ligament and the ureter cause a paralysis of the lower end of the ureter with subsequent loss of contractile power in this segment which in turn results in dilatation and protrusion into the vesical lumen.

It seems rather evident that both the two factors of stenosis and muscular weakness taken together lie at the foundation of ureterocele. The normal physiological action of the ureteral musculature is impaired by this anatomical weakness. Pyeloscopy studies of the upper urinary tract have revealed the continuous peristaltic waves that are present in the normal ureter. Any weakness or malformation in the intramural portion of the ureteral musculature would interfere with this

physiological dynamism and invite formation of a ureterocele.

The accompanying drawing shows the several stages by which a ureterocele would be formed as it is theoretically explained (Fig 5). The longitudinal muscular fibers supplying the ureter are diverted to right and left like a fan at the point where the ureter enters the vesical wall leaving a weak spot in the bladder wall even in the normal individual. Given a muscular tissue of inferior constitution with few longitudinal fibers, or even none at all in certain cases we have a ureteral wall composed almost solely of mucosa and submucosa. Such a canal easily falls a prey to dilatation and hernia as the peristaltic action above exerts continuous hydraulic pressure downward into the bladder.

The pathogenesis of ureterocele as a disease entity may, accordingly, be summed up by saying that it is quite similar to that of diverticulum of the urinary bladder, and that it has much of both the congenital and the acquired factors in its origin. The paramount factors in the formation of ureterocele thus appear to be (1) the congenital narrowing of the intravesical portion of the ureter, (2) congenital weakness or absence of the longitudinal muscle fibers of the terminal portion of the ureter, resulting in abnormal mobility of the trigone, (3) loosening up of the vesical mucosa at the point where the ureter enters the bladder, (4) disturbances of dynamism and hydraulic pressure within the ureter, (5) lack of drainage due to obstruction in the lower ureter, (6) presence of infection or other concomitant pathological lesions of the ureter and bladder.

Finally, we cannot overlook the fact of the important rôle played by other anomalies of the ureter in the causation of ureterocele, as is clearly evident in cases in which ureteroceles are formed from an ectopic or supernumerary ureter which opens anywhere in the bladder or urethra. Nor can we ignore the fact that cases of ureterocele in double ureters and double kidney pelvis with hydro-ureter and hydro-nephrosis in one of the two ureters are quite commonly observed (Fenwick, Kohlschütter, Caille, Neelsen, Bostroem, English, Gutierrez, Campbell, Lazarus, Muschat,

Young, and many others). All these associated congenital malformations of the ureters prompt us, therefore, to consider the rôle of the anomalous ureter as an important factor in the pathogenesis of ureterocele

PATHOLOGY

In the beginning stages a ureterocele is usually such a slight lesion that nothing is observable beyond an insignificant dilatation of the intravesical portion of the ureter, and there are no symptoms to call attention to its existence. Such a ureterocele would, therefore, be an accidental finding during routine cystoscopic examination, at operation, or autopsy, of the presence of which the patient had been wholly unaware. In other cases, however, there are very severe disturbances of the entire urinary system. Clinically there may be dysuria, frequency of urination, "colic," ureteritis, pyelitis and pyelonephritis; or difficult and painful micturition, with chronic total or partial retention, or again, under conditions that reduce tension, such as lying down, there may even be incontinence.

The position of the ureterocele in the bladder has much to do with the severity of the symptoms. If it is small and lies relatively far back from the bladder neck, and is limited to one-half of the trigone, there may be no urinary disturbances. If, however, it is so placed that the stenosis of the ureteral orifice is of high degree or if the pull of the abnormally pedicled ureter from time to time causes temporary complete abolition of its lumen, there occurs, first, a urinary stasis in the portions of the urinary tract which lie above the obstruction, which results in a dilatation of the upper ureter and the renal pelvis. If neglected, this stagnation will in course of time lead to an enormous extrarenal hydronephrosis and, of course, a corresponding hydro-ureter. However, in some cases, in which the pressure within the ureter and the kidney pelvis is very strong, and yet the pelvis has not the capacity to yield outwardly by a dilatation, the result is a hydronephrotic atrophy of the kidney parenchyma, through which the kidney is converted into a huge thin-walled sac, constituting an intrarenal hydronephrosis or pyonephrosis. As the ureterocele is espe-

cially prone to develop in a urinary system in which there are double ureters, it not infrequently happens that a dilatation appears in one of the duplicate organs that drains only a portion of the kidney from which it proceeds. In such case only that portion of the kidney will dilate, and the other part of the kidney may remain in a sound condition, at any rate for a long time.

In very far advanced cases, if the ureterocele has reached a high degree of dilatation and assumed a considerable size, then the process as a rule not only has an injurious effect on the entire upper urinary tract of that side but will also occasion changes within the bladder. The natural course of the growth of the ureterocele is along the trigone into the region of the internal neck of the bladder. In addition to this, it happens that the abnormally lengthened submucosal course of the ureter always brings it into a rather close proximity to the internal vesical orifice. If it has grown so far as to reach this, difficulties in emptying the bladder at once arise. The ureterocele lies over the bladder outlet like a valve, and, acting like a foreign body, causes the patient to suffer from edema and polyposis of the vesical orifice, cystitis with increasing urgency, dysuria, and bladder tenesmus.

In extreme cases an attack of complete retention may occur, which may again disappear if the cyst shrinks or bursts, only to reappear according to changes occurring in the latter. But there may also be all grades of incomplete retention and residual urine, associated with painful urinary disturbances. The bladder wall always shows, and usually quite early, a trabecular muscular hypertrophy representing a compensation for the enormously increased work on the part of the detrusor muscle, increased by dysuria.

If the ureterocele extends so far that the orifice of the healthy ureter is compressed and becomes closed upon contraction of the bladder, then a high grade stagnation of urine occurs in the other kidney also, which may in very advanced cases lead to complete anuria. Such cases are not very infrequent in the literature, so that despite unilateral formation of the ureterocele, a high grade hydronephrosis may develop on the other side as well.

Fig 6 Schematic drawing from Case 4 illustrating a right ureterocele complicated with stone and multiple prostatic calculi. Diagnosed cystoscopically and treated satisfactorily by simple fulguration of the meatus of the ureterocele and further cystoscopic treatments with dilations of the ureters and kidney pelvis lavage.

As soon as the factor of infection is added to the renal and ureteral stasis the entire picture changes quite radically, and we observe signs of acute and chronic cystitis, ureteritis and pyelitis. Conditions that are at first simply catarrhal may then turn into very severe inflammations, accompanied by hemorrhagic and ulcerative complications. From simple dilatation of the ureter and kidney pelvis there may arise the worst forms of pyelitis and pyonephrosis. In some instances for lack of drainage and due to infection stones are readily formed in the ureterocele (Fig 6).

In some cases chronic masked forms of mucosal inflammation and bulbous edema are found upon cystoscopic and macroscopic examination, to be cases of chronic cystitis accompanied by glandular and follicular involvement. This chronic inflammatory condition of the bladder mucosa inevitably proves eventually a source of contamination of the sound kidney, through vesico-ureteral reflux so that the entire urinary system becomes diseased and incapable of performing its proper functions.

The prolapse of the ureterocele through the female urethra must be regarded as a special variation of the anatomical and pathological picture (Fig 4). Upon straining to urinate and thus to get rid of the foreign body that the patient feels within the bladder the blad-

der muscle presses the cyst outward through the dilated urethra, and there is then seen the picture of a tumor lying in front of the external meatus which can with little difficulty be pushed back into the bladder temporarily. Upon the prolapsed portions of mucous membrane there are often seen signs of chronic inflammation, such as hornification of the epithelium and leucoplakia. Several of the earliest cases of ureterocele reported were of this nature, in young female children. All the early cases of this kind were fatal, the entire urinary system being invariably found in a state of inflammation, with abscessed kidneys, and the like, from ascending infection that had arisen from the sloughing off of the invaginated mucosa within the meatus.

DIAGNOSIS

In early times, before the arrival of the modern urographic and cystoscopic era the diagnostician had to depend on the symptomatology, which in reality has nothing characteristic about it to differentiate it from "cystitis" or other irritant conditions of the bladder. These symptoms may be due to infection or to obstruction. In some cases there may indeed be no symptoms at all in the early stages of the dilatation. We know that a large number of cases in the literature gave no trouble during life and were diagnosed only at postmortem. Symptoms due to infection may consist of the usual dysuria, frequency, pyuria and hematuria that characterize cases of cystitis. Symptoms due to obstruction or stricture of the ureteral orifice consist of attacks of ureteral and renal colic and the usual manifestations of retention in advanced cases that have gone on to hydro-ureter and hydronephrosis. But there is nothing characteristic about these symptoms, and our main dependence for diagnosis must be placed on the cystoscopic and urographic findings. Chromocystoscopy is also of value making it possible to watch the ejaculators more clearly. It is fortunate that by these means we are able today to recognize and interpret these findings when the ureterocele is in its early stages.

When a ureterocele is still in its initial stage, it is observed cystoscopically, that immedi-

ately before the ureteral ejaculation occurs, a flattened tumor is formed at the level of the ureteral orifice, resting against the bladder wall, where it obliquely follows the direction of the ureter. At this moment the submucous wall of the ureter becomes transparent, the ureteral orifice, surrounded by this encircling prominence, dilates, then, at the moment of ejaculation, it retracts and the dilatation disappears, to return again with the next ureteral contraction.

In the second stage, the little tumor has become a permanent projection into the bladder. It presents the appearance of a rounded prominence, smooth and shiny, with a broad base covered with healthy or slightly inflamed mucous membrane, on the surface of which a fine tracery of vessels can be observed. On its summit the round and contracted orifice can as a rule be seen. Sometimes this orifice is absent, either because it is really lacking or because it is dissimulated between the posterior wall of the cyst and the wall of the bladder. When the cyst is distended, causing its walls to become thin, it takes on an appearance of transparency and can be transilluminated, especially if the cystoscope is placed deep within the bladder, close to the ureterocele, just as a flash light is applied to a hydrocele. The same changes can be observed with the rhythmic movements of the ureter as in the first stage of its evolution, but now, after the ejaculation, the cystic formation does not entirely disappear as it did before. In one of my cases these alternations appeared every 30 seconds.

In the third stage of development, the ureterocele becomes more or less pedunculated, its distended walls have become inert, its size remains constant, it prolapses more or less into the bladder toward the internal orifice of the urethra, with which it has a tendency to make connection. One characteristic observed is that if the structure is touched with the tip of an instrument, it reacts like a rubber ball, with a momentary depression that disappears when the pressure is removed.

When the condition of ureterocele is discovered on cystoscopic examination, it is always wise to catheterize the ureters whenever possible; and also to take a plain roentgeno-

gram with the catheters and instrument in position as well as retrograde uretero-pyelograms, not only for the purpose of confirming the diagnosis of ureterocele, but also to rule out concomitant anomalies or other pathological conditions of upper urinary tract (Fig 9).

In the differential diagnosis, ureteroceles are not likely to be confused with polyps, since the only character they have in common is their site. Polyps are not transparent, their size is constant, their pedicle is long and thin, and the urine is seen to escape around the tumor and not at its summit. Nor will a stone wedged in the lateral wall of the bladder or a benign tumor invested with a layer of fibrinous exudate on its surface be readily mistaken for a ureterocele. The only real confusion will lie between the latter and a prolapse of ureteral mucosa into the bladder. One way of recognizing such a prolapse, which after all is not very common, is that it can ordinarily be reduced by pressure on its summit. It has also been observed that in prolapse the movements are only in and out, while in cystic dilatation there is also an expansion and a retreat like that observed in an aneurysm. Prolapse mostly occurs through an enlarged ureteral orifice, while the ureterocele forms a pocket closed on all sides and opening into the bladder by an orifice that is ordinarily much contracted. Marked edema with swelling of the intravesical portion of the ureter when produced by impacted ureteral calculi is easily differentiated, since it is readily observed that when the ureteral stone is dislodged and expelled, the edema that surrounds the mouth of the ureteral orifice finally subsides. Ureterocele must also be differentiated from cyst of the prostate, cystitis and ureteritis cystica, and other pathological conditions of the urinary bladder, such as hypertrophy of the interureteric ridge or "floating trigone," pedunculated solid tumors and diverticula of this viscus. Moreover, when the ureterocele prolapses from the meatus of the urethra and becomes an extravesical ureterocele, it must be differentiated from polyps, papilloma, prolapse of the urethral mucous membrane, caruncle, condyloma, peri-urethral abscess of Skene's glands, carcinoma, and other common pathological conditions of female urethra.

Fig 7 Drawing from an intravenous urogram revealing the two round filling defects in the area of the bladder with marked hydro ureter and hydronephrosis on the right side. Filling defects of this type in a cystogram are pathognomonic of ureterocele

Finally, intravenous urography is of great help in the diagnosis of ureterocele and should be used as a routine method of examination, since in a good film one can visualize the condition of the upper urinary tract and at the same time readily detect any filling defect in the cystogram appearing as a superimposed round shadow of the opaque substance retained within the sac or balloon of the ureterocele (Figs 7 and 8). When this type of shadow is present in the cystogram, it should be considered as a pathognomonic urographic sign for the diagnosis of this condition. However, this beautiful urographic finding should always be checked cystoscopically in order to rule out uric acid or cystine stone, diverticulum, and bladder tumor.

TREATMENT

Treatment consists of medical and surgical measures

Urological measures These will include cystoscopic dilatations of the mouth of the ureterocele with ureteral bougies and catheters and irrigation of both the renal pelvis and ureters with antiseptic solutions, such as silver nitrate, acriflavine or rivanol dextrose 1:2000. The dilatations should be done at weekly intervals and continued until a No. 9, 10, or 12 catheter can be readily passed to the kidney pelvis without obstruction. In this way an improved drainage is assured and the degree of infection reduced, the constant irritation of the bladder wall is relieved, and the dysuria and other urinary symptoms diminished resulting in a general amelioration of the patient's condition.

Surgical treatment According to the stage of evolution of the ureterocele, minor transurethral surgical measures or more radical open procedures are indicated. *Minor surgical measures* consist of transurethral treatment that can be carried out cystoscopically. This may be either one of two kinds: (1) simple fulguration with a point electrode, (2) ureteral meatotomy carried out by cutting with minute scissors or knife electrode.

When more radical operative procedures must be considered, these again fall into two main groups, according to the pathological lesion present: (1) cystostomy and (2) combined ureteronephrectomy.

(1) If the ureterocele is of large size or is accompanied by infection, tumor, stone, or other complication, cystostomy must sometimes be done for its complete removal. (2) If the ureterocele is of long standing and obstruction has reached such a high degree that the ureter and kidney have been severely compromised, usually resulting in hydro ureteronephrosis, then combined ureteronephrectomy may become necessary.

Minor transurethral surgical procedures may be described as follows:

A. In simple unilateral ureterocele, when the cyst is small and without complications, the best procedure is simple fulguration of the ureteral orifice carried out cystoscopically. A fulgurating point electrode is inserted in the ureteral orifice of the ureterocele, the high frequency current is applied and the entire surface of the ureterocele is destroyed by ap-

Fig 8 Drawings from intravenous urograms of bilateral ureteroceles in two adult female identical twins (Riba's case) A, at left Note the obstructing pathology of the upper urinary tract, with bilateral ureterocele, a slight degree of hydro-ureteronephrosis and evidence of megalo-bladder B, Drawing from the intravenous urogram of the second twin, showing the presence of bilateral ureteroceles in the cystogram

plication of the electrocoagulating current, under cystoscopic control. The simplicity of the procedure and the good results uniformly obtained commend this above all other procedures. Fulguration will also permit the passage of a stone if any happens to be impacted in the intramural portion of the ureter or within the ureterocele, as occurred in 2 of my cases reported here. The patient should receive bladder irrigations at least twice a week after the fulguration; then after sloughing of the fulgurated tissue is complete and healing has taken place, which will be in about 2 or 3 weeks, dilatations of the ureters and kidney pelvis lavages should again be carried out in order to secure perfect drainage and prevent constriction of the mouth of the ureteral orifice. The scar resulting from this operation provides as a rule a good sphincter at the mouth of the ureter, and thus prevents vesicorenal reflux.

When the opening of the ureteral orifice is so minute that it cannot be properly visualized through the cystoscope, or when it is concealed by the position of the ureterocele, and the point electrode cannot therefore be placed within the ureteral meatus, the electrode should be placed in the most prominent part of the pseudocyst, in order that thorough fulguration at that point may destroy the whole structure, which will then gradually slough off and permit adequate drainage.

B As a modern alternative to fulguration, in the same type of simple case, a *ureteromealotomy* may be performed by the electric cutting current, the mouth of the ureteral orifice being cut away and the superfluous tissue removed either by means of minute cystoscopic scissors or by a knife electrode such as Kelly, Papin, Caulk, Bumpus, Collins, Moore, Riba, Beer and others, have devised for transurethral surgical work. This can be

Fig 7 Drawing from an intravenous urogram revealing the two round filling defects in the area of the bladder with marked hydro ureter and hydronephrosis on the right side. Filling defects of this type in a cystogram are pathognomonic of ureterocele

Finally, intravenous urography is of great help in the diagnosis of ureterocele and should be used as a routine method of examination, since in a good film one can visualize the condition of the upper urinary tract and at the same time readily detect any filling defect in the cystogram appearing as a superimposed round shadow of the opaque substance retained within the sac or balloon of the ureterocele (Figs 7 and 8). When this type of shadow is present in the cystogram, it should be considered as a pathognomonic urographic sign for the diagnosis of this condition. However this beautiful urographic finding should always be checked cystoscopically in order to rule out uric acid or cystine stone, diverticulum, and bladder tumor.

TREATMENT

Treatment consists of urological and surgical measures

Urological measures These will include cystoscopic dilatations of the mouth of the ureterocele with ureteral bougies and catheters and irrigation of both the renal pelvis and ureters with antiseptic solutions, such as silver nitrate, acriflavine or rivanol dextrose 1:2000. The dilatations should be done at weekly intervals and continued until a No 9, 10 or 12 catheter can be readily passed to the kidney pelvis without obstruction. In this way an improved drainage is assured and the degree of infection reduced, the constant irritation of the bladder wall is relieved, and the dysuria and other urinary symptoms diminished resulting in a general amelioration of the patient's condition.

Surgical treatment According to the stage of evolution of the ureterocele, minor transurethral surgical measures or more radical open procedures are indicated. *Minor surgical measures* consist of transurethral treatment that can be carried out cystoscopically. This may be either one of two kinds: (1) simple fulguration with a point electrode, (2) ureteral meatotomy carried out by cutting with minute scissors or knife electrode.

When more radical operative procedures must be considered, these again fall into two main groups, according to the pathological lesion present: (1) cystostomy and (2) combined ureteronephrectomy.

(1) If the ureterocele is of large size or is accompanied by infection, tumor, stone or other complication, cystostomy must sometimes be done for its complete removal. (2) If the ureterocele is of long standing and obstruction has reached such a high degree that the ureter and kidney have been severely compromised, usually resulting in hydroureteronephrosis, then combined ureteronephrectomy may become necessary.

Minor transurethral surgical procedures may be described as follows:

A. In simple unilateral ureterocele, when the cyst is small and without complications, the best procedure is simple fulguration of the ureteral orifice carried out cystoscopically. A fulgurating point electrode is inserted in the ureteral orifice of the ureterocele, the high frequency current is applied and the entire surface of the ureterocele is destroyed by ap

first of ligation and section of the ureter at its base, close to the bladder, done either through the oblique incision running parallel to Poupart's ligament or through a median line or pararectus incision, not exceeding 5 to 6 centimeters in length, carried out extraperitoneally and retroperitoneally (3) After this the last stage, consisting of the removal of the kidney and attached ureter, in a single piece, is done through the usual lumbar incision When the kidney has a double pelvis and double ureters with evidence of hydro-ureter and hydronephrosis in only one-half of the organ, and the other ureter is functioning satisfactorily, a combined uretero-heminephrectomy may properly be carried out

The advantage of this new mode of attack is that it avoids opening the bladder and makes unnecessary the drainage of this viscus, which might materially prolong the post-operative care of the patient.

REPORT OF ILLUSTRATIVE CASES

From the series of 18 cases observed and treated by the author, the following 9 cases have been selected as typical illustrations of the findings, tending to confirm the conclusions which have been set forth in the preceding pages

CASE 1 Simple unilateral ureterocele in a young female patient with frequency of urination, dysuria, urgency and bladder tenesmus, also complaining of indefinite abdominal and lumbar pain, diagnosed cystoscopically and relieved by cystoscopic fulguration of the ureterocele and further dilatations of the ureter with bougies and catheter drainage

Miss S F, 20 years of age, came to my office for examination in October, 1925, complaining of pain across the back, frequency of urination, and nocturia three to four times nightly, also bladder tenesmus and nervousness She had been receiving treatments from a local doctor without relief Cystoscopic examination revealed the presence of a left ureterocele about the size of a small olive During ejaculation the mouth of the left ureteral orifice was seen to be very small and of the pin-point type A No 4F catheter was difficult to pass, owing to the obstruction The right ureteral orifice was normal in all respects and could easily be catheterized with a No 6F catheter It was decided to fulgurate the mouth of the left ureteral orifice, in order to destroy the mucous membrane of the ureterocele Three weeks later both ureteral orifices were easily catheterized with a No 6 catheter without meeting obstruction The specimen collected from each side

was clear. Both kidneys were irrigated with acriflavine 1:1000 This treatment was carried out on several occasions until a bougie No 9 passed into each kidney pelvis without obstruction The cultures of the catheterized specimen were negative. The urinary symptoms cleared up and patient has been well ever since

CASE 2 Unilateral ureterocele in a female patient complaining of acute cystitis, pyelitis, and pyelonephritis, with urographic evidence of hydro-ureter and hydronephrosis, successfully relieved by cystoscopic fulguration of the ureterocele, dilatations of the ureters and kidney pelvis lavage

Mrs K S, 34 years of age, was referred for persistent bladder symptoms by her husband in September, 1930 She had been suffering for 3 years with bladder tenesmus, dysuria, burning at urination, pyuria, and pain in right lumbar region radiating to the right lower quadrant She had been married for over 10 years and had no children Menstrual history was normal The voided specimen of urine was cloudy and contained pus Cystoscopic examination revealed the presence of a small ureterocele at the mouth of the right ureteral orifice, which admitted a No 4 catheter with some difficulty The left ureteral orifice was normal and admitted a No 6 catheter without obstruction The specimen collected from the right kidney was hazy, while that from the left kidney was clear. The phenolsulphonphthalein test showed that renal function was slightly diminished on the right side but was normal on the left The right pyelogram revealed a considerable degree of hydronephrosis with pyelitis and pyelonephritis, as well as dilatation of the ureter throughout its entire length The culture was positive for *Bacillus coli* and *streptococcus* infection The diagnosis was right ureterocele with hydronephrosis, pyelitis and pyelonephritis

Treatment was carried out cystoscopically with fulguration of the ureterocele, dilatation of the ureters, and kidney pelvis lavage with rivanol dextrose 1:2000 Patient was cystoscoped regularly at intervals of 2 and 4 weeks until a No 8 bougie passed repeatedly into the kidney pelvis without obstruction All symptoms cleared up and she is now enjoying good health

CASE 3 Unilateral left ureterocele in a male patient who complained of pain across the lower back, slight frequency of urination and persistent microscopic pyuria and hematuria, causing his rejection by a life insurance company Cystoscopic examination revealed the presence of a left ureterocele about the size of an olive and the urographic studies showed a moderate degree of hydronephrosis with left pyeloureteritis, relieved by cystoscopic fulguration of the ureterocele, dilatation of ureters, and kidney pelvis lavage

Mr Ch C, married, 28 years of age, engineer, came to my office June 23, 1932, complaining of frequency of urination with dysuria, pain across back, and persistent microscopic pyuria and hematuria He had been operated upon for left varicocele

readily applied through an ordinary cysto scope or, preferably, through the panendo scope

An inconvenient feature of this method is that it is not easy to control the exact amount of tissue cut away, and it is possible to excise too much of the wall of the intravesical ureter, carrying away a part of the muscularis fibers when, properly, in most instances only the mucosa should be cut. Moreover, the sphincter action of the new orifice may be unsatisfactory, and the procedure may result in regurgitation with vesicorenal reflux. Other ingenious devices for conservative trans-urethral treatment have also been presented for intravesical use, such, for instance, as various forms of snares devised by Burger, Foley, and others.

C Finally, there is the loop electrode method in use for endoscopic prostatic resection, which in some instances can be turned to good account for destroying and removing ureteroceles, just as it has been for removing a median prostatic lobe or solid tumors of the urinary bladder.

Open surgical procedures It goes without saying that many unnecessary operations have been done for exposing and ascertaining the condition present within the bladder, in cases in which diagnosis has not been properly made before operation. In these modern urographic and cystographic days there is little reason to resort to cystostomy for diagnosis. Still there are vivid records in the literature of cases in which on the basis of a cystoscopic diagnosis of tumor of the bladder this viscus has been opened and a ureterocele discovered, which has been surgically removed by accomplishing a ureteroclectomy, followed by the placing of interrupted or continuous sutures around the mucosa of the ureter and bladder at the mouth of the ureteral orifice. Such a procedure has been reported with apparent success by Cohn Bazy, Pasteau, Albarran, Fedoroff, Gayet, Cathelin, Patch, Papin, and others.

Another type of open surgery of ureterocele has consisted in plastic repair of the ballooning portion, as in an ordinary hernia operation. Such a method was reported by Young in 1912, also with apparent success.

But a fact that must unfailingly be kept in mind, in open surgical operations for ureteroceles, is that in advanced cases of this kind, a hydro-ureter and a hydronephrosis are almost certainly present, and in most cases these organs have become functionless. Partial measures directed to the removal of the ureterocele alone accomplish nothing where such conditions have arrived. When the cystoscopic findings reveal a large ureterocele and the pyelographic findings give evidence of an advanced stage of destruction in the upper urinary tract, the indications are given for a combined ureteronephrectomy, or even a partial cystoureteronephrectomy, provided the condition is unilateral and there is assurance of a well functioning kidney on the opposite side. This operation, done in two stages, I described in 1931, in a paper on the indications for combined ureteronephrectomy, and I have emphasized the importance of ureterocele as one of the causes of hydro-ureter and hydronephrosis, in the third edition of Cabot's *Modern Urology*.

It appears therefore that, if this condition is discovered in early life it may be possible not only to treat it successfully by conservative measures, with dilatations of the ureter or fulguration of the ureterocele, but also to save the patient from further disease of the upper urinary tract, leading to acute conditions which may ultimately require radical surgery such as combined ureteronephrectomy.

In these advanced cases, in which kidney function has been lost through the obstructive effect of a ureterocele, and in which marked hydro ureter and hydronephrosis are present, the surgical procedure may be simplified by doing it in three stages (1) The destruction cystoscopically of the ureterocele by simple fulguration, without opening the bladder (2) If later on, the urographic studies reveal that the kidney and ureter are still hydronephrotic and functionless with urographic evidence of hydro ureter and hydronephrosis, the second procedure, or ureteronephrectomy, which I have described elsewhere and which is in itself a dual one to be done in one sitting, can then be instituted. This will consist

first of ligation and section of the ureter at its base, close to the bladder, done either through the oblique incision running parallel to Poupart's ligament or through a median line or pararectus incision, not exceeding 5 to 6 centimeters in length, carried out extraperitoneally and retroperitoneally (3) After this the last stage, consisting of the removal of the kidney and attached ureter, in a single piece, is done through the usual lumbar incision When the kidney has a double pelvis and double ureters with evidence of hydro-ureter and hydronephrosis in only one-half of the organ, and the other ureter is functioning satisfactorily, a combined uretero-heminephrectomy may properly be carried out

The advantage of this new mode of attack is that it avoids opening the bladder and makes unnecessary the drainage of this viscus, which might materially prolong the post-operative care of the patient.

REPORT OF ILLUSTRATIVE CASES

From the series of 18 cases observed and treated by the author, the following 9 cases have been selected as typical illustrations of the findings, tending to confirm the conclusions which have been set forth in the preceding pages

CASE 1 Simple unilateral ureterocele in a young female patient with frequency of urination, dysuria, urgency and bladder tenesmus, also complaining of indefinite abdominal and lumbar pain, diagnosed cystoscopically and relieved by cystoscopic fulguration of the ureterocele and further dilatations of the ureter with bougies and catheter drainage

Miss S F, 20 years of age, came to my office for examination in October, 1925, complaining of pain across the back, frequency of urination, and nocturia three to four times nightly, also bladder tenesmus and nervousness She had been receiving treatments from a local doctor without relief Cystoscopic examination revealed the presence of a left ureterocele about the size of a small olive During ejaculation the mouth of the left ureteral orifice was seen to be very small and of the pin-point type A No 4F catheter was difficult to pass, owing to the obstruction The right ureteral orifice was normal in all respects and could easily be catheterized with a No 6F catheter It was decided to fulgurate the mouth of the left ureteral orifice, in order to destroy the mucous membrane of the ureterocele Three weeks later both ureteral orifices were easily catheterized with a No 6 catheter without meeting obstruction The specimen collected from each side

was clear Both kidneys were irrigated with acriflavine 1:1000 This treatment was carried out on several occasions until a bougie No 9 passed into each kidney pelvis without obstruction The cultures of the catheterized specimen were negative. The urinary symptoms cleared up and patient has been well ever since

CASE 2. Unilateral ureterocele in a female patient complaining of acute cystitis, pyelitis, and pyelonephritis, with urographic evidence of hydro-ureter and hydronephrosis, successfully relieved by cystoscopic fulguration of the ureterocele, dilatations of the ureters and kidney pelvis lavage

Mrs K S, 34 years of age, was referred for persistent bladder symptoms by her husband in September, 1930 She had been suffering for 3 years with bladder tenesmus, dysuria, burning at urination, pyuria, and pain in right lumbar region radiating to the right lower quadrant She had been married for over 10 years and had no children. Menstrual history was normal The voided specimen of urine was cloudy and contained pus Cystoscopic examination revealed the presence of a small ureterocele at the mouth of the right ureteral orifice, which admitted a No 4 catheter with some difficulty The left ureteral orifice was normal and admitted a No 6 catheter without obstruction The specimen collected from the right kidney was hazy, while that from the left kidney was clear The phenolsulphonphthalein test showed that renal function was slightly diminished on the right side but was normal on the left The right pyelogram revealed a considerable degree of hydronephrosis with pyelitis and pyelonephritis, as well as dilatation of the ureter throughout its entire length The culture was positive for *Bacillus coli* and streptococcus infection The diagnosis was right ureterocele with hydronephrosis, pyelitis and pyelonephritis

Treatment was carried out cystoscopically with fulguration of the ureterocele, dilatation of the ureters, and kidney pelvis lavage with rivanol dextrose 1:2000 Patient was cystoscoped regularly at intervals of 2 and 4 weeks until a No 8 bougie passed repeatedly into the kidney pelvis without obstruction All symptoms cleared up and she is now enjoying good health

CASE 3 Unilateral left ureterocele in a male patient who complained of pain across the lower back, slight frequency of urination and persistent microscopic pyuria and hematuria, causing his rejection by a life insurance company Cystoscopic examination revealed the presence of a left ureterocele about the size of an olive and the urographic studies showed a moderate degree of hydronephrosis with left pyelo-ureteritis, relieved by cystoscopic fulguration of the ureterocele, dilatation of ureters, and kidney pelvis lavage

Mr Ch C, married, 28 years of age, engineer, came to my office June 23, 1932, complaining of frequency of urination with dysuria, pain across back, and persistent microscopic pyuria and hematuria He had been operated upon for left varicocele

4 years before and had been cystoscoped elsewhere, but without diagnosis. Treatments for cystitis had given no relief. Cystoscopy now revealed the presence of a left ureterocele with a much congested bladder mucosa and evidence of cystitis. Catheterization of the ureters was easily accomplished with two No 5F catheters. Cultures of the catheterized specimens were negative. Phenolsulphonphthalein appeared in 4 minutes on the right side and in $4\frac{1}{2}$ on the left with fairly good concentration of the dye. Ureteropyelograms disclosed the presence of a moderate degree of left hydronephrosis with marked pyelectasis and ureterectasis. He was treated cystoscopically with fulguration of the left ureterocele and subsequent dilatations of the ureters and kidney pelvis lavage, together with administration of urinary antiseptics and forced fluids. Urinary symptoms gradually disappeared and a cystogram taken 3 months later showed a normal bladder with no evidence of vesico uretero renal reflux.

CASE 4. Ureterocele complicated with an impacted stone at the mouth of the right ureteral orifice of a pin point meatus. Diagnosed cystoscopically in a patient with prostatitis seminal vesiculitis and multiple prostatic calculi. Relieved by endoscopic fulguration of the ureterocele which made possible not only the delivery of the ureteral stone but the final correction of the ureterocele.

Mr R F D aged 45 years married for 17 years no children. Patient was referred for examination on January 16 1934 complaining of hematuria pyuria and pain in right kidney region. He had suffered from arthritis for several years. He had been passing stones from childhood, with attacks of chills fever and pain the last stone having been passed in July 1933. He complained of frequency urgency nocturia dysuria and cloudy and foul urine. Rectal examination disclosed a moderately enlarged prostate of boggy consistency and with multiple calculi. Microscopic examination of the prostatic fluid revealed 40 per cent pus cells per field. The right kidney was enlarged and tender on palpation. Cystoscopic examination revealed the presence of right ureterocele surrounded by bulbous edema and much congestion of the entire bladder mucosa. A small ureteral calculus could be seen lying at the mouth of the very minute right ureteral orifice and protruding from its lumen. The left ureteral orifice was normal. Right ureteral catheterization was impossible due to the impacted stone in the protruding ureterocele. Roentgenographic examination disclosed the presence of the stone in the ureter and multiple stones in the prostate while intravenous urograms showed a slight degree of dilatation of the right kidney pelvis and ureter. The entire ureterocele was fulgurated to allow the passing of the calculus which was afterward removed from the bladder by cystoscopic manipulations. Patient was apparently completely relieved of the acute symptoms caused by the obstructing ureterocele.

CASE 5. Bilateral ureterocele in male patient suffering from lumbago marked dysuria and frequency

of urination. Diagnosed by cystoscopic examination and cured by cystoscopic fulguration of the congenitally minute mouth of both ureteral orifices.

Mr D J S aged 43 years married suffering from persistent prostatitis and seminal vesiculitis for the last 10 years apparently following an attack of gonorrhea. He was examined in February 1933 at which time he complained of frequency dysuria hesitancy and persistent lumbago. He was operated upon for chronic appendicitis 7 years ago. The voided specimen of urine was clear, with shreds. Microscopic examination of the prostatic fluid revealed 20 per cent pus cells per field. Cystoscopy disclosed slight congestion of the entire bladder mucosa and two very minute ureteral orifices one on each side of the trigone. The ballooning of the ureteroceles which were about the size of lima beans could be observed during ejaculation. A No 6F failed to pass and ureteral catheterization was accomplished with difficulty passing a No 4F. Specimen collected from each kidney was clear and cultures negative. An electrode was placed at the mouth of each ureteral orifice and both ureteroceles were thoroughly fulgurated. The bladder was irrigated with silver nitrate 1:5000 twice a week and when patient was cystoscoped 3 weeks later both ureters appeared wide open and within normal limits. The lumbago and urinary symptoms disappeared and patient is cured at the present time.

CASE 6. Bilateral ureterocele in a female patient suffering with arthritis frequency of urination microscopic pyuria headache nervousness and bladder tenesmus with evidence of marked cystocele chronic cystitis pyelitis pyelonephritis nephropathy kinking of the ureters and hydronephrosis and hydronephrosis successfully relieved by cystoscopic fulguration of the ureteroceles and kidney pelvis lavage.

Mrs J L 58 years of age housewife came to the office for examination on April 4 1936 suffering from arthritis and intermittent pain in both kidney regions sometimes radiating down along the course of the ureter to the bladder region and accompanied by frequency day and night dysuria and evidence

Fig 9. Bilateral ureterocele with a stone on one side causing complete retention of urine in a female patient with duplication of the ureters and kidney pelvis (Case 7). 1. Cystoscopic view of the bladder showing the actual size of the two ureteroceles producing mechanical obstruction at the vesical orifice. 2. Cystoscopic view showing the two congenitally narrow ureteral orifices during ejaculation. 3 and 4. Cystoscopic view of the right and left ureteral orifices 3 weeks after ureterotomy by fulguration showing the sloughing tissue around the newly opened ureteral orifices. The stone which was in the right ureterocele and which was removed by cystoscopic manipulation can now be seen lying in the bladder after fulguration. 5. Bilateral pyelo urogram made after the fulguration of the ureteroceles showing the duplication of the ureters and kidney pelvis on both sides. 6. Drawing from the bilateral pyelo urogram showing graphically the concomitant anomalies which can be discovered only by routine urologic and urographic examination.

5

6

Fig 9
(Legend on opposite page)

of microscopic pyuria and hematuria. Had hysterectomy 15 years ago for fibroid tumor. On physical examination both kidneys were low and palpable and there was evidence of marked degree of cystocele. Cystoscopy disclosed much congestion of the bladder mucosa throughout. The meatus and both ureteral orifices were diminutive in size. The ballooning of the cystic dilatation of the intravesical portion of both ureters could be seen during ejaculation. Ureteral catheterization with No. 6F was difficult but two No. 4F passed easily and without obstruction to each kidney pelvis. Specimen collected from each kidney was hazy. Cultures revealed the presence of *Staphylococcus albus*. Phenolsulphonphthalein appeared with fairly good concentration in $3\frac{1}{2}$ minutes from both kidneys. The retrograde pyelo ureterograms revealed the presence of bilateral hydronephrosis and hydro ureter with kinking of the ureters, nephroptosis, and bilateral pyelitis and pyelonephritis. Patient was put on urinary antiseptics, forced fluids and kidney pelvis lavage. On the second visit both ureteroceles were cystoscopically fulgurated. Bladder irrigations and kidney pelvis lavages were continued in order to secure better drainage and relieve infection. Patient showed improvement 2 weeks after the fulguration of the ureteroceles. The urine cleared, cultures became negative and while she still suffers from a mild degree of cystitis due to cystocele she declares her general condition is much better and declines further operation.

CASE 7. Bilateral ureterocele with stone in a female patient suffering from difficult urination, bladder tenesmus and intermittent attacks of complete retention of urine in which urographic studies revealed the presence of a reduplication of kidney pelvis and ureters on both sides opening into two separate ballooning ureteroceles, one of which contained a stone about the size of a pigeon's egg. Diagnosed cystoscopically and relieved by cystoscopic fulguration and litholapaxy.

Mrs. M. G. aged 40 years, complained of intermittent attacks of retention of urine with dysuria, frequency and burning, dribbling and slight incontinence of urine, also of persistent lower abdominal pain for which she had been operated upon for chronic appendicitis without relief. Cystoscopic examination revealed two pedunculated mobile masses in the bladder. The one on the right side was so large that it covered the beak of the cystoscope and suggested a large tumor of the bladder but careful inspection of the left ureteral orifice during ejaculation of urine disclosed the presence there of a small ureterocele. It was then discovered that the large pedunculated mass on the right side was a large ureterocele. Both ureteral orifices were of the pin point type and neither one could be catheterized. Both orifices were fulgurated through the cystoscope in an effort to destroy the ureteroceles and create new ureteral orifices. This was successfully accomplished and 3 weeks later cystoscopic examination showed a good sized stone in the fundus of the

bladder, which had come from the large ureterocele. The stone was crushed with a cystoscopic rongeur and completely removed by cystoscopic manipulations. At a later date both ureters were catheterized with ease and retrograde bilateral ureteropyelograms taken. These films showed a congenital malformation of the upper urinary tract with reduplication of ureters and renal pelvis on both sides with a slight degree of pyelitis, pyeloureteritis, hydronephrosis, kinking of the ureters and right nephroptosis. Due to the presence of this infection a course of cystoscopic treatments was given with dilatation of the ureters and lavage of the renal pelvis. This promptly relieved the symptoms and there has been no recurrence up to the present time. Cystograms were taken which proved to be normal. There was no evidence of vesico uretero renal reflux.

This case illustrates the important rôle played by anomalies of ureters and kidneys in diseases and surgical conditions of the upper urinary tract, which can be cleared up only by proper urologic and surgical treatment.

CASE 8. Left blind ureter in an elderly female patient causing blind ureterocele with complete destruction and calcification of the corresponding left functionless kidney.

Mrs. M. B., 76 years of age, had been suffering from arthritis and complaining of chronic inflammation of the bladder for several years with a high degree of cystitis accompanied by dysuria and frequency of urination. The voided specimen of urine was hazy and microscopic examination of the sediment revealed 50 per cent white blood cells and 10 red blood cells per field. On cystoscopic examination the left ureteral orifice could not be seen in the bladder. The right ureter was normal in location, shape, and position. In the area of the trigone where the left ureteral orifice was supposed to open a slight protrusion or cystic dilatation about the size of an olive could be seen which appeared to be a blind ureterocele. Attempts to catheterize this with all sorts of bougies and catheters failed repeatedly, while the right ureteral orifice was easily catheterized with a No. 6F Chromocysto-coy. X-ray negative in that the administration of the blue dye intravenously showed a good elimination from the right kidney while it failed to reveal any from the left side. X-ray and intravenous urograms revealed the presence of a normal hypertrophic right kidney with good function and normal pelvis but no excretion whatever of the dye from the left kidney in the three hour film. Although in the plain roentgenogram there was evidence of multiple calcifications in the area of the left kidney, surgical treatment was not carried out because of the patient's advanced age and the fact that she was comfortable with bladder irrigations and medical care.

CASE 9. Ureterocele arising from a diverticulum of the urinary bladder into which the minute ureteral orifice opened and which ballooned in and out of the

bladder during peristaltic ejaculations of the ureter or whenever the patient engaged in coughing or other similar muscular activities. Diagnosed cystoscopically and relieved by simple cystoscopic fulguration, subsequent dilatations of the ureter and kidney pelvis lavage.

Mr J W, aged 29 years, complained chiefly of frequency of urination, dysuria, pain in the suprapubic region, lumbago and cloudy urine, which persisted after an attack of gonorrhea. Urinalysis showed microscopic pyuria and hematuria. Rectal examination disclosed a moderate degree of prostatitis and seminal vesiculitis. Microscopic examination of the prostatic fluid revealed 20 per cent pus cells per field. No Neisser gonococci were found in the smear. The cultures were positive for *Bacillus coli*. Cystoscopy revealed slight hypertrophy of the trigone with marked elevation of the interureteric ridge and gradual disappearance of the left prominent angle of the trigone, where the opening of a diverticulum could be seen. During peristaltic contractions of the ureter or during ejaculation of urine or other abdominal contractions, the cyst-like formation could be observed ballooning in and out of the diverticulum (Fig 2). The ureteral orifice on the left side was so minute that it was rather difficult to catch the ureter during the brief moment of its appearance. It admitted a No 4F catheter only with great difficulty, while the right one was catheterized with a No 6F without obstruction. The minute mouth of the ureteral orifice was lightly fulgurated, inserting a small point electrode, after which the patient received a course of cystoscopic treatments with dilatations of the ureters and kidney pelvis lavage. His urine and symptoms cleared up satisfactorily. The conditions improved and he was discharged practically free of symptoms.

SUMMARY AND CONCLUSIONS

The modern concept of ureterocele, together with its diagnosis and surgical treatment, has been outlined.

A new anatomoclinicopathologic classification of the different stages and types of ureterocele has been presented.

The writer has had the opportunity to observe and treat 18 cases of ureterocele, 10 of which were in females and 8 in males.

Of this total, 5 cases were simple unilateral ureterocele; in 4 of these the condition was on the right side and in 1 on the left, showing the predominance of right sided ureterocele. Ten cases were simple bilateral ureteroceles, and included pseudocysts of all sizes, great and small; in all of these the characteristic ballooning and shining appearance of the sac of the ureterocele was demonstrated. Two cases had a stone in the ureterocele and here too the

condition was observed on the right side. There was one case of blind ureterocele in an elderly female patient suffering with arthritis and with radio-urographic evidence of complete calcification of the corresponding functionless kidney.

The condition of ureterocele can be discovered cystoscopically and visualized urographically in a good cystogram. The differential diagnosis from other lesions of the bladder is of importance, and it should always be made in a clear-cut way before operation.

Meatoscopy or careful cystoscopic examination of the ureteral orifices, regarding form, size, position, time of ejaculation and caliber of its lumen, is of great clinical and pathological importance, not only for establishing a proper diagnosis, but also for determining the prognosis of a given case.

Cystoscopic ureteral meatotomy, or opening of the intravesical ureteral orifice in these and similar cases, is of great value, not only because it allows better drainage from the kidney and ureter, but it also serves to prevent and correct the formation of ureterocele.

In this series of cases of ureterocele treated by simple cystoscopic fulguration, no complications have been encountered and the phenomenon of vesico-uretero-renal reflux has not been observed.

The occasional bilaterality, as well as the frequent concomitance of other anomalies, suggests the congenital nature of this malformation of the intravesical portion of the ureter. Certain other etiological forces, however, appear to play a contributory part in the progress of the disease. The paramount factors in the formation of ureterocele thus appear to be (1) the congenital narrowing of the intravesical portion of the ureter with a very minute meatus, (2) congenital weakness or absence of the longitudinal muscle fibers of the terminal portion of the ureter, resulting in abnormal mobility of the trigone, (3) loosening up of the vesical mucosa at the point where the ureter enters the bladder; (4) disturbances of dynamism and hydraulic pressure within the ureter, (5) lack of drainage due to obstruction in the lower ureter, and (6) presence of infection or other concomitant pathological lesions of the ureter and bladder.

In all the cases observed by the author, there was evidence of narrowing at the mouth of the ureteral orifice, causing obstruction, urinary stasis and pyelitis and pyelonephritis and in some of the cases there was urographic evidence of hydro ureter and hydronephrosis.

In one case of bilateral ureterocele, in a woman, the cyst on the right side which was a balloon shaped mass as large as a pear, contained a calculus the size of a pigeon's egg, it produced mechanical obstruction at the internal vesical orifice, resulting in intermittent attacks of complete retention of urine and sometimes dribbling and incontinence. In this case, which was successfully treated by cystoscopic fulguration and litholapaxy, pyelography at a later date revealed multiple anomalies of the upper urinary tract, exhibiting the presence of two kidneys and two ureters on each side in addition to the bilateral ureteroceles.

Another case of unilateral ureterocele was complicated by a small stone about the size of an olive pit, which, after cystoscopic manipulations, was passed without further surgical measures. This patient also showed evidence of multiple prostatic calculi.

Finally, an interesting case was observed of unilateral ureterocele which arose from a diverticulum in the urinary bladder at the left angle of the trigone, and which could

cystoscopically be seen ballooning in and out of the orifice of the diverticulum.

In all the cases of this series the patients were suffering with urinary symptoms, such as dysuria, frequency, urgency, incontinence, pyuria, hematuria, renal and ureteral colic, lumbar and lower abdominal pain, chronic uremia, and, in one case, even complete retention of urine. Nearly all had marked bladder symptoms with chronic pyelitis and pyelonephritis, and in 6 instances there was urographic evidence of marked hydro-ureter and hydronephrosis, which were apparently relieved by cystoscopic fulguration of the ureterocele, dilatations, and kidney pelvis lavage.

While ureteronephrectomy might have appeared to be indicated in some of these cases as in a case recently reported by Gibson, and as I have myself advocated for advanced cases, no true indication for this radical procedure was present in this series, since it was possible in all cases to restore the kidney function to normal and to overcome the urinary stasis and infection by the routine urologic treatment of cystoscopic fulguration with dilatations of the ureters and kidney pelvis lavage. Hence we may believe that in the majority of cases, when the diagnosis is made early, before irreparable disintegration of the kidney has occurred, minor transurethral surgical procedures will achieve permanent cure.

NOTE.—Complete bibliography will appear in reprints of this article.

ASEPTIC NECROSIS OF BONE

II. Infarction of Bones of Undetermined Etiology Resulting in Encapsulated and Calcified Areas in Diaphyses and in Arthritis Deformans

S C KAHLSTROM, M D , Bath, New York, and C C BURTON, M D , F A C S , Dayton, Ohio

D B. PHEMISTER, M D , F A C S , Chicago, Illinois

NO RECORD has been found in the literature of massive multiple infarcts of shafts and epiphyses of bones similar to those reported in Part I occurring in patients who give no history of having worked in compressed air. For that reason the following 3 cases are of particular interest.

CASE 1. T M , a 58 year old, single, white male, was admitted to the Veterans Administration Facility, Bath, New York, November 30, 1934. He had always worked at railroad construction except for a period of military service from 1917 to 1919. His complaints were weakness, shortness of breath, and swelling and stiffness of the left knee. He stated that 18 years previously he had a severe case of "inflammatory rheumatism" which confined him to bed for 6 weeks and he was told that the heart was involved. On admission to the Army in 1917, a heart murmur was present. He had an attack while in the Army with swelling of the left knee but remained on duty. There was a similar attack with the left knee in 1920. Following that he was more or less free until 2 years ago, and worked at railroad construction for a period of 8 years in Siberia and Central America. For 2 years the left knee has been continuously swollen and painful and he suffered from shortness of breath and occasional pain over the heart.

No other serious illness or accidents were reported. Venereal disease was denied. He drank alcohol in moderation but used no tobacco. On examination the well-nourished and developed individual, whose intelligence was above average, presented the following essential findings: Blood pressure, 170/100, some thickening of the peripheral arteries, slight cardiac enlargement with definite thrill and murmur of mitral stenosis, occasional extrasystole, no edema. The extremities were normal except the left knee which was markedly swollen and tender with an extension of the fluctuant swelling upward on the lateral aspect.

Dr. Kahlstrom and Dr. Burton, from the U. S. Veterans Administration.

Dr. Phemister, from the Department of Surgery of The University of Chicago.

Part I appears in the February 1, 1939, issue of this journal.

of the thigh. No abnormal findings of the nervous system were noted. Laboratory examinations were limited to urinalysis and blood Wassermann, which were negative.

Roentgenological examination of the left knee region (Fig. 1) presented a sharply outlined, smooth, mottled, dense interior of the lower 11 centimeters of the shaft and the condyles of the femur. There was a dense narrow zone of demarcation about it and the cancellous bone peripherally located in the epiphysis and metaphysis was less dense than that of the interior. A similarly dense circumscribed central zone was present in the upper end of the shaft of the tibia. The cartilage space and articular cortex of the tibia were practically unchanged.

Roentgenograms were then made of the remaining skeleton, except the hands and feet. A similar central involvement was found in the lower end of the right femur (Fig. 2) and in both ends of the shaft of each tibia. Anteroposterior views of the tibias (Fig. 3) showed the lower limits of the central dense areas at the upper ends terminating hazily above the junction of the upper and middle thirds. The involvement at the upper limits of the shafts of the tibias is seen in Figures 2 and 3. The process was more sharply circumscribed at the lower ends terminating bluntly about 2 centimeters above the ankle joint on the right side and extending to the internal malleolus on the left side. There was a medullary shadow resembling a healed fracture near the middle of the left fibula. No abnormality was noted in the skull, either humerus, radius, ulna, the pelvis or upper ends of the femurs. The lumbar spine showed a hypertrophic spondylitis in its lower portion.

No appreciable change in the patient's condition occurred until April, 1936, when he expired 72 hours after a cerebral hemorrhage developed.

The essential necropsy findings were cerebral hemorrhage, cardiac hypertrophy (580 grams), moderate sclerosis of coronary arteries with patent lumina, myocardium of normal appearance without scarring or fibrosis, chronic nephritis, no signs of infarcts in kidneys, spleen, liver, or intestines, a mild atheromatous change involving the intima of the aorta, much less than might be expected in view of the subject's age, the other larger vessels were essentially normal, adrenals and thyroid normal, parathyroid tumor searched for but not found. Microscopic examination of the myocardium, lungs, liver, spleen,

Fig 1. Case 1. Walled off dense areas in lower third of femur and in upper diaphysis of tibia

hypophysis thyroid prostate and kidneys gave little evidence of old or recent damage to parenchyma and nowhere did the arteries show changes of unusual type suggestive of healed or active rheumatic fever or polyarteritis nodosa.

Skeletal system. There was a moderate hypertrophic spondylitis most marked about the upper dorsal vertebrae. A most interesting lesion of the left knee prevailed. It was swollen and fluctuant the swelling extending about one third the way up the lateral aspect of the thigh. Incision disclosed a large multilocular cyst like projection of the synovial membrane (Baker's cyst) filled with fairly clear yellowish odorless synovial fluid of a syrupy consistency. The lining membrane which averaged 3 millimeters in thickness presented especially in the joint capsule proper innumerable villi averaging 1 centimeter in length yellow pedunculated soft and homogeneous in consistency (Fig 4). There was slight synovial overgrowth of the margins of the articular cartilage with destruction of cartilage in some places. In others the cartilage showed flat nodular hypertrophy.

Microscopic sections of the villi showed them to consist of an interior of vascularized loose connective tissue and fat with a thickened synovial covering and many large to small subsynovial areas of round cell infiltration. The picture was like that commonly seen in chronic proliferative arthritis.

The distal 16 centimeters of the femur was removed. Roentgenograms of the specimen (Fig 5) showed no perceptible changes over those revealed in Figure 1 representing the condition on admission 15 months previously. Coronal sections through the

Fig 2. left. Case 1. Right knee changes similar to those in left.

Fig 3. Case 1. Lesions at ends of diaphyses of tibia similar to those in femur.

bone (Fig 6) disclosed a shaft and condyles of normal diameter. The periosteum was normal in appearance and a viable looking cortex was present which in the region of the shaft consisted of a thin dense outer portion and a less dense lamellated inner portion. Adjacent to the cortex and in the bulk of the epiphysis was viable spongy bone but the central portion of the diaphysis was occupied by a mottled yellowish to dark gray lusterless tissue which extended downward into the central portion of the mesial condyle in this plane and into the lateral condyle in a more posterior plane. Its lower part contained cancellous bone which faded out in the upper portion. This central area was surrounded by a narrow dense dark zone which sharply demarcated it from the cancellous bone externally and from the medullary cavity at the upper limit of the specimen. Microscopic preparations were made of transverse sections of the upper end of the anterior half.

A longitudinal section cut from the remaining portion was roentgenographed (Fig 7) decalcified sectioned in celloidin and stained with hematoxylin and eosin (Fig 8). Microscopic examination showed that all of the bone of the central area within the zone of demarcation was dead. Its trabeculae were of normal size and arrangement but its lacunae were totally devoid of cells.

Fig 4 Case 1 Front and back views of sectioned femur and of villous synovia

Its cancellous spaces were filled very largely with necrotic fatty marrow which had retained to a remarkable degree the contour of the fat cells (Fig 9). In about half its extent and especially centrally the fat spaces were discrete and clear as if still occupied by fat, but the condition was apparently an edema *ex vacuo*. In most of the remaining portion and especially toward the periphery the cell outlines were more or less confluent and occupied by a granular debris or coagulum, stained faintly with eosin. The narrow zone of demarcation (Fig 10) consisted of fibrous tissue filling the cancellous spaces, much of which had undergone very extensive calcification and to a less extent ossification. The calcification was seen to be progressive, especially internally. In some regions a very acellular fibrous tissue extended inward from it, usually for a short distance replacing the dead marrow. Along the mesial side above the middle the fibrous invasion of the dead area was extensive (Fig 6) and at its lower limit there was a transverse streak of calcification extending into it (Figs 7 and 8). All around the periphery of the dead area was more or less extensive granular calcification of the necrotic marrow. This calcification of its limiting wall was mainly responsible for the greater

Fig 5 Case 1 Roentgenogram of excised end of left femur. Like Figure 1, taken 16 months before

density of the shadow of the necrotic area in the roentgenograms. The bone and marrow outside the zone of demarcation were alive with the exception of portions of a few trabeculae along its surface which were dead and in process of replacement by living bone. In the zone of demarcation itself there was also some old dead bone which showed sluggish signs of creeping substitution by new bone (Fig 11). The live bone of the diaphysis surrounding the dead area measured 6 to 12 millimeters and was streaked by wavy longitudinal trabeculae. The cortex increased to normal thickness at the upper limit of the lesion. The trabeculae of the spongy bone of the epiphysis were less dense than those of the dead area above, which suggested that the dead area was originally larger and had been partly replaced by new bone. The periosteum was essentially normal in appearance. It contained a moderate number of arteries and arterioles. An occasional artery showed arteriosclerosis with calcification. No sign of thrombosis or embolism was discernible in or about the necrotic area.

At the articular margins of both condyles there were small osteophytes and villous synovia showing round cell infiltration. The articular cartilage as

Fig 8 Case 1 Microscopic section of slice showing infarct demarcated by dense zone, a

Fig. 9. Case 1. Periphery of infarct showing central necrotic bone *a*, zone of demarcation *b* and surrounding living bone *c*.

Fig. 10. Case 1. Central necrotic bone. Trabeculae not eroded. Outline of dead fat cells preserved in some places *a* but lost in others *b*.

seen in Figures 4, 6 and 8 was somewhat unequal in thickness and at the mesial and lateral margins it had been replaced by fibrocartilage which was continuous over the marginal spurs. There was a variable amount of proliferation, degeneration, fibrillation and cavitation in the more superficial portions of the rest of the cartilage.

The lesion of the femur was a massive infarct of the interior of long standing which had been partly replaced by new bone about its periphery but replacement had practically come to a standstill and the fibrous zone of replacement had calcified and ossified. Since there were no signs of sequestration or of inflammation present it must be concluded that the necrotic area had not been infected. And although there was no pathological examination of the lesions of the other bones, the similarity in roentgenographic appearance leaves no doubt that they were of the same nature and that the condition was that of multiple massive infarction of bone. Since the nature of the condition was not recognized during life there was no special inquiry for etiological factors as work

in caissons or old injury that might have produced symmetrical fat embolism of the bones.

CASE 2. J. J., white male aged 45 years, occupation automobile mechanic entered the United States Veterans Administration Facility, Dayton, Ohio, January 22, 1935, complaining of pain and stiffness in hip, knees and shoulders and swelling of the feet and ankles. He was in military service in 1918-19 and a month after discharge in 1919 developed a lump in the left hip. Although the difficulty progressed it was possible for him to work as an automobile mechanic fairly steadily until 1926. He then developed pain in the right hip and ankle region with swelling of the ankles and had to give up work. Aching pains also appeared in the shoulders more marked in the left. He could recall no injury to any joints. The pain and stiffness in the involved joints had slowly increased since then and he had been unable to work. Several teeth had been extracted because his condition was thought to be due to focal infection. In 1934 he had a sudden attack of dizziness and fell out of a chair. He had remained in general good health.

Past history. He was unusually healthy as a child and had no childhood diseases, no history of rheumatism. His first work was in a machine shop and after that he served continuously as an automobile mechanic except for military service. He did not have worked in a caisson or under increased air pressure in any form.

Family history. Father died of an injury at the age of 74, mother at the age of 76, cause unknown. Four brothers and 1 sister were living and in good general health. One sister died of a tumor at the age of 45 years, 1 brother of a stroke at the age of 57 years. The patient knew of no illness similar to his in the family.

Physical examination showed a well developed and nourished man who walked poorly with the aid of a cane because of pain and stiffness in the lower extremities. The only abnormal physical findings aside from the extremities were perforation of the left ear

Fig. 11. Case 1. Zone of demarcation showing old dead bone *a*, calcified fibrous tissue *b* and living replacement bone *c*.

Fig 12 Case 2 Increased density in humeral head

drum with hearing—left, 15/20, right, 20/20, and several missing teeth. Blood pressure was 160/110. Urinalysis was negative, no Bence-Jones protein. Red blood cells numbered 4,400,000, hemoglobin was 85 per cent, white blood cells, 11,000, no abnormal cells, Wassermann and Kahn tests were negative.

Extremities The upper extremities were free aside from slight limitation in the shoulders, more marked in the left. The lower extremities showed brawny swelling below the calves of the legs. The hips showed marked limitation of abduction and rotation with flexion to almost 90 degrees. No limitation of motion and no tenderness in knees and ankles were revealed, no outwardly visible varicose veins.

Roentgenograms were made of the entire skeleton. The head of the left humerus contained a large irregular oval subcortical area of markedly increased density and there was slight lipping of the inferior margin of its articular surface (Fig 12). The upper metaphysis of the right humerus contained a few, small, scattered areas of increased density, without any changes in the shoulder joint. A roentgenogram of the pelvis showed extensive changes in the hip joints, especially in the heads of the femurs (Fig 13).

Fig 13 Case 2 Old transformed necrotic areas in heads of femurs with secondary deforming arthritis in hip joints

Fig 14, left Case 2 Remnants of old necrotic areas in ends of left tibial shaft casting heavy calcium shadows

Fig 15 Case 2 Remnant of old necrotic area in upper end of right tibial shaft partly replaced by new bone and partly calcified. Mottled central trabeculae at lower end possibly indicate previous necrosis completely replaced by new bone.

The left hip, which had produced symptoms longer, showed flattening of the head of the femur, marked narrowing of the cartilage space of the joint, and marginal lipping. There was a large area of increased density in the head underlying the fovea and extending into the proximal portion of the neck. It was irregularly lamellated near the fovea. Opposite the superior and lateral portion of the head there was an oval subchondral area of reduced density in the acetabulum. The right hip showed little reduction in

Fig 16 Case 2 Areas of increased density in internal and external supracondylar regions and posterior portion of external condyle right femur. Calcified remnants of old necrotic bone

Fig 17 Case 2 Roentgenograms showing areas of increased density in the internal and external supracondylar regions left femur

cartilage space and moderate marginal lipping. At the top of the head there were shadows of two depressed fragmented dense areas consisting of articular cortex and underlying bone which were separated from the remaining head by a zone of reduced density. The surrounding bone extending into the proximal portion of the neck was irregularly increased in density. At the superior lateral margin of the acetabulum there was a large oblong area of reduced density with a surrounding zone of increased density.

The roentgenological findings indicated that there had been extensive necrosis in the heads of the femurs with subsequent breaking down or bony replacement or calcification of the necrotic regions. Two aseptic sequestra had been separated by weight bearing at the top of the head of the right femur and a cavity had formed at the superior and lateral margin of either ilium.

The left tibia revealed a blotchy oblong area of markedly increased density in either end of the shaft as shown in Figure 14. The fibula showed no change. There was a lesion in the upper third of the shaft of the right tibia similar in nature roentgenologically but slightly smaller than that in the left tibia (Fig 15). The lower end of the right tibia showed slight irregularity of trabeculae as if a similar lesion may have existed which had been completely absorbed and replaced by new bone. The lower end of the shaft of the right femur showed 2 central areas of increased density, the larger in the external supracondylar region and the smaller in the internal supracondylar region. The posterior portion of the external condyle also showed an oval area of increased density. The supracondylar region of the right femur showed 2 centrally situated oval areas of increased density, the larger one being lateral and the smaller

medial. The posterior part of the external condyle also contained an oval area of increased density (Fig 16). The supracondylar region of left femur contained 2 irregular oblong areas of increased density, one medial and the other lateral, much larger than those on the right side (Fig 17). The bones and joints of the rest of the skeleton showed no changes except a slight narrowing and bony bridging of the tenth thoracic intervertebral space.

The patient remained for 3½ years in the Facility with but slight increase in his symptoms, and roentgenograms taken at the end of that period showed very little change in the picture.

The diagnosis was made of old multiple aseptic necrosis of epiphyses and diaphyses of long bones of the extremities with secondary arthritis deformans and partial bony replacement and partial calcification of the necrotic areas.

CASE 3. C. W. aged 43 years entered the U. S. Veterans Administration Facility Bath New York July 22, 1938 complaining of pain in the extremities, most marked in the legs. For about 9 months he had had aching pains and a feeling of stiffness in the lower extremities from the hips downward. There had also been neuralgic pains in the upper extremities but apparently much less severe. At no time had he been laid up because of the complaint and he was able to get around with ease.

Past history revealed the usual diseases of childhood, fractures of both bones of both legs at 15 years followed by healing and complete return of function, gunshot wound of left thigh region and right Colles fracture during World War. No other illnesses or injuries were mentioned.

Previous to World War service patient worked as a railroad brakeman and since then as a laborer.

Fig 18 Case 3 Views of right tibia

Fig 19 Case 3 Left tibia

about mines. He had never worked underground or under compressed air and had never had rheumatic fever.

He used alcohol to excess periodically, smoked about 10 cigarettes daily.

Venereal disease denied. No hereditary diseases in the family.

Physical examination revealed a fairly well developed and well nourished man who was ambulant and active and not acutely ill, weight 140 pounds. Blood pressure was 130/84. Regional examination of head, neck, thorax, abdomen, and genito-urinary tracts was essentially negative. A soft mass was present over the back of the right olecranon process. There was no limitation of motion in any joints and no tenderness on palpation of the joints or of the brachial plexus or sciatic regions. The pupils reacted to light and accommodation and the reflexes in the extremities were normal. No disturbance of sensation was elicited. Wassermann and Kahn reactions were negative. Urine and blood examinations revealed essentially normal findings.

Roentgenograms were made of shoulders, chest, lumbar spine and pelvis, shafts of both femurs, tibias and fibulas, and of the right elbow and wrist. They revealed normal bone and joint shadows aside from the shoulders and shafts of tibias and femurs. Shadows of bony calluses were noted at the seats of the fractures in both fibulas and the right tibia. Blotchy areas of increased density were evident in the upper thirds of the tibias as shown in Figures 18 and 19. Similar regions about 2 inches in length were noted in the lower third of the shaft of each femur (Fig 20). Degenerative changes as shown in each shoulder joint also were noted. The rest of the skeleton and the thoracic viscera cast normal roentgenological shadows.

In view of the history and the similarity of shadows of increased density in this and the preceding

cases, a diagnosis was made of old aseptic necrosis of relatively small areas of the interior of the bones with organization by irregular calcification and ossification. No other explanation was found for the stiffness and pains in the extremities. Also there was nothing in the history to which the lesions might definitely be attributed. Judging by the other cases the lesions were of much longer standing than indicated by the history of pains in the limbs over a period of 9 months. However, the patient was unobserving and may have given an incorrect anamnesis.

In view of the great similarity of roentgenological and pathological findings in the first 3 cases and in the 4 cases reported in Part I, the condition might readily be explained on

Fig 20 Case 3 Blotchy increased density in lateral portion of lower diaphysis of each femur

the basis of aseptic necrosis of the bones produced by caisson disease.

In Case 1, which was the first to be examined at autopsy, there was no history of work in caissons but since caisson disease was not suspected during life, no inquiry was made about it. In view of his occupation as a railroad construction worker, there is a bare possibility that the attack of "rheumatism" 18 years before admission was due to caisson disease. In Cases 2 and 3, on repeated inquiry and after stressing the possible etiological relationship no history of work in caissons could be elicited. Unrecognized fat embolism is a possibility to be considered. Case 3 had a severe injury with fractures of both bones of both legs at 18 years and of a gunshot fracture of the left ilium and a Colles' fracture of the right radius at 23 years. Case 1 showed in roentgenograms of the left fibula a transverse shadow like that produced by an old fracture but there were no roentgenographic signs of old fractures in Case 2. No report was found of bone infarction produced by fat embolism but should it occur the lesions might well be as symmetrically distributed as those resulting from nitrogen gas in caisson disease.

That the cause of the necrosis was an agent which interrupted the blood supply without leading to infection of the involved area is indicated by failure of sequestration of the dead bone and by the resemblance of the invasion and creeping replacement of the dead bone to that seen in caisson disease and that reported by Axhausen (11b), Phemister (11, 12), Schmorl, Santos, Gastreich and others in the necrotic head of the femur resulting from intracapsular fracture of the neck. There was a difference in that the fractures were of shorter duration and there was rarely calcification in the zone of fibrous invasion and replacement by new bone.

If the lesions were the result of simple obstruction of arteries, what vessels were involved? In case of the heads of the femurs and left humerus and the external condyle of the right femur the epiphyseal vessels could be blocked as their branches in adults may be end arteries especially in the case of the head of the femur. The lesions in the diaphyses of the tibiae of Case 1 and of tibiae, fibulae and

femurs in Case 2 were in the distribution of the nutrient arteries supplying the ends of the shaft. But the lower epiphyses of the femurs were involved along with the diaphyses in Case 1. Assuming that blockage of the nutrient artery would cause necrosis of the interior of the lower end of shaft of femur, it would be necessary that there be a reorganization of blood supply of the epiphyses after closure of the epiphyseal line in order to have it involved in a system of end arteries with the shaft. While the experimental evidence is somewhat averse to this theory, there are limited but concrete necropsy observations of anemic infarcts in adults involving both ends of shaft and epiphyses.

Kistler blocked aseptically the nutrient arteries of the femur of the rabbit by the injection of finely powdered charcoal which filled the vessels to their finer terminals. When epiphyseal lines were open there resulted necrosis of medullary contents of diaphysis extending sometimes to the epiphyseal cartilage plates and also of the inner one half to two thirds of the cortex. In adult dogs where the lines were closed there was more limited necrosis confined to the medulla away from the ends. Simple ligation or division of the nutrient artery resulted in either much less or no necrosis. This would suggest that obstruction followed by thrombosis extending distally to the terminal branches would be most likely to cause necrosis.

Other evidence that obstruction of the main nutrient vessel at one point would not produce massive infarction is the fact that it does not follow fracture of the shaft of a long bone with severance of the nutrient artery. It is extremely rare that roentgenographic changes are observed after fracture of the shaft of a long bone which give the appearance that necrosis of a fragment has followed as in the case reported by Ransohoff where marked irregular absorption of distal diaphysis suggesting necrosis resulted from fracture just above the middle. But 15 months later it had largely disappeared and 11 years later the roentgenographic appearance was normal showing that if necrosis did occur it was completely repaired and that medullary calcification was not a sequel. Injection studies by

Fig 21 Case 4 Slipped left capital femoral epiphysis with dense areas in weight bearing portion of head and in the metaphyses beneath the greater trochanters interpreted as necrotic lesions, A

Nussbaum, Lexer and others, have shown that during childhood small end arteries enter from the periphery and supply parts of the metaphysis. According to Nussbaum the epiphyseal arteries in childhood are not end arteries. That after closure of the epiphyseal lines end arteries may come into existence which overlap the end of the shaft and the epiphysis is shown by the following classical case of multiple anemic infarction reported by Axhausen.

A 46 year old laborer who died of cirrhosis of the liver had a large infarct in the upper metaphysis of the right tibia and three infarcts of the right femur, one of which involved the head and a part of the neck, one the lower metaphysis and a small portion of epiphysis, and one the mesial condyle bordering on the articular cartilage. They were all relatively recent infarcts with a zone of fibrous tissue in the marrow immediately surrounding the necrotic area in which there was beginning absorption of the dead bone and replacement by newly formed bone. Microscopically there was no sign of infection although *Streptococcus brevis anhemolyticus* grew on cultures of the infarcts. Axhausen considered them due to vascular blockage by emboli which contained the streptococci that were too avirulent to set up infection in the infarcted fields. It should be noted, however, that no emboli were seen in microscopic sections of the infarcts, neither were vegetations noted on heart valves nor mural thrombi on the walls of left heart or aorta.

Axhausen maintained that this case supports the variously advocated view that Legg-Perthes' disease, Osgood-Schlatter's disease,

Koehler's diseases of the tarsal, navicular and metatarsal bones, Kienbock's malacia, and osteochondritis dissecans are anemic infarcts of the epiphyses or short bones. He thought that some are due in part and others exclusively to bland embolism. Freund, Chandler, and others have reported large areas of aseptic necrosis in the head of the femur, sometimes bilateral, arising in adults without known cause. Multiple necrosing lesions of the epiphyses and to a lesser extent of the metaphyses of unknown etiology occurring during adolescence have been reported by Harbin. The metaphysis may be involved without the co-existence of necrosis of its epiphysis as in the following case under the care of Dr. Compere.

CASE 4 A 13 year old girl had slipped epiphysis of the head of the left femur, producing symptoms for 1 1/4 years. A roentgenogram (Fig 21) showed downward displacement of the head of the left femur and flattening and greater density of its weight bearing portion indicative of necrosis. Oblong areas of increased density in the metaphyses were also present beneath the greater trochanters, which were interpreted as having undergone aseptic necrosis and as being in the process of organization. A roentgenogram 16 months later showed that the dense shadows in the left head and subtrochanteric region had disappeared and there was great reduction in density of the shadow in the right subtrochanteric region.

It is conceivable that this same process may occur in adults and affect nutrient arteries as well as metaphyseal and epiphyseal arteries.

As to the disease process which blocked the arteries in the first 3 cases there is even greater uncertainty than as to the exact vessels that were blocked. Embolism and polyarteritis with or without associated thrombosis are the two conditions to be considered. In Case 1 it is fair to assume that the infarction dates from the occurrence of the attack of "rheumatism" 19 years before as judged from the history and the pathology. If the so called rheumatism were rheumatic fever, could it have produced either embolism or polyarteritis in the bones with the resultant infarction?

The old mitral and aortic stenosis may have resulted from rheumatic endocarditis but the vegetations in rheumatic valvular disease are small and firm and are not definitely known to give rise to emboli with resultant anemic infarction. Secondary infection in rheumatic valvular disease by *Streptococcus viridans* gives the picture of subacute bacterial endocarditis often with visceral infarction and a fatal termination in a very high percentage of cases. But no reports were found in the literature of bone infarcts in subacute bacterial endocarditis, although there is little evidence that an extensive systematic search for them has ever been made. A strong point against embolism from thrombi or vegetations in this case is the absence of old infarcts in the other organs containing end arteries. Also the mathematical probability that embolism aside from gas or fat embolism would produce such symmetrical lesions is so small as practically to rule it out.

Arteritis is known to occur in various infectious diseases as shown by the recent review of the literature by Karsner and Bayless. In a complicated case of scarlet fever reported by Høyne there was symmetrical gangrene of the hands, feet, cheeks, and ears. Rheumatic fever commonly produces coronary arteritis as shown by the reports of Von Glahn and Pappenheimer, Karsner and Bayless and others, and sometimes it results in occlusion with or without thrombosis and severe myocardial damage. The peripheral arteries however are much less frequently involved. Von Glahn and Pappenheimer found specific rheumatic lesions of the arteries of the lungs, kidneys, perirenal and periadrenal connective tissues

and testes in 10 of 47 autopsied cases of rheumatic carditis. They consisted of isolated swelling of the endothelium, necrosis of muscle and elastica, fibrinous exudation and cellular infiltration about the periphery. Necrotizing arteries may occur in the aorta and Neale and Whitford reported 2 cases which resulted in rupture of the aorta and death. No report was found of arteritis of the skeletal or any other extremity arteries in rheumatic fever. This fact and the absence of a history of acute arthritis in Case 2 makes it impossible to conclude that rheumatic fever or arteritis was the causative factor in either reported case.

Periarteritis nodosa with or without associated rheumatism produces markedly obstructive lesions which if situated in the bones, might well result in infarction, but the fact that this patient survived the initial attack for 19 years practically excludes it from consideration since periarteritis nodosa is a fatal disease. Arterial spasm as in Raynaud's disease or thrombo angustis obliterans are highly improbable factors.

Small septic emboli, which are the initial stage of perhaps most cases of pyogenic osteomyelitis, result in infarcts in the ends of the shafts of the bones of children. Large septic emboli have been held by Axhausen and Winkelbauer to account for the cases of osteomyelitis with very extensive bone necrosis and little associated pus. However, in these septic cases the area of dead bone is soon more or less absorbed and sequestered and the surrounding bone invaded by the inflammatory process so that the infarct soon becomes unrecognizable. If early death occurs the infarcts may be seen. The case of von Volkmann reported in 1864 was of this kind.

A 12 year old boy died of acute vegetative endocarditis which produced a septic picture with pain, swelling and abscess in the left ankle region. Necropsy disclosed 3 hemorrhagic infarcts of the calcaneus and infarction of the entire talus with surrounding abscess formation. Two large and 9 small infarcts were seen in the lower portion of the left tibia, some of them being in the epiphyses. Also a large infarct was present in the proximal one third of the right ulna. Vegetations on the mitral valves and embolism had resulted in septic infarcts with pus in lung, brain, kidneys and small intestine. As would be expected there was a complete lack of symmetry in the distribution of the infarcts.

The chronic arthritis of the left knee in Case 1 and of hips and shoulders in Case 2 may be explained as in caisson disease on the theory advocated by Axhausen, Wollenberg, and others of primary aseptic necrosis of bone bordering on the articular cartilage of the joint as a result of blockage of its blood supply. Necrosis at the knee may have reached the articular surface in some place at the onset in which case the cartilage suffered necrosis followed by arthritic changes and the synovia became secondarily involved. The case reported by Hirsch and Ryerson of massive aseptic necrosis of a femoral condyle had an associated chronic arthritis. Also fracture of the neck of the femur followed by death of the head and bony union results in late arthritis even when the head becomes replaced by new bone without any collapse as observed by one of us (D B P) in 2 cases.

SUMMARY

A case of symmetrical massive infarcts of bones and chronic arthritis of the knee is reported which came to autopsy and which presented roentgenological and pathological findings of the same character as those reported in caisson disease and published in Part I of this series. Two other cases are reported which presented similar roentgenological findings. In no case was there a history of work in caissons. In Case 1 there was a history of a severe attack of "rheumatism" at the onset. Rheumatic fever producing embolism or peripheral arterial disease and other forms of arteritis obstructing intra-osseous vessels were considered but no proof was found at autopsy that any known disease producing vascular lesions was the cause of the infarction. In the 2 other cases there was no history of disease previous to the onset of the extremity and joint pains which initiated the clinical manifestations. Undiagnosed fat em-

bolism was considered because of the symmetrical distribution of the lesions and of the history of ancient multiple fractures in Case 3 and radiographic signs of ancient fracture in Case 1. The cases are discussed in relation to published reports of idiopathic necrosing lesions of the epiphyses and metaphyses seen not infrequently in late childhood and adolescence, and rarely in adult life. They demonstrate the rôle that vascular blockage followed by aseptic necrosis of bone bordering on joints may play in the causation of certain forms of chronic deforming arthritis.

THE DIAGONAL CONJUGATE VERSUS X-RAY PELVIMETRY

A LOUIS DIPPFL, M D, F A C S, Baltimore Maryland

ALTHOUGH the external conjugate or Baudelocque diameter of the pelvis is still widely employed in obstetric mensuration, there is ample evidence to show that this measurement is totally unreliable as a gauge of the true pelvic inlet. When Baudelocque recommended the measurement some 120 years ago he believed that this diameter was in the same plane as that of the conjugata vera and, as it were, represented simply a linear extension of the conjugata vera anteriorly through the symphysis pubis and posteriorly through the sacrum. Accordingly in order to estimate the conjugata vera, he advised that a figure representing the thickness of the pubis plus that of the sacrum be subtracted from the external conjugate. On the basis of measuring 33 pelvises at autopsy he stated that the figure to be subtracted was 8 centimeters ('trois pouces, 8 1/2 centimeters'). So certain was Baudelocque that the thickness of the sacrum and pubis was constant that he claimed an accuracy in estimating the conjugata vera of ± 2 millimeters (\pm "une ligne," 2.5 millimeters).

It has been known for many years that the obstetrical conjugate and external conjugate are not in the same plane as may be seen in Figure 1, in many pelvises the angle between the two diameters is even greater than is shown here. This fact alone annuls the theoretical basis of Baudelocque's conception. More important is the fact that the thickness of the sacrum and pubis is not constant but shows the greatest variation. As a result of these two sources of error, the amount to be subtracted from the external conjugate to give the conjugata vera is not constantly 8 centimeters but as shown by Dohrn, von Schubert, Skutsch, Thoms, Schumann and Yamabe ranges from 3.9 to 13.0 centimeters.

In a study of 115 pelvises some normal and some abnormal, we have found that the dif-

ference between the external conjugate or Baudelocque diameter of the pelvis and the obstetrical conjugate ranges from 4.93 to 13.5 centimeters. The great variation in this figure is shown in Figure 2, where it may be seen that the difference lay between 7 and 9 centimeters in only 51.3 per cent of the cases; in 11.3 per cent the difference was 6 to 7 centimeters, in 19.13 per cent it was 9 to 10 centimeters. In view of these facts which incidentally are not new but have been known since the days of Baudelocque it is perfectly apparent that the external conjugate measurement is not only useless but may be misleading and might well be discarded as an obstetric procedure.

If it be granted that the external conjugate measurement is of no practical value what measurement of the pelvis shall the practitioner of obstetrics employ in determining whether the pelvic inlet is normal or contracted? This question has been answered by Thoms with the statement that every primigravida should have the benefit of x-ray pelvimetry. It is certain that no method in common use equals x-ray pelvimetry in precision.

Thus Thoms, whose pioneer work in this field represents one of the most important advances in modern obstetrics has shown that the conjugata vera can be estimated by his x-ray method with an error of only 2 millimeters. Similarly Schumann has shown that the Thoms method is accurate to within 2 millimeters. Using the Hodges method of lateral stereoscopic x-ray pelvimetry, we have compared in 25 cases the obstetrical conjugate as measured by x-ray with the actual obstetrical conjugate as measured at operation by a specially devised pelvimeter. The results are shown in Table I where it may be seen that the average error was 0.16 centimeter, and the greatest error 0.3 centimeter in 15 out of the 25 cases the error was less than 0.2 centimeter.

Fig 1 Sagittal view of normal pelvis showing the measurement of the external conjugate or Baudelocque diameter, this diameter does not lie in the same plane as the obstetrical conjugate

For ideal obstetrics then, there can be no question of the validity of these claims that every primigravida should have x-ray pelvimetry. But practically this would mean that some 625,000 x-ray studies on primigravida would have to be carried out each year in the United States alone. If this is necessary for the safety of our mothers, steps should be taken in some way or another to make it possible, but the important question arises, is x-ray pelvimetry necessary in every primigravida in order to determine whether the pelvis is adequate for the purpose of childbearing?

The most important single pelvic diameter in obstetrics is, of course, the obstetrical conjugate or the shortest anteroposterior diameter of the inlet. It is upon this measurement that Michaelis based all our modern knowledge of contracted pelvis. This diameter extends from the sacral promontory to the posterior aspect of the symphysis, but for obvious reasons can not be readily measured directly on the living patient. Since, however, it may be roughly computed from the diagonal conju-

Fig 2 The distribution of the difference between the external conjugate (Baudelocque diameter) and the obstetrical conjugate (x-ray) in 115 cases. Mean difference is 8.53 centimeters, least difference 4.93 centimeters, greatest difference 13.5 centimeters

gate, as may be inferred from Figure 3, this latter measurement, the diagonal conjugate, has served as a basis for our classification of inlet contraction of the pelvis since the time of Litzmann. It will be recalled that the diago-

Fig 3 Sagittal view of pelvis to show the obstetrical conjugate and the diagonal conjugate diameter of pelvis

Fig 4 The measurement of the diagonal conjugate diameter. The tip of the middle finger is held against the sacral promontory, the base of the index finger is elevated to the undersurface of the symphysis and the point where this finger passes beneath the symphysis is marked with the fingernail of the other index finger

nal conjugate measurement is taken as is demonstrated in the accompanying diagram, Figure 4, and as is described in any textbook of obstetrics

In case the examiner can not reach the promontory of the sacrum, he should, nevertheless, direct his fingers toward the promontory and press his hand inward as far as possible. If at this moment he will take the measurement in the usual manner even though his finger has not reached the promontory, he will know that the diagonal conjugate measurement is greater than the figure he has obtained.

The figure to be subtracted from the diagonal conjugate in order to arrive at an estimate of the obstetrical conjugate is variable and depends upon 3 variations of the symphysis pubis, namely, its height, thickness and inclination, and upon one variation of the sacral promontory, i.e., its relation in level to that of the upper border of the symphysis pubis. Of these variations, those relating to the symphysis may be measured with at least some degree of accuracy, whereas the level

of the sacral promontory with relation to the superior border of the symphysis can be estimated only by palpation. As a result, there has arisen considerable difference of opinion as to the exact amount to be deducted from the diagonal conjugate in order to arrive at the value of the obstetrical conjugate diameter.

Basing their calculations on the general development of the bony pelvis or upon the height of the symphysis pubis, Michaelis, Eden and Holland, Edgar, and Polak recommended a deduction of 1.3 to 2.0 centimeters from the diagonal conjugate in order to arrive at an estimate of the conjugata vera. Jarcho uses 1.5 to 2.0 centimeters and these are the factors generally employed by both European and American obstetricians. Yamabe, determining from lateral roentgenograms, both diagonal conjugate and obstetrical conjugate measurements, found a difference varying from +0.5 to +2.4 centimeters with an average difference of +1.48 centimeters. Subtracting as the standard difference 1.5 centimeters from the diagonal conjugate he finds that in 90 per cent of the cases the obstetrical conjugate is obtained within an error of ± 0.5 centimeter. Jacobs found that in moderately contracted pelvis the true conjugate ap-

Fig 5 The distribution of the obstetrical conjugate measurement (x-ray) in 61 cases in which the diagonal conjugate was greater than 11.5 centimeters. Mean length of obstetrical conjugate is 11.41 centimeters, shortest length 10.0 centimeters, greatest length 13.72 centimeters

proaches, equals, or exceeds in length the diagonal conjugate diameter.

It is the purpose of this paper to present evidence concerning the practical value of the diagonal conjugate measurement as an index of the adequacy of the pelvic inlet for childbirth. Does it give the practitioner sufficient information about the pelvis for clinical purposes or should it be superseded, in primigravida at least, by x-ray pelvimetry? The study includes 115 cases in which both the diagonal conjugate diameter and the obstetrical conjugate were measured, the latter from lateral stereoscopic films by the Hodges method.

In 61 cases, the diagonal conjugate measurement was found to be greater than 11.5 centimeters, i.e., it fell within the normal range of this diameter. In 15 of these patients the promontory was palpated, in the remainder it could not be reached but was measured as greater than 11.5 centimeters. Turning now to the obstetrical conjugate measurement in these 61 cases, it may be seen from Figure 5 that this diameter ranged from 10 to 13.72

centimeters. In the whole group there was no case in which the obstetrical conjugate measurement was below 10.0 centimeters, or in other words, no case in which there was an anteroposterior contraction of the pelvis of significant degree. This fact seems to us to have considerable practical importance because it means that the pelvis in which the practitioner has found the diagonal conjugate to be greater than 11.5 centimeters may be regarded as ample for childbirth in its anteroposterior diameter. Thus, in our opinion, a diagonal conjugate measurement which is found to be greater than 11.5 centimeters rules out anteroposterior contracture of the pelvic inlet.

When the diagonal conjugate measurement is 11.5 centimeters or less, it is important to know precisely what this diameter indicates in regard to contraction of the obstetrical conjugate diameter. Within the contracted pelvis range, the question we want answered is: How much is the obstetrical conjugate contracted? We have already indicated that considerable difference of opinion exists concern-

Fig 6 The distribution of the difference between the diagonal conjugate and the obstetrical conjugate (x ray) in 54 cases in which the diagonal conjugate measured 11.5 centimeters or less. Mean difference is +1.6 centimeters. Greatest difference +3.14 centimeters. Least difference +0.2 centimeters.

ing the figure to be subtracted from the diagonal conjugate in order to obtain the obstetrical conjugate. In our total series of 115 cases, there were 54 instances in which the diagonal conjugate diameter was 11.5 centimeters or less. The difference between the diagonal conjugate and the obstetrical conjugate is shown in Figure 6. It is perfectly clear from this chart that this figure is not constant but ranges from +0.2 centimeter to more than +2.0 centimeters. In 27 cases or exactly one half it ranged between 1.0 and 1.6 centimeters, in 15 cases or more than one quarter it was below 1.0 centimeter, in 12 cases or more than one fifth it exceeded 1.6 centimeters. Within the contracted pelvic range then, the diagonal conjugate measurement does not yield the precision we should like in regard to the obstetrical conjugate. Indeed, a diagonal conjugate measurement of 10.5 centimeters may be associated in one case with an obstetrical conjugate of 10.2 centimeters and in another case with one of 8.2 centimeters. In the former instance, the patient would probably deliver spontaneously without difficulty, but in the latter she would likely meet with grave pelvic dystocia.

What then are we to conclude concerning the relative value of the diagonal conjugate measurement and x ray pelvimetry in obstetrics?

As we have indicated, it is our opinion that a carefully performed diagonal conjugate measurement which exceeds 11.5 centimeters rules out anteroposterior contraction of the pelvis. We do not feel that routine x ray pelvimetry is necessary in this class. It should be noted that into this group will fall more than 90 per cent of all white women. On the other hand, when the diagonal conjugate measurement is 11.5 centimeters or less, the information given by this diameter is only of an approximate character. It may be argued that there are so many other factors in labor, namely, the size of the baby and the character of the uterine contractions, that an approximation is enough. We do not agree with this viewpoint. The very fact that these other factors are difficult to evaluate accurately, makes it all the more important, in cases of contracted pelvis, that we should have as precise information as possible concerning the one factor that we can measure with precision. Accordingly, we believe that patients in whom the diagonal conjugate measurement is 11.5 centimeters or below, certainly when it is under 11 centimeters, should be given the benefit of that precision in pelvimetry which only x ray methods can yield.

CONCLUSIONS

- 1 The external conjugate measurement of the pelvis is a misleading obstetric procedure and might well be discarded.
- 2 The diagonal conjugate measurement is of great value for the reason that this diameter, when greater than 11.5 centimeters, rules out anteroposterior contraction of the pelvis.
- 3 When the diagonal conjugate diameter is 11.5 centimeters or less the information given by this measurement is of an approximate character only and x ray pelvimetry is desirable.
- 4 In measuring the obstetrical conjugate the Hodges stereoscopic method of x ray pelvimetry gives an average error of ± 0.16 centimeter and a maximum error of ± 0.3 centimeter.

The author wishes to express sincere appreciation to Dr. J. W. Pierson and his staff for roentgenological assistance.

PAUWELS' RECLINATION, A PHYSIOLOGICAL RECONSTRUCTION FOR NON-UNITED FRACTURE OF THE NECK OF THE FEMUR

GEORGE J. KARFIOL, M D, San Francisco, California

NUMEROUS methods of treatment for non union of the neck of the femur have been advised and employed. Chief among these are (1) those of the osteosynthetic method: sutures, short metal, bone or ivory pins or screws, grafts, Kirschner wire, the Smith Petersen nail, the method of Boehler, Sven Johanson, etc., (2) plastic resections and extirpations of the head, and (3) reconstruction operations such as those of Albee, Brackett, and Whitman, with their various combinations and modifications, as well as those advocated by Froehlich, Spitz, Lexer, and many others.

Although many requirements for an ideal treatment of fractures have been achieved, and many studies have been made of the anatomical conditions of the neck of the femur in relation to the formation of callus, the chances for direct stimulation of such formation have not been improved very considerably. Another approach, therefore, proved to be of great importance in the further development of this problem: namely a method of supportive osteotomy presented by Lorenz and Schanz.

Lorenz rediscovered an operation the description of which was first published in 1894 by Kirmisson in the *Revue d'Orthopédie*. This operation had been used by Hoffa, Drehmann and Froehlich but had been forgotten. Lorenz saw as an important factor of his "bifurcation" the support given to the acetabulum by the angle of the osteotomy fragments. Baeyer who developed the same method, believed the increased tension of the pelvotrochanteric muscles to be the most important factor. Schanz used another osteot-

omy which provided support for the lower border of the pelvis by angulation of the fragments of the femur. Thus subtrochanteric osteotomy, originally worked out for the treatment of congenital dislocation of the hip, results in artificial lengthening of the leg, abduction, and prevention of further upward gliding of the head. Hass modified the method of Lorenz and Schanz and recommended the intertrochanteric osteotomy.

These methods, already suggested as means of support to the pelvis, thereby reducing the weight bearing of the head, and the reconstruction of the physiological relations of muscle, led finally to the work of Pauwels, Camitz, and McMurray.

The operation which Camitz (Gothenburg) described in a publication, 1931, was based on observations on the gliding mechanism of the trochanter, which caused a steady up and down movement in the fracture line, and thus led to resorption and necrosis. Camitz performed a straight or wedge shaped extra capsular osteotomy in the upper part of the femur with an angulation of the fragments of from 20 to 30 degrees in order to restore the support of the weight of the body to its normal place under the center of the acetabulum.

This was also McMurray's idea, and the results of the two operations are almost identical. Both of these methods of osteotomy considered the damaging influence of shearing forces upon the fragments and tried to eliminate them as nearly as possible. One decisive factor in the maintenance of the non union was improved thereby, namely the mechanical alterations and correlations of the fragments. The factor remaining was the ability of the bone to form callus.

Pauwels attacked the problem by constructing new physiological conditions which might, through their mechanical efficiency,

Fig 1, left Drawing showing the direction and quality of pressure, R , acting on the heads of both femurs as the subject stands on both legs S_4 is the point of gravity

Fig 2 Drawing demonstrating the change in the direction of the pressure on the head of the femur as the subject walks R , is the pressure on the head, M indicates the muscle forces in effect, and K , the proportional weight of the body S_5 is the point of gravity

increase the ability of the bone to form callus and, at the same time, give sufficient stability and support to the pelvis. In 1929, he published the first reports on the actual proportions of strength and effectiveness of those forces which influence regeneration of the fractured neck of the femur. In these reports he demonstrated how, depending on their strength and quality, mechanical forces influence the healing process.

The basis of Pauwels' ideas is the law of Roux, the anatomist, namely, that functional pressure promotes the formation of bony callus, while, on the other hand, tension or shearing force not only inhibits the formation of callus but also stimulates the formation of fibrous connective tissue. This law is of special importance in dealing with the neck of the femur because of its particular anatomical construction.

In brief, Pauwels' conclusions on the mechanical relations of the fracture and femoral neck are: The head of the femur is

exposed to a certain amount of pressure in a vertical direction, which changes greatly with the position of the body. Figure 1¹ shows the direction of this pressure, R , with a normal and symmetrical stand on both legs. During the period of standing on one foot while walking the direction of pressure changes as is demonstrated in Figure 2. S_5 is the point of gravity, K the proportional weight of the body, M the effective muscle forces. These relations differ greatly under pathological conditions. In a limping walk due to a disturbance to the hip, the general distribution of forces is as shown in Figure 3, *fi*.

When the neck of the femur is fractured, the general pressure force, R , is divided into two partial forces (Fig. 4), the actual pressure component, P , and a shearing component, S , which has the gliding tendency. Both of these are important because of their biological effect on the formation of new bone, and the course

PAUWELS' RECLINATION, A PHYSIOLOGICAL RECONSTRUCTION FOR NON-UNITED FRACTURE OF THE NECK OF THE FEMUR

GEORGE J. KARFIOL, M D, San Francisco, California

NUMEROUS methods of treatment for non union of the neck of the femur have been advised and employed. Chief among these are (1) those of the osteosynthetic method: sutures, short metal, bone or ivory pins or screws, grafts, Kirschner wire, the Smith Petersen nail, the method of Boehler, Sven Johanson, etc., (2) plastic resections and extirpations of the head, and (3) reconstruction operations such as those of Albee, Brackett, and Whitman, with their various combinations and modifications, as well as those advocated by Froehlich, Spitzzy, Lexer, and many others.

Although many requirements for an ideal treatment of fractures have been achieved, and many studies have been made of the anatomical conditions of the neck of the femur in relation to the formation of callus, the chances for direct stimulation of such formation have not been improved very considerably. Another approach, therefore, proved to be of great importance in the further development of this problem, namely a method of *supportive osteotomy* presented by Lorenz and Schanz.

Lorenz rediscovered an operation the description of which was first published in 1894 by Kirmisson in the *Revue d'Orthopedie*. This operation had been used by Hoffa, Drehmann and Froehlich, but had been forgotten. Lorenz saw as an important factor of his "bifurcation" the support given to the acetabulum by the angle of the osteotomy fragments. v. Baeyer, who developed the same method, believed the increased tension of the *pelvotrochanteric muscles* to be the most important factor. Schanz used another osteo-

my which provided support for the lower border of the pelvis by angulation of the fragments of the femur. This subtrochanteric osteotomy, originally worked out for the treatment of congenital dislocation of the hip, results in artificial lengthening of the leg, abduction, and prevention of further upward gliding of the head. Hass modified the method of Lorenz and Schanz and recommended the *intertrochanteric osteotomy*.

These methods, already suggested as means of support to the pelvis, thereby reducing the weight bearing of the head and the reconstruction of the physiological relations of muscle, led finally to the work of Pauwels, Camitz, and McMurray.

The operation which Camitz (Gothenburg) described in a publication, 1931, was based on observations on the gliding mechanism of the trochanter, which caused a steady up and down movement in the fracture line, and thus led to resorption and necrosis. Camitz performed a straight or wedge shaped extra capsular osteotomy in the upper part of the femur with an angulation of the fragments of from 20 to 30 degrees in order to restore the support of the weight of the body to its normal place under the center of the acetabulum.

This was also McMurray's idea, and the results of the two operations are almost identical. Both of these methods of osteotomy considered the damaging influence of shearing forces upon the fragments, and tried to eliminate them as nearly as possible. One decisive factor in the maintenance of the non union was improved thereby, namely, the mechanical alterations and correlations of the fragments. The factor remaining was the ability of the bone to form callus.

Pauwels attacked the problem by constructing new physiological conditions which might through their mechanical efficiency,

Fig 5 A, Drawing showing a fracture of the first degree, the angle of the fracture line is 30 degrees. Only the pressure force is in operation. B, A fracture of the second degree, the angle of the fracture line is 50 degrees. Only the shearing force *S* is in operation. C, A fracture of the third degree in which the angle of the fracture line is 70 degrees. The shearing force, *S*, and the tension force, *T*, are both in operation.

of the formation of callus. The technical, merely preparatory, procedure of reclamation is accomplished by means of Schanz' high subtrochanteric osteotomy.

The procedure is as follows. The degree of the angle between the line of the fracture and the transverse diameter of the pelvis is determined. The roentgenogram is best taken when the patient is in a standing position with the legs parallel. If such a film cannot be obtained, the method as demonstrated in Figure 7 will give satisfactory results. In order to achieve an angle of less than 30 degrees the number of degrees the fracture line must be decreased is calculated. An osteotomy either straight or wedge shaped is performed below the lesser trochanter. Prevention of later self-straightening of the fragments, as has been frequently seen, makes a removal of a wedge advisable.

The most important orthopedic procedure actually consists in rotating the head of the femur and the fracture line downward to the angle determined necessary for an effective direction of pressure force, this can easily be done by rotation of the head halfway downward and the rest of the correction may be obtained by abduction of the distal fragment of the shaft. The osteotomy fragments are fixed in the desired position. The use of Schanz' screws or pins, which are later incor-

Fig 6 Drawing illustrating the effects of the change in the angle of the fracture line. A shows the normal conditions, the physiological body-gravity, *R*, and its pressure, *P*, upon the head of the femur, the position of the greater trochanter, *T*, and the physiological tension of the pelvotrochanteric muscles. B shows the conditions existing in non-union of the neck of the femur: the free acting shearing force *Ks*, the upward displacement of the greater trochanter and the disarrangement of the coordination of the pelvotrochanteric muscles. C, After the reclamation operation, the pressure force *P*, is again in operation, the free shearing force has been eliminated, downward replacement of the greater trochanter has been accomplished, further displacement is prevented, and the pelvotrochanteric muscles are again coordinated.

porated into the cast, is very helpful. One is driven into the upper fragment, connecting the greater trochanter and the head of the femur, which facilitates the rotation of this part and prevents moving or slipping of the head. The other pin is placed below the site of the osteotomy. These pins not only allow exact measuring of the angulation, but also guarantee dependable fixation. These two factors, rotation of the fracture line and fixation of the osteotomy fragments, are the important features for achieving the expected result of the reclamation.

The rest of this operation is technically very simple. The proximal screw should be inserted at a right angle to the femur. The distal screw is placed at an angle of 90 degrees minus the angle around which the fracture line is to be rotated. This allows the lower screw to be brought parallel to the upper one after the osteotomy (Fig 8). If a wedge shaped osteotomy is done, the point of the wedge should be directly underneath the trochanter minor. It is advisable to make the distal line of the wedge more or less straight transversely with the upper line slanting downward. This will prevent an upward gliding of the distal fragment before the cast is applied.

Fig 3 Drawing showing the distribution of the forces illustrated in Figure 2 in a subject who walks with a limp caused by injury to the hip (see Fig 2)

of the process of healing will be determined by which of these 2 forces is predominant. According to the law of Roux if the shearing force outweighs the pressure force, the growth of bony callus will be prevented but formation of connective tissue will be stimulated. This shearing tendency also causes a tractive force, either of which is able to transform even well developed bony tissue into faulty connective tissue.

The effect of free shearing force varies greatly since it depends on the direction of the fracture line that is the angulation of the fracture line in relation to the transverse diameter of the pelvis. Pauwels proved that this force becomes effective first when the angle is about 25 degrees. At a smaller angle, functional pressure alone acts upon the regeneration. With an increasing angle there is less pressure and increased shearing.

The head fragment can be exposed to 3 mechanical forces different in principle: namely, pressure, shearing and tension. For purposes of prognosis and therapy, therefore, 3 groups of fractures can be distinguished: (1) Fractures of the first degree in which the angulation of the fracture line to the transverse diameter of the pelvis is 30 degrees or less. The mechanical force results in functional pressure only or at least predominantly upon the zone of regeneration. (2) Frac-

Fig 4 Drawing showing the change in the pressure force after fracture of the neck of the femur. R (see Fig 1) is now divided into the pressure component P , and a shearing component S .

tures of the second degree with the angle of the fracture line above 30 degrees. The mechanical force in this fracture is free shearing, S , and the force of pressure does not operate. (3) Fractures of the third degree in which the fracture line is usually above 70 degrees. In these cases the mechanical force is that of free shearing S , combined with traction or tension, T , thus constituting two injurious forces (Fig 5).

As Pauwels found that free shearing force is almost eliminated when the angle of the fracture line is less than 30 degrees, any therapeutic procedure should diminish the existing angle to one of 30 degrees or even less so that only the pressure component will act upon the fragments. The operation fulfilling these conditions is called "reclination". Its object is to transform the existing fracture into a fracture of the first degree according to the classification given above so that the mechanical force, existing in the non union, is changed from shearing or tension to functional pressure. The operation of reclination is therefore different from all other methods because instead of merely applying support to the fracture in an attempt to induce healing, this operation utilizes a new principle: functional pressure as a healing agent.

The orthopedic significance of the Pauwels operation is the change in the mechanical set up to obtain a physiological basis for the healing of the fracture. The angle of the fracture line in relation to the transverse diameter of the pelvis is changed so that it becomes less than 30 degrees. This leads not only to correction and adjustment of anatomical features but also to a physiological stimulation

injury does not seem to make much difference in the final result, in the literature are reports of cures 2½ years after the fracture. One of my own patients (Case 1) was operated on 6 years after injury.

As has been explained, reclamation is expected to result in physiological stimulation of the formation of callus and stabilization of the fracture. Moreover we find the following secondary results no less important: (1) increased abduction of the injured leg; (2) lengthening of the leg to partial or full correction of the shortening, and (3) disappearance of the Trendelenburg phenomenon.

The elimination of the shearing force is the primary requisite for a successful osteotomy of the neck of the femur. The various types of osteotomy advised for these non-united fractures have proved successful for the most part. Although devised primarily to relieve the head of the femur by giving additional support, they also resulted usually in the elimination of shearing forces. It is this feature which made them successful. Gaenslen, who first mentioned the name of Pauwels in the American literature, advocated Schanz's high subtrochanteric osteotomy, "provided that the distal fragment of the neck can be so placed as to provide an under pinning for the head and, therefore, an elimination of the shearing action at the fracture site." While this is possible only when the angle of the fracture line is reduced, Pauwels' reclamation has the latter as its starting point. Naturally, there can be no one method of treatment for the non-united fracture of the neck of the femur, for every different kind of fracture has its special mechanical correlations. It is necessary, therefore, to know the acting forces and their mechanical effectiveness in each case.

The results of the reclinations done so far have proved very satisfactory. The comparatively simple procedures which make the exposure of the joint, capsule, or fracture line unnecessary, considerably reduce the risk of any major operation of this type.

It has been demonstrated that after the reclamation operation, even a fibrous union may be transformed into real bony tissue which is proof of the effectiveness and im-

Fig 8 A, left The proximal screw should be inserted at a right angle to the femur, and the distal screw at an angle of 90 degrees, minus the angle around which the fracture line is to be rotated. B, After the osteotomy the 2 screws are parallel.

portance not only of the mechanical forces but also of the change and restoration of the physiological forces. The knowledge that mechanical forces decidedly influence the healing process of the fractured neck of the femur brings the problem considerably closer to a solution, improves the prognosis, and after more experience, will probably greatly affect our indications for operation.

CASE HISTORIES

CASE 1 (Figs. 9, 10) S. M., a tailor, 52 years of age, was first seen in September, 1935. Six years previously he had fractured the neck of the left femur. He wore a cast for 3 months, then began to walk with a spica cast applied from hip to knee. After 2 months of this, he walked with crutches and later with a cane. He was unable, however, to walk more than 3 or 4 blocks without becoming tired and suffering pain in the left hip. This had become worse during the last 2 years.

On examination, the left leg was found to be 1½ inches shorter than the right and the muscles were atrophied. Flexion of the hip joint was 25 degrees, abduction 20 degrees, and adduction 15 degrees. The Trendelenburg phenomenon was positive. X-ray examination showed a non-united fracture of the neck of the left femur.

Pauwels' reclamation was done on October 29, 1935, and, on December 10, the cast was removed from the knee down. Six days later the screws were removed and, on December 24, the remainder of the cast was taken off. Within a week the patient was allowed to sit on the side of the bed, and on January 1, 1936, he was able to walk with crutches. On the sixteenth he was discharged from the hospital, using canes. One week later he returned to his work as a tailor and, a month after his discharge from the hospital, he was able to walk without the use of a cane.

Fig 7 Drawing to illustrate the calculation necessary for the Pauwels operation A The angle of the fracture line to the transverse diameter of the pelvis is 60 degrees B The angle of the fracture line is rotated so that it be

comes less than 30 degrees (in this instance 25 degrees) A rotation of 32 degrees was required C To accomplish the rotation required a wedge with an angle of 32 degrees at the point is removed D The end result

One of the advantages of this operation is that minor technical failures do not affect the end result. In the first case done in California the displacement mentioned occurred—that is, slipping of the distal fragment. The x-ray film (Case 1) showed a result almost like that of a bifurcation yet there was no delay or disturbance in healing. Neither does it matter whether the site of the osteotomy is chosen slightly above or below the determined place, a factor which in other types of procedures may doom the operation to failure.

In addition to those mentioned, other advantages are. The original fracture and the osteotomy fragments are firmly fixed by means of the pins or screws which are incorporated into the cast (a single spica including the foot). Any motion of the fragments is prevented and the patients suffer no pain. They can easily be moved in bed without great discomfort so that the treatment during the entire period in which the cast is on can be managed easily and comfortably. The patient can be turned upon his abdomen frequently if he chooses or if delayed bowel movement makes it necessary.

In the average case a slight formation of callus around the osteotomy should be present by the sixth week after operation. At this time the screws are removed. Two days later

the cast is opened and the patient remains for 2 or 3 days in the lower shell which is then removed. Almost from the beginning the patient is advised to exercise his quadriceps muscles and is taught to do so. In most cases I removed the lower part of the cast, from the knee joint down about the third or fourth week and advised exercises to prevent stiffness in the knee after removal of the cast. Such stiffness will delay the entire progress. After the seventh or eighth week the patient should be able to be out of bed part of the time. Any forced movements are strictly forbidden. The patient may receive some heat and careful massage and should be able to move about on crutches after 5 or 6 days. After walking about 2 weeks with crutches in the hospital he should go home with canes that is at or about the tenth week after operation.

It is not necessary to wait until callus has formed in the fracture; this usually takes several months, but in spite of this fact the bearing power of the injured leg will develop surprisingly fast and a comparatively fast resumption of work can be expected. A tailor (Case 1) and a secretary (Case 2) were able to work 12 weeks after the operation. Patients between the ages of 12 and 65 years have been operated on and no failures have been reported so far. The length of time after the

Fig 11 (Case 2) A, Roentgenogram showing the patient's condition before operation, 2½ years after injury

B, Roentgenogram taken 5½ weeks after operation
C, Roentgenogram taken 15 months after operation.

tion was performed and a cast applied. The patient used a walking caliper brace until May, 1937, when the roentgenogram showed non-union still present.

On May 24, 1937, Pauwels' reclination was done. On July 8, the screws were removed and 1 week later the cast was taken off. Within a week he was able to walk with two crutches and early in August he used only one cane. In October, he was discharged to return to duty which would not require long periods of walking or standing.

CASE 5¹ Mrs T B, 45 years of age, had a fracture of the neck of the left femur on December 24, 1936. It was reduced and a cast applied. The patient remained continuously in bed for 5 months when x-ray examination showed non-union of the fracture.

On May 24, 1937, Pauwels' reclination was done. On July 8, the screws were removed and 1 week later the cast was taken off. The osteotomy had united, but there was a contracture of the left knee, the

¹Patient of Dr E M Townsend

right knee was slightly affected also. The patient was very nervous, both legs were tender, and she refused to attempt any exercises. For many weeks she could not stand, even with the support of crutches. By December, 1937, however, she was able to walk comfortably on crutches.

CASE 6 (Fig 13) Mrs G B, 36 years of age, sustained a fracture of the neck of the right femur in March, 1933. Traction was used, then a Whitman cast, and finally a supportive walking brace. A roentgenogram made in January, 1934, showed non-union. Pauwels' reclination was done on April 11, 1934, and the patient left the hospital 10½ weeks later. Within 4 months after discharge she was able to engage in her usual activities.

CASE 7² (Fig 14) G D, a lumber worker, 56 years of age, fractured the neck of the right femur on April 11, 1937. A Whitman cast was applied, but on July 28, no union had occurred. Pauwels' reclina-

²Patient of Dr John and Dr Edward LeCocq, of Seattle

Fig 12 (Case 2) A, Before operation, B, 15 months after operation

Fig 13 (Case 6) A, left Roentgenogram 9 months after accident, before operation, B, 6 months after operation

Fig 9 (Case 1) A Roentgenogram showing the condition before operation more than 6 years after the accident B, 4 weeks after operation C 1 year and a half after operation

Examination 9 months after his discharge showed the left leg to be only half an inch shorter than the right abduction was 40 degrees and the Trendelenburg phenomenon was negative He was able to stand on the left leg without difficulty and walked with no pain or discomfort His limp was very slight

CASE 2 (Figs 11, 12) Miss H C 30 years of age fractured the neck of the right femur in October 1933 She wore a cast for 3 months but had no further treatment She used crutches for 5 months Fourteen months after the injury she first noticed discomfort and a cracking sound in the right hip which disappeared Six months later discomfort and the cracking became worse so that she began to limp and within a few months she was unable to walk without crutches She could bear no weight on her right leg

Examination in February 1936 showed the right leg to be $1\frac{3}{4}$ inches shorter than the left and muscular atrophy was noted There was no abduction or rotation and flexion was limited to about 60 degrees X-ray examination showed a non united fracture of

the neck of the right femur with atrophy of the head and arthritic changes of the head and acetabulum

Pauwels reclinination was done on February 5 1936 After 4½ weeks the lower part of the cast was cut off and the screws were removed a week later The remainder of the cast was taken off on March 21 Because of pyelitis and nephrolithiasis the patient was unable to be out of bed until April 1 when she began to walk with crutches Two weeks later she was discharged from the hospital able to walk with the aid of 2 canes and by May 1 she resumed her work as a secretary

This patient was examined again on July 1 1936 At that time she walked comfortably without support suffered no pain and had a scarcely perceptible limp The right leg was about three quarters of an inch shorter than the left The Trendelenburg phenomenon was not evident

CASE 3 F W B, a painter 49 years of age suffered a fracture of the neck of the right femur in May 1935 Traction was applied and a Thomas splint was used A week after the accident, a Whitman reduction was performed and a cast was applied In September he began to walk on crutches with the aid of a caliper brace Two months later a roentgenogram showed non union and an increased absorption of the neck of the femur

On December 5 1935 Pauwels reclinination was performed and on January 17 the cast was removed from the knee down On January 31 the screws and the rest of the cast were removed Four days later he was able to be up on crutches He had unusual difficulty in adducting the right leg and flexing the right knee On March 20 1936 he was discharged from the hospital At present he has neither pain nor discomfort and walks with a very slight limp

CASE 4 F F a seaman 22 years of age fractured the neck of the right femur on August 28 1936 Traction was employed for 1 month then manipula-

Fig 10 (Case 1) Nine months after operation

ing to non-union. Their damaging action cannot only be eliminated but can actually be transformed into physiologically important pressure forces by changing the mechanical requirement, that is by decreasing, to less than 30 degrees, the angle of the fracture line to the transverse diameter of the pelvis. This operation, called reclination, is accomplished by means of Schanz' high subtrochanteric osteotomy.

The results expected and obtained in all the patients operated on so far, are

1. Physiological stimulation of the formation of callus as a result of the elimination of the shearing forces and the substitution of pressure forces upon the fragments

2. Prevention of further displacement through upward gliding of the fragment of the shaft

3. Stability of the affected leg with the safe bearing of weight

4. Reconditioning of the pelvotrochanteric muscles

5. Downward replacement of the greater trochanter

6. Increased abduction of the injured leg

7. Artificial lengthening of the leg

8. Disappearance of Trendelenburg's phenomenon

In addition the reclination operation has certain advantages not found in other methods

1. The operation is technically simple and can be performed in a comparatively short time

2. There are few chances for technical failure

3. There is little pain after the operation

4. The management of treatment during the period when a cast must be worn is easy, as is the after-treatment

5. The period of hospitalization is comparatively short, (usually from 10 to 11 weeks)

6. Early bearing of weight may be permitted, it is not necessary to wait for the formation of callus

7. The patient may return to work comparatively early

I wish to express my thanks to Dr L. D. Prince, Dr E. M. Townsend, chief surgeon of the U. S. Marine Hospital, San Francisco, and to Dr John and Dr Edward LeCocq, of Seattle, for their co-operation in allowing me to use their material for operation and presentation of these cases

Fig 14 (Case 7) A Roentgenogram taken 3 months after the accident before operation B, Roentgenogram taken 3 1/2 weeks after operation C Roentgenogram 8 weeks after operation

tion was done on August 1. Seven weeks after operation the screws were removed and a week later the cast was taken off. Two days after removal of the cast the patient was up on crutches. On October 6, however, the patient was dropped by a hospital employee and had to be kept in bed for several weeks. He was discharged from the hospital on November 3, 1937, still using crutches. By January, 1938, he was able to walk without support.

All these patients had satisfactory results as to the expected features. The youngest patient was 22, the oldest 56 years of age. The latter (Case 7), was operated on soonest after injury (4 months). It was felt that the delayed union would lead to a long period of disability even if a later union should occur, and that the operation might shorten the convalescence. Case 1 is interesting because it demonstrates that, even 6 years after the fracture, the defectively built union between neck and head was gradually being transformed into bony callus. Because of the increased stability after the operation, this man as well as the patients described in Cases 2, 4 and 6, were able to start work long before the formation of callus was evident in the roentgenograms.

Two patients had never walked during the time between the accident and the operation. A third one walked a few months with crutches and caliper brace (Case 3). He had

difficulty mostly in adduction of the affected leg and flexion of his knee joint which caused some delay in his return to work. Stability and weight bearing were satisfactory about 10 weeks after the operation. In Case 5 there was an unusual weakness and atrophy of both legs as well as stiffness of both knee joints. Several weeks after the cast was removed sufficient stability of the leg could be proved, weight bearing was possible, and passive motions in all directions had greatly improved. Yet there was extremely slow progress in walking. In Cases 3 and 5, the full length of the cast was kept on for about 1 week, a fact which indicates the importance of the early use of motion and exercises, especially of the knee joints. Even though the patient might be slightly more comfortable in the full length of the cast, it is advisable to remove the cast from just above the knee downward at about the third to fourth week. This procedure is particularly wise in those patients who, before the operation, show either marked muscular atrophy or limitation of the mobility of the knee.

SUMMARY

Pauwels found that shearing and traction forces decidedly hinder the healing processes of the fractured neck of the femur, thus lead

considered mentally and physically unsuitable for they will prove as unsatisfactory as do similar patients with any plastic operation. The complications to be feared should be carefully explained to the patient before operation. In our experience they have not been serious but may be troublesome. Despite the magnitude of the operation there has been no mortality and the dangers are purely those of a general surgical nature. The commonest is necrosis of areas of the skin flaps used in the reconstruction, but with improvement in technique and care taken not to make these skin flaps either too thin or too long this should rarely occur. Partial necrosis of the pedicles or the nipple is now a rare complication and occurred more frequently when the external breast pedicle was utilized. Despite the size and importance of the long thoracic artery, its value as a source of supply to the nipple and areola is not great. The nipple largely depends on the perforating branches of the internal mammary artery. Partial necrosis of the breast pedicle itself is unquestionably the result of bad technique. Either the blood supply has been cut down too much, or the pedicle rotated too abruptly with interference to the blood supply. Hematomas may occur but are unusual if hemostasis has been carefully attended to and drainage instituted for 48 hours. Sepsis is uncommon and is usually the result of a hematoma or an infected stitch. The treatment of these complications will be dealt with later.

PRE-OPERATIVE PREPARATION

On the evening before operation the entire chest, back and front, is prepared together with the arms and upper part of the abdomen, ether, soap, and spirit being used. The whole area is painted with acriflavine solution 1:1000 and covered with a sterile jacket. This treatment is again applied on the operating table.

OPERATING PRINCIPLES

The surgical ideal is not only to reduce the breast to a normal size but to restore it as far as possible to its classic shape, retaining as much of its normal function as possible. To do this the breast tissue and the covering skin constitute two separate problems. Reduction in the amount of breast tissue is carried out in two ways:

a Resection of the lateral half of the breast preserving the perforating branches of the internal mammary artery to form a freely vascular internal pedicle with the nipple and areola near the most dependent portion.

b Resection of the upper and middle portion of the breast to form a double shaped pedicle so

Fig 1 Operative position half sitting with arms spread to give access to axilla. Breasts dependent.

preserving the lateral thoracic artery in addition to the medial blood supply and carrying the nipple at the apex of the U.

Reduction of the covering skin has also taken two forms:

a A single upper flap through which the nipple is transposed thus giving a single transverse scar in the submammary line.

b Double lateral flaps with excision of an inverted V shaped portion between the nipple and the transverse submammary incision. The former is to be preferred if the transverse scar can be made so short that it does not project into the axilla. It is inconspicuous, does not limit movement in the breast in any way, and except in its most lateral portion is not usually hypertrophic in character. Two stages are almost always required for its satisfactory use. The latter has the advantages of producing a better shaped breast with a shorter submammary transverse scar, and the operation can more frequently be performed in one stage than with the single upper flap.

SELECTION OF TYPES OF OPERATION

The internal pedicle is used in almost all cases and has been found entirely satisfactory as a means of preserving the blood supply of the nipple. The double pedicle has its particular field in those cases in which general obesity is a factor and in which a well marked axillary fold is characteristic of that individual. Here it is as well to make a breast in keeping with the type of body habitus of the patient rather than attempt to construct something of more classical proportions. Formerly we adhered as far as possible to the single upper flap method of skin reconstruction because we felt that the cosmetic result was better without a vertical scar and the liability to skin necrosis less. Since we have adopted the manual method of skin separation, however, necrosis has practi-

CLINICAL SURGERY

FROM ST BARTHOLOMEW'S HOSPITAL

THE TECHNIQUE OF MAMMAPLASTY IN CONDITIONS OF HYPERTROPHY OF THE BREAST

SIR HAROLD GILLIES, CBE, FRCS FACS (Hon), and
ARCHIBALD H McINDOE MS MSc, FRCS FACS, London England

TODAY there is little need to justify plastic surgical procedures on the pendulous breast. It is a field as genuine as any other in reconstructive surgery provided its limitations are recognized and the cases are carefully selected. Mammary hypertrophy and ptosis probably result from hereditary influences, glandular excesses or deficiencies, repeated pregnancies, obesity, or other factors acting on a poorly fixed structure. A constantly repeated series of physiological changes gives little opportunity for the recovery of lost tone. The retro-mammary fascia and suspensorium mammae are in themselves weak supports and are unable to sustain any prolonged increase in the weight of the breast. The skin, probably the most important of the fixative structures, must retain its tonal quality and elasticity if increase in gland weight is not to be followed by stretching and mammary descent. The difference between the ordinary ptotic breast and the huge hypertrophy of gynaecomastia is probably determined by these hereditary and mechanical factors and the degree of endocrine influence.

TYPES OF MAMMARY HYPERTROPHY

- 1 Long flabby pendulous breasts with or without glandular hypertrophy of the most dependent portion and characteristic of the adolescent girl of otherwise normal build. Such breasts in all probability are of purely hereditary and endocrine origin.
- 2 Broad heavy breasts which develop with obesity and are associated with it and with pregnancy.
- 3 Sac-like dependent breasts following obesity, reduction and pregnancy.
- 4 True gynaecomastia. A hypertrophic condition of the glandular elements of the breast resulting in one of enormous proportions. These cases are not common.

5 Asymmetry. This is probably a congenital deformity.

Primarily the indications for operation are concerned with the undesirable symptoms produced by the size of the breasts themselves i.e. weight, general tiredness, backache, faulty posture, sub-mammary intertrigo and so forth. Many of these enlarged breasts are painful, and the patient can be observed in the out-patient department of the hospital supporting the breast with her hand while waiting for examination. Limitation of social activities are of importance, for riding, swimming and dancing become impossible and the patients often exhibit psychic disturbances as a consequence. It is prudent, however, to be cautious with many of these patients for we are dealing with a type in whom no plastic operation should be undertaken without great circumspection. It is important to discriminate carefully between those who will derive lasting benefit and happiness from operation, and those who will never be satisfied whatever is done. The procedure should be fully explained to the patient and the nature of the scars shown to her, if possible by means of photographs, so that she fully realizes what the end result will be.

This is an operation of considerable magnitude. It is done largely for the comfort of the patient so that if it is worth while the risk must be correspondingly small. The patient must be in good health prior to operation and the operation itself conducted under ideal circumstances. Complete physical examination should be insisted upon and the co-operation of the patient's general practitioner sought in order that nothing is overlooked. Operation should not take place during the menstrual period. Patients in poor general condition and particularly those of asthenic habits with bad skins should be avoided or given an opportunity of putting themselves in the best possible condition. One should eliminate those who might be

Fig 3 a, Even and firm stretching of nipples by assistant, circumcision of areola b, Double upper flap method c, Single upper flap method d, Superficial undercutting of skin surrounding areola, thus avoiding injury to subareolar plexus of vessels e, Application of four forceps at indicated points Extension of undermining at deeper level

from the new nipple position to the top of the areola, and from the bottom of the areola downward to the submammary groove. It is better to mark out on both sides with Bonney's blue all proposed incisions before the skin is actually cut in order that no mistakes be made in the symmetrical placing of the breasts. These markings, however, must be used rather as an initial than as a final guide, for minor alteration may be necessary when the skin flaps are eventually adjusted to fit the breast tissue (Fig 2).

Operative details The areolæ are now circumcised superficially and the skin undermined for a distance of half an inch laterally without damage to the subareolar plexus of veins. The vertical or transverse line is opened and preparations are made for the separation of the breast tissue from its skin covering. Formerly this was carried out by undercutting with a knife, a procedure associated with considerable blood loss and much shock to the patient. It has been supplanted by an almost bloodless method which can be rapidly

Fig 4 a, Separation of breast tissue from skin by stripping with gauze b, Incision line for formation of internal pedicle c, Incision lines for double breast pedicle

performed. After the preliminary periareolar undercutting has been done, the gland is separated from the skin by blunt dissection with gauze held in the fingers almost in the same way as one would skin a rabbit. It will be found that the breast shells out with ease and with a minimum of bleeding, thus leaving the important subcutaneous plexus of vessels attached to the skin. The few bleeding points are secured and tied (Figs 3 and 4).

The formation of the breast pedicle The internal breast pedicle is made by an S shaped incision which begins along the lower border of the second rib, sweeps down vertically at the level of the inner border of the areola, turns laterally to skirt the nipple, and is carried off medially to the end of the pendulous breast. The double pedicle is made by the removal of a V shaped portion of the upper middle segment of the breast followed by complete mobilization of the inner and outer pedicles which are reduced in size to form a U shaped tube of breast tissue carrying the nipple at the apex of the U. In the case of the single internal pedicle, it is rotated upon itself laterally until the nipple corresponds to the position as marked on the skin,

Fig 2 a Determination of new nipple position by intersecting circles using the suprasternal and xiphoid notches as centers. Radii vary with body habitus but are within limits indicated b and c Position of scars after operation b after double flap operation c after single flap operation In both cases nipples look forward and outward

cally disappeared so that the lateral flap method which does not require a secondary operation so frequently is becoming more popular. There are two absolute indications for its use: (a) In moderate degrees of ptosis when the upper flap is so short that the new position of the nipple is too close to the submammary incision; (b) when the submammary incision would otherwise be too long and reach into the axilla.

Anesthesia. Light general anesthesia—gas and oxygen superimposed on preliminary avertin or evipan—is used routinely, as little ether being used as possible. If this is given through a nasal intratracheal tube the draping of the operation field is greatly facilitated and the proximity of the anesthesiologist to the operative field dispensed with.

Position on the table. It is an advantage to use an operating table which breaks in the center so that the two ends can be elevated to give a semi-sitting position with the patient's chest at an angle of 45 degrees to the horizontal. Thus the breasts fall into their normal dependent position and the measurements for the position of the nipples can be more carefully made. With the anesthesiologist supporting the head and a nurse pulling forward on each arm the anesthetized patient is drawn up into full sitting position and the skin of the entire chest and upper back again sterilized. She is then laid squarely back on a sterile sheet placed beneath her, care being taken to see that the shoulders are level. The arms are then placed akimbo with the hands behind the hips. The anterior surface of the chest is towelled off from the sternal notch above to the upper abdomen below, and laterally excluding the axillae and arms. If this is done symmetrically the accurate placing of the breasts will not be confused by extraneous irregularities (Fig 1).

Measurements for the nipple positions and marking of incision lines. A great number of methods have been described for the accurate placing of the nipples. Some of them are complicated and difficult to apply. While it is true that an appreciation of the classic form is probably helpful in deciding this point, some form of accurate measurement should be made to avoid mistakes in the level of the breasts and the internipple distance, for an error of half an inch becomes painfully apparent at a later date. Unquestionably the patient's general configuration, size and body habitus must be taken into account. Assuming that the levels are correct, the commonest mistake is to get the nipples and breasts too close together. We have found a large compass of great aid in calculating the new nipple position. Using the sternal notch as the center a circle is drawn with a radius varying between 6 to $7\frac{1}{2}$ inches depending upon the height and shoulder width of the patient. This is intersected by a second circle on the xiphoid notch as center with a radius half an inch less than the previous circle. The intersection of the two circles gives the approximate position of the nipples. The internipple distance should rarely be less than 9 inches and minor corrections can be made according to the judgment of the surgeon. The new position for the nipple is then marked by stabbing the skin with Bonney's blue. The assistant then stretches the areolae tightly and evenly with two hands and a $1\frac{1}{4}$ inch circle is drawn round them with a smaller compass. This particular measurement varying in accordance with the wishes of the patient. If the single upper flap method is to be used a transverse line with its convexity upward is marked out from the inner end of the submammary groove. If the second method is to be utilized a vertical line is made

Fig 7 Double upper flap method a, Skin flaps held with forceps fitted round cone of breast tissue Marking of excision line b, Removal of excess skin to form double upper flap Insertion of upper and lower sutures Cutting off apex of cone to expose nipple c, Suture of nipple and vertical scar

gauze dressing is then applied with mastisol fixation, and this covered with wool and bandage

Possible second stage operation Three to 4 months after the first operation the condition is reviewed and careful note made of any irregularities of contour or scars The latter can be excised and sufficient skin lifted to enable redundant areas of breast tissue to be removed At the same time the transverse submammary scars can be placed accurately in the submammary groove, and the closure effected by means of subcuticular sutures As a rule no drainage is required at this operation As a preventative against the development of keloid scars a dose of x-rays may be given one week before and one week after this operation

POSTOPERATIVE CARE

It must not be forgotten that some of the factors which produce shock are present, loss of body heat, extensive tissue exposure, and loss of body fluid. In our clinic the patient is transferred from the operating table into a warm bed brought into

Fig 8 a, Dependent excess of skin drawn downward and marked for excision b, Excess turned upward and completion of marking in submammary groove c, The same process is carried out in the single upper flap method

the theater at the end of the operation No further lifting or disturbance is necessary for some hours Postoperative rectal fluid is always given as a routine and consists of hot tap water given by the drip method Sedative drugs can be given as indicated As soon as the patient is fully conscious she may be raised from the prone to a sitting position. The first dressing should be done at the end of 48 hours, when if indicated the tubes may be removed Routine cleansing of the whole area with saline and subsequent drying with spirit is all that is required Stitches must be removed in a good light with toothless forceps and fine sharp pointed scissors The alternate sutures round the nipple may be removed on the fourth day, and on the fifth day the remainder may come out together with a few from the main scars All the stitches from the latter should be out by the tenth day, the last being those bearing tension at the corners of the flaps Subcuticular stitches will also come out easily by this time, but must be left longer if they will not slip out painlessly. After final removal of stitches application of a little sterile paraffin will soften and cleanse the scars

Fig 5 a Formation of internal pedicle of left breast. Deep incision to expose pectoral fascia. Hand holds part to be removed. b Internal pedicle complete. Rotation indicated. c Formation of double pedicle following removal of upper central portion of breast tissue.

Fig 6 a Rotation of pedicle and correct placing of nipple. b, Fixation of breast cone to pectoral fascia. Infolding sutures inserted to bring nipple forward. c Method of suture for double pedicle.

the tail being secured to the pectoral fascia at the level of the second rib. By judicious placing of plain catgut sutures it is then built up into a cone pointing forward and outward with the nipple on its apex. The cone should not be dragged or pulled in such a way that interference with the blood supply occurs. In the case of double pedicles these are folded in W form to produce the desired contour of the breast. In both cases the base of the cone is fixed to the pectoral fascia and muscle by a series of interrupted catgut sutures (Figs 4, 5, 6).

Treatment of the skin flaps. The upper skin flap is brought down over the breast cone and sufficient of the submammary skin is excised to allow of easy approximation of the edges to form a single transverse submammary scar. As a rule the upper flap is larger than the lower and should be "fanned in" with interrupted sutures to make it as short as possible. A fine hook is then inserted into the marked position of the new nipple on the upper flap; a cone of skin is lifted and cut off with sharp scissors. This will give a perfect circle and

the nipple itself will be found lying beneath. It is then extruded and sutured to the skin edge with finest silk. In the formation of lateral flaps the entire excess of skin is drawn together and downward and a series of Allis forceps are applied from the marked position of the new nipple to the submammary groove. These are adjusted in such a way that the skin fits comfortably over the cone of breast tissue; the slack being taken up in the grip of the forceps. The amount of tension is not so great as to interfere with the blood supply of the flaps. The excess skin is cut away vertically as a Λ and this suture line is completed. A circle is then drawn round the marked position of the nipple incised and the nipple extruded and sutured with fine silk as before. The transverse excess is then trimmed in the submammary region, closure being effected with fine interrupted silk sutures (Figs 7, 8, 9). If there is any excess of skin at the ends of the transverse incisions these are treated by the usual triangular excision (Fig 9 d e f). A small tube should be inserted at each end of the incisions and fixed with a suture. Dry

skin The abscess should be opened and drained Within a few days the necrotic portion of the pedicle can usually be seen and as much as possible cut away with scissors through the small opening necessary to drain it Eusol irrigation will aid the removal of necrotic material

GENERAL PROGNOSIS

The relief of intertrigo and the feeling of weight is immediate The latter in due course leads to improvement in posture especially in young girls. From the psychological point of view the patient finds herself able to go among her friends with a new-found equanimity Those girls who feared married life with a sensitiveness amounting almost to melancholia regain their self-confidence Nipple sensation becomes fully established in 70 per

cent of cases, and erectile innervation is preserved in all cases. Anatomically lactation should take place as some of the parenchyma with its ducts is left attached to the nipple, but it is doubtful whether it would be entirely satisfactory It must be remembered that an unoperated upon hypertrophied breast is not usually a satisfactory milk-producing organ. Data on the subject of postoperative lactation are not yet sufficient as in experience many of our patients are unwilling to institute breast feeding being overwhelmed by the quite unfounded fear that hypertrophy may recur.

In conclusion there would appear to be no question as to the satisfactory end-results of this operation provided that all the precautions enumerated are carried out

Fig 9 a Closure of submammary incision with interrupted fine silk sutures b Suture completed double upper flap method c Suture completed single upper flap method Upper flap is fanned into shorter lower one d e f Method of dealing with excess skin at ends of incision without increasing total length of scar

As regards convalescence many of these patients tend to overtax their strength too soon after operation. They feel their friends expect them to resume their social activities as soon as they leave the hospital on the fourteenth day and consequently they are apt to suffer from a marked nervous reaction to what must of necessity have been a profound physiological and psychological disturbance. This can easily be avoided by a short period of convalescence in the country or preferably at the seaside. This gives an opportunity for nerve recovery and stimulates healing softening of the skin flaps, and absorption of bruising. Arm exercises may be commenced during this time but vigorous movements should not take place until at least 4 to 6 weeks have elapsed following the operation.

POSSIBLE COMPLICATIONS

Possible complications which may follow operation are (1) hemorrhage, (2) sepsis (3) partial necrosis of skin flaps or pedicles.

Hemorrhage of slight reactionary type is coincident with recovery from the anesthetic, but if the tubes have been inserted as described will give rise to no disturbance. Secondary hemorrhage is uncommon and may produce external bleeding, or more possibly a concealed hematoma which is revealed in time by severe bruising loss of contour, and interference with circulation. The treatment is to evacuate the hematoma with all aseptic precautions as there is a liability to infection.

Sepsis may be evidenced by mild local stitch infection. Here variation of treatment is the keynote of success. The removal of the infected stitch may be followed by dressings with eusol, hypertonic saline, or glycerine and magnesium sulphate paste. The aim is to establish mild antiseptics without damage to tissues. If the patient is strong enough immersion in a warm saline bath is satisfactory so long as the whole breast area is carefully dried with spirit subsequently. Infection of a hematoma requires thorough opening and drainage as soon as the diagnosis is made, a sinus forceps being passed through one of the incision lines into the collection and followed by a tube which is left *in situ* until drainage ceases. Generalized sepsis is very rare in our experience and is evidenced by rapid rise in temperature and pulse with signs of diffuse local inflammation. In the only case in which it occurred the breast was thrown open immediately and Carrel-Dakin treatment instituted with satisfactory results. Should the incision lines be opened for this or any other reason they should be left to heal of their own accord. It is a good rule in plastic surgery to avoid secondary suture wherever possible.

Partial necrosis of skin flaps is an annoying complication inasmuch as healing will be considerably retarded. Discoloration of the affected portion rapidly occurs and in a day or two the line of demarcation is established. In the case of single upper flaps it is the lower edge and in the case of lateral flaps the medial and lower corners. Occasionally the applications of warm saline every 15 minutes will prevent more than a very superficial loss but if the necrosis is more extensive it should be encouraged to separate as soon as possible in order that epithelization may proceed. The skin loss is rarely more than one square inch, and as a rule is not worth grafting. A simple dressing of tulle gras renewed daily after a warm bath will effect rapid improvement. If the scarring resulting from the skin loss is unpleasant it is best removed at the second stage operation.

Necrosis of a portion of the pedicle will be evidenced by an abscess pointing underneath the

Wm P Didusch 1931

Fig 1 Anterior surface of right kidney which has been delivered through wound, showing accessory vessels at lower pole, which caused pressure, kinking, and obstruction to ureter. No stricture was found on external or internal examination. Vessels were too large to divide. Plastic on pelvis designed to eliminate obstructive contact. The postoperative result is shown in Figure 4. B U I 19905

and junction, serving to draw these structures away from the vessels. In 3 of these it was of the Y-plasty type, and in 1, the Heineke-Mikulicz. In 2 cases the vessels were divided and a Y-plasty made on the junction. In the seventh case, the vessels were divided and a thorough dilatation of the stricture with bougies was carried out. The eighth patient (B U I 25859) a child of 2½ years, was not thought at the time of operation to have a stricture. The vessels were divided and the kidney was suspended, but 2 years later a urogram showed a conspicuous narrowing at the

ureteropelvic junction with no appreciable decrease in the size of calyces or pelvis. Apparently the stricture was unrecognized because of the small size of the structures.

A comparison of these 2 groups of cases reveals several interesting facts. In Group A, the average age of onset was 24 years, and in Group B, 13 years (Table I). When the symptoms first appeared, the majority of patients in Group A were over 16 years, and in Group B, one half were under 10 years.

TABLE I—COMPARISON OF AGE INCIDENCE

Age at onset in years	Group A Accessory vessels without stricture	Group B Accessory vessels with stricture
1 to 5	None	3
6 to 10	2	1*
11 to 15	None	1
16 to 20	5	1
21 to 25	None	1
over 25	4	1

*This case (B U I 26210) had symptoms referable only to one kidney, but both were found by excretion urography to be hydronephrotic.

TABLE II—COMPARISON OF DURATION OF SYMPTOMS

Duration of symptoms	Group A Accessory vessels without stricture	Group B Accessory vessels with stricture
Less than 1 month	1	1
1 to 3 months	2	1
4 to 8 months	None	1
9 to 11 months	None	None
1 to 3 years	3	4
Over 3 years	5	None

73 per cent of patients in Group A had symptoms for 1 year or longer, and in Group B, 43 per cent for 8 months or less.

ACCESSORY RENAL VESSELS

Their Influence in Certain Cases of Hydronephrosis

HUGH JUDGE JEWETT, M D, Baltimore, Maryland

ALTHOUGH nearly 100 years have elapsed since Rayer first pointed out the causal relationship of anomalous renal arteries to hydronephrosis, there is still no unanimity of opinion among urologists upon this subject. There are, essentially, three divergent views concerning the principal factor in the causation of obstruction at the ureteropelvic junction associated with accessory vessels at the lower pole of the kidney. The first is that the vessel, probably as the result of some change in its relationship to the ureter or pelvis, is itself the most important single cause. The influence of ptosis in producing such an altered relationship is a matter of some dispute and will be considered in detail later. The second is that a stricture at the junction, or somewhere along the course of the ureter, perhaps overlooked in the urogram, initiates a dilatation and, as this progresses, the pelvis, becoming increasingly heavy with retained urine, sags over a vessel which originally caused no obstruction. The third view is that a disturbance of the neuromuscular mechanism of the renal pelvis results in such diminished peristaltic activity that the contained urine cannot be expelled through the ureteropelvic junction.

I am greatly indebted to Dr. Hugh H. Young for permission to study the 70 cases of hydronephrosis in the records of the Brady Urological Institute in which dilatation commenced in the region of the ureteropelvic junction, caused by mechanical obstruction at this level as proved at operation. Thirty of these (42.9 per cent) uncomplicated by renal calculi, were found to be associated with accessory vessels at the lower pole of the kidney. An analysis of these cases was undertaken in an attempt, first, to clarify the different concepts of the etiological or precipitating factors, and, second, to reveal what features influence the ultimate postoperative result. No attempt has been made in this paper to evaluate the merits of the various plastic operations for stricture at the ureteropelvic junction.

These 30 cases, for the purpose of convenience have been grouped as follows:

I. Conservative surgical procedures 19 cases

From the James Buchanan Brady Urological Institute, Johns Hopkins Hospital, Baltimore, Maryland

(A) Accessory renal vessels, the only demonstrable cause of obstruction 11 cases, (B) Accessory renal vessels associated with stricture at the ureteropelvic junction, 8 cases

II. Nephrectomy, 11 cases (C) Accessory renal vessels the only demonstrable cause of obstruction, 9 cases (D) Accessory renal vessels associated with stricture at the ureteropelvic junction, 2 cases

I. CONSERVATIVE SURGICAL PROCEDURES

Group A. Accessory renal vessels the only demonstrable cause of obstruction, 11 cases. There were 6 instances in which complete relief of the obstruction was afforded by simple ligation and division of the vessels as was evidenced by the prompt emptying of the distended pelvis. In the 5 remaining cases, the pelvis was opened and the ureteropelvic junction was explored before excluding the presence of stricture. In 2 of these the vessels were merely ligated and divided. In the 3 remaining, the vessels because of their large size were not divided, and the obstruction was relieved in 1 case by reimplantation of the ureter and in the 2 others by the resecting portions of the pelvic walls and closure in such a way as to eliminate contact between the ureter and vessels. The technique described by Young was employed (Fig. 1). The ureteropelvic junction itself was of normal caliber, and consequently was not subjected to plastic operation. Pre-operative and post-operative urograms have been obtained in 9 of the 10 cases in which the ureter was not operated upon (Figs. 2 to 10). These results, obtained by simple removal of the contact between vessels and ureter, either by division or by drawing the ureter away from the vessels show that such contact was in itself productive of obstruction.

Group B. Accessory renal vessels associated with stricture at the ureteropelvic junction, 8 cases. The presence of stricture was recognized at operation by a definite narrowing of the upper end of the ureter through which the pelvic contents would not readily escape after elimination of the contact between vessels and ureter (Fig. 11). In 4 instances the vessels were of large size and therefore not disturbed. Obstruction was eliminated in these cases by a plastic operation on the pelvis.

II NEPHRECTOMY

Groups C and D, comprising 11 cases in which nephrectomy was carried out, will be considered together because they resemble each other in nearly all respects. The average age of onset was 33 years, 6 months. The average duration of symptoms was 5 years, 6 months. This coincides with the history obtained from the patients in Group A and suggests that some factor, besides that of duration, causes the condition requiring nephrectomy.

In this group of 11 cases, the kidneys in 6 were hardly more than shells. One kidney was smaller but functionless, another was the seat of a severe chronic pyelitis, and two showed acute and chronic pyelonephritis with abscesses. In the sixth case (B U I 22083) the kidney was removed because of accidental trauma during exposure. Its cortex was very thin and was torn during manipulation. The reasons for nephrectomy were (1) functionless kidney, 7 cases (64 per cent), (2) severe infection, 3 cases (27 per cent); (3) accidental trauma, 1 case. The chief factors responsible for the condition necessitating nephrectomy seem to be (1) completeness of obstruction, acting for a variable length of time, and (2) severity of infection.

UNDERLYING CAUSES OF OBSTRUCTION

The mechanical basis. A careful study has been made of Groups A and C, totalling 20 cases, in which the vessels were the apparent cause of obstruction, and this shows that there is much room

Fig 7 a, left Pre-operative intravenous urogram in a 37 year old man who had had episodes of pain in right flank for 10 years. There was no excretion of medium by the right kidney in 35 minutes, which is represented by a large mass in the film. Urine was sterile. b, Intravenous urogram 3 weeks after resection of large extrarenal pelvis to eliminate contact between ureter and accessory vessels. c, Intravenous urogram 2 years later, showing marked reduction in size of calyces and pelvis, and upper ureter well filled. There was marked improvement in function, and symptoms completely relieved. B U I 24390

for speculation concerning the nature of the precipitating factor in the causation of the hydronephrosis. In our series the condition is chiefly one of early adult life. The accessory vessels, however, had been present ever since the kidney reached its definitive position in the embryo, but had not caused obstruction until this relatively late date. One, therefore, must conclude that some additional factor appeared at this time and altered the innocent relationship between ureter and vessels. This concept is given further emphasis by the well known fact that accessory renal vessels at the lower pole are sometimes encountered when no obstruction exists. That this factor varies in different patients is at once apparent from a study of the cases in this series and of the literature.

Fig. 2 a left Pre operative retrograde pyelogram in a 19 year old boy who had had attacks of right abdominal pain for 7 weeks. Function was somewhat impaired but urine was sterile. b Intravenous urogram 7 months after division of accessory vessel showing marked reduction in size of calyces and pelvis. The function was normal and symptoms completely relieved. B U I 2,280

The average duration of symptoms in Group A was 5 years, and in Group B 1 year, 6 months (Table II). Although it is always hazardous to draw conclusions from statistics based on a small series of cases, the discrepancies between these two groups are striking. The duration of the symptoms in those patients without strictures was nearly 4 times as long as that in the group with strictures. If such strictures are caused by the trauma resulting from long continued contact between vessels and ureter, one would expect them to have occurred in the older group of patients

Fig. 3 a left Pre operative left pyelogram in a 19 year old boy with bilateral hydronephrosis and uremia. There was no history of pain. Urine sterile. b Pyelogram 5 1/2 years after ligation and division of accessory vessels showing considerable reduction in size of pelvis and calyces. There was marked functional improvement in this patient. B U I 19905

with symptoms for a longer period. That strictures at the ureteropelvic junction without associated vessels are not infrequently encountered adds additional evidence to support the contention that the stricture may be a primary pathological entity.

Of the 11 cases in Group A only 3 kidneys were found infected on admission and of the 8 in Group B, only 1 was infected. None of the other patients gave even a previous history of pyuria or vesical irritation. The etiological relationship, therefore, between urinary tract infection and stricture, in this series at least, is not established.

Fig. 4 a left Pre operative right pyelogram in same case as Figure 3. Urine badly infected. Pelvis drained by indwelling ureteral catheter for several weeks and no phthalate appeared for 11 days. After that it increased rapidly. b Pyelogram about 5 1/2 years after resection of large portion of pelvis eliminating contact between accessory vessels and ureter. Improvement in renal function was marked but residual infection was considerable.

Fig. 5 a left Pre operative pyelogram showing markedly dilated pelvis and calyces in a 62 year old man who had had episodes of renal colic for 20 years. Function as determined by excretory urography was practically normal and urine sterile. b Pyelogram 2 years after ligation and division of accessory vessels showing marked shrinkage in size of calyces and pelvis. Symptoms completely relieved. B U I 22314

Fig 11 1, Dilated pelvis sagging over accessory artery to lower pole of kidney 2, Sectional view showing stricture at ureteropelvic junction Complete destruction of kidney requiring nephrectomy, although pelvis only moderately distended Patient aged 5 years B U I 22466

It has been suggested that over-rotation and under-rotation of the kidney about its vertical axis may serve in some cases to allow the ureter to press upon the vessels sufficiently to cause obstruction to the free flow of urine. In 4 of our 20 cases, not associated with stricture, such rotation was present, but no mention was made of its direction. It is evident that under-rotation would be of significance only if the vessel passed in front of the ureter, and over-rotation only if the vessel passed behind.

According to Sanford, Liek believed that the lower polar vessel may not grow as rapidly as the renal pedicle, and it is conceivable that such a disproportionate rate of growth might result in contact between vessel and ureter. In 2 of our 20 cases without stricture, the vessels were described as being taut. In only one, however, was the longitudinal axis of the kidney perpendicular instead of inclining towards the midline above the kidney. Since ptosis was absent, thereby elimi-

nating the possibility of pendulum rotation, the change in the vertical axis may have been caused during development by traction exerted by the vessel upon the lower pole of the kidney.

After a consideration of all these theories regarding the basic cause of the obstruction, it would seem that the most plausible explanation lies in the fact that the kidney undergoes a remarkable change in shape during its growth to adult size. Kelly and Burnam showed that in the infant the kidney is arched upon itself to such an extent that the 2 poles approach each other very closely over the enclosed pelvis (Fig 12). In the adult the poles have diverged markedly from each other, and by this straightening process the pelvis has become largely extrarenal. As is well known, the pelvis usually presents on the posteromesial aspect of the kidney, but it sometimes lies on the anteromesial aspect. Therefore, it would seem possible that in certain cases an accessory vessel attached to the lower pole could be carried

Fig 8 a left Pre-operative retrograde pyelogram showing moderately dilated calyces and pelvis. In a 41 year old married woman had pain in the left flank and vesical irritability for 10 years. The function was normal and the urine was sterile on admission. b Intravenous urogram 3 weeks after simple ligation and division of an accessory vessel showing diminution in the size of the calyces and pelvis and a patent ureter. Symptoms were completely relieved. BUI 24912

Ptosis has long been held the underlying cause of obstruction in cases of this sort, and it is true that in the majority some descensus of the kidney can be demonstrated. In 4 of our 30 cases however the presence of ptosis was denied. Blanc and Bourland also stated that it was absent in 3 of their cases and Winsbury White and others assert that renal mobility *per se* is a very doubtful cause of hydronephrosis. In the last 250 cases of

Fig 10 a left Pre-operative pyelogram showing moderate dilatation of pelvis and calyces in a 24 year old man with only pyuria for 4 years. b Pyelogram 16 years after simple ligation and division of accessory vein showing diminution in the dilatation. BUI 1935

hydronephrosis of all types operated upon in the Brady Urological Institute not one could be attributed to ptosis alone. Furthermore ptosed kidneys with accessory vessels at the lower pole without hydronephrosis are not infrequently observed. The distal attachment of the vessel runs downward with the kidney, so some other factor must be present in most cases at least to bring about the necessary fixation of the ureter. Fiehorn from a study of 24 cases collected from the literature, to which he added one of his own made the interesting observation that vessels pursuing a diagonal course running across the ureter either anteriorly to pass beneath the ureter in the posterior aspect of the hilum or lower pole, or vice versa were the ones much more apt to cause obstruction. Foley recently has emphasized this point. In 6 of the cases reported by Fiehorn, in which the diagonal course of the accessory vessel was clearly described 4 crossed behind the ureter. In none of our cases was any note made of vessel running in such a manner as Fiehorn described.

Foley has stressed the importance of horizontal axial rotation of the kidney or a forward pitching of the upper pole in bringing about contact between ureter and vessels. According to him this condition can be diagnosed from the pyelogram by the presence of a shortened longitudinal axis together with the closing of the angles between the calyces. In one of our cases this condition was observed (BUI 26210).

Quimby believes that the accessory renal artery through constant pulsation against the wall of the pelvis or ureter, finally interrupts the peristaltic waves and produces pelvic dilatation. In 2 of our cases the only vessel present was a vein

Fig 11 1, Dilated pelvis sagging over accessory artery to lower pole of kidney 2, Sectional view showing stricture at ureteropelvic junction Complete destruction of kidney requiring nephrectomy, although pelvis only moderately distended Patient aged 5 years B U I 22466

It has been suggested that over-rotation and under-rotation of the kidney about its vertical axis may serve in some cases to allow the ureter to press upon the vessels sufficiently to cause obstruction to the free flow of urine. In 4 of our 20 cases, not associated with stricture, such rotation was present, but no mention was made of its direction. It is evident that under-rotation would be of significance only if the vessel passed in front of the ureter, and over-rotation only if the vessel passed behind.

According to Sanford, Lick believed that the lower polar vessel may not grow as rapidly as the renal pedicle, and it is conceivable that such a disproportionate rate of growth might result in contact between vessel and ureter. In 2 of our 20 cases without stricture, the vessels were described as being taut. In only one, however, was the longitudinal axis of the kidney perpendicular instead of inclining towards the midline above the kidney. Since ptosis was absent, thereby elimi-

nating the possibility of pendulum rotation, the change in the vertical axis may have been caused during development by traction exerted by the vessel upon the lower pole of the kidney.

After a consideration of all these theories regarding the basic cause of the obstruction, it would seem that the most plausible explanation lies in the fact that the kidney undergoes a remarkable change in shape during its growth to adult size. Kelly and Burnam showed that in the infant the kidney is arched upon itself to such an extent that the 2 poles approach each other very closely over the enclosed pelvis (Fig 12). In the adult the poles have diverged markedly from each other, and by this straightening process the pelvis has become largely extrarenal. As is well known, the pelvis usually presents on the posteromesial aspect of the kidney, but it sometimes lies on the anteromesial aspect. Therefore, it would seem possible that in certain cases an accessory vessel attached to the lower pole could be carried

Fig. 12 The divergence of the two poles in the adult kidney is clearly shown. This process enlarges the hilum and pushes the pelvis outside. An accessory lower polar vessel may be carried downward and outward across the external pelvis. (From Kelly and Burnam.)

downward and outward across the pelvis which has been extruded in such a way as to press upon this vessel sufficiently to cause obstruction. Although all kidneys with accessory vessels are not hydronephrotic almost all those in which obstruction exists have extrarenal pelvis. Therefore, a variability in the factor of growth could explain the inconstancy both of the obstruction and within certain limits of the age at which it occurs.

From the foregoing it is evident that many different factors have been considered responsible for setting into motion the mechanism of obstruction. In certain cases, 33 per cent of our series

a definite stricture is present and, as dilatation progresses the effect of an accessory vessel may be of only secondary importance. But in others, no such stricture can be found and the accessory vessels assume the leading rôle although thrust into prominence by the operation of one or more subsidiary and variable forces.

The neuromuscular basis. Recently many articles have appeared in the literature regarding the neuromuscular mechanism of the pelvis and ureter. Some authors state that a disturbance of pelvic peristaltic activity is the primary factor in the production of the hydronephrosis and the importance of an associated vessel is more ap-

parent than real. In order to understand this neuromuscular mechanism one must consider both its extrinsic and intrinsic components.

The extrinsic components can be interrupted by a careful denervation of the renal pedicle. Extensive literature exists on this subject, and sympathectomy has been recommended for pelvic atony, or adynamia, as well as for hyperdynamic motility. Most of these operations, however, are carried out simply for the relief of pain. Occasional cases of pyelectasis, as described by Braasch, have been reported in which marked hypertonicity of the musculature of the pelvis and ureter apparently gave rise to obstruction at the ureteropelvic junction through spasm. Periarterial sympathectomy is thought by some surgeons to be of value here, although Allemann prefers a longitudinal incision through the pyeloureteral sphincter down to the mucosa. It is possible that a dysfunction of the extrinsic nerves is responsible for such dynamic obstructions, but, aside from these rare instances, it is generally agreed, according to Hinman, that no persistent anatomical change occurs after sympathectomy.

As regards the intrinsic components, little is known. The fact that pelvic and ureteral peristalsis is retained after denervation of renal pedicle and ureter proves the existence of an intrinsic mechanism of the pelvis and ureter. Moreover, the persistence of peristaltic activity for a time after nephro-ureterectomy also indicates that peristalsis is not entirely dependent upon the extrinsic nerve supply. It is conceivable that if some disturbance of this intrinsic mechanism actually occurred, it might result in such diminished peristaltic activity that the pelvis would be unable to expel its contents into an unobstructed ureter. Such

Fig 13 Rabbit's kidney showing intrarenal pelvis and close proximity of two poles to each other, somewhat resembling the condition in the infant (See Fig 12.)

a condition, obviously, would lead to hydronephrosis. There are a few alleged cases of this sort on record, but none is acceptable unless meticulous care has been exercised to exclude a mechanical obstruction. In many instances the presence of angulation and slight fixation of the ureter may not be apparent after operative delivery of the kidney, for such manipulation may free adhesions and change the relationships which existed *in situ*. In some cases, a small stone passed unnoticed before admission to the hospital is the true but undetected cause of the hydronephrosis. In the 70 cases from which the material for this paper was gathered, a mechanical obstruction responsible for the hydronephrosis was identified in every instance. An adynamic pyelectasis, therefore, must be rare.

The hydropelvis resulting from alleged vascular obstruction in the region of the ureteropelvic junction in the typical case is at first pyriform, as described by Braasch. It is also predominantly

Fig 14, left Pyelogram showing an intrarenal hydronephrosis. At operation obstruction was found to be caused by accessory lower polar vessels. B U I 25427

Fig 15 a, center Intravenous urogram of normal extrarenal pelvis. b, Same kidney 3 months later, showing hydronephrosis, predominantly pelvic in type, resulting from an infiltrating tumor of the bladder, obstructing the intramural ureter. FIG. 16 Hydroureter and hydronephrosis resulting from a ureteral stricture. Renal parenchyma shows very little compression and dilatation is almost entirely pyelo-ureteral. Pelvis is extrarenal and grossly funnel shaped with widely divergent renal poles. BUI 14114 (See Fig. 12)

extrarenal and later exhibits a globular appearance in the pyelogram. It therefore differs markedly from the intrarenal hydronephrosis caused by high or low ureteral obstructions in experimental animals. The globular form appears very different also from the grossly funnel shaped pelvis seen in patients with an obstruction involving the lower ureter. These observations led Horsford to conclude that such an extrarenal, globular

dilatation must be attributed to a disturbance of the neuromuscular mechanism of the renal pelvis.

We believe that factors other than primary neuromuscular derangements are sufficient to explain the variations encountered. In the first place there is considerable evidence to support the contention advanced by Hinman and by Hepler that the type of dilatation produced depends upon whether the pelvis is intrarenal or extrarenal. Rabbits, the animals used by Horsford, have completely intrarenal pelvis (Fig. 13). When a rabbit's ureter is obstructed an intrarenal hydronephrosis develops. If a high ureteral obstruction occurs in a patient whose pelvis is intrarenal an intrarenal hydronephrosis naturally results (Fig. 14). If the pelvis is extrarenal the result will be an extrarenal hydronephrosis (Fig. 15). Intermediate types are also observed.

The majority of pelvis in the human being are partially, if not largely extrarenal and this may be explained by the mechanism of renal growth as described by Kelly and Burnam (Fig. 12). The difference in the type of hydronephrosis in the case of an extrarenal pelvis apparently is due to the fact that the renal parenchyma fails to envelop completely the pelvis. An extrarenal pelvis which has no surrounding parenchyma to enclose and support it, cannot resist an increase in intrapelvic pressure. The assistance rendered by overlying renal parenchyma in resisting intrapelvic pressure is further emphasized by cases in which thin atrophic areas undergo dilatation out of all proportion to the rest of the kidney. Horsford also produced a saccular dilatation of an infarcted area of renal cortex in a rabbit by obstructing the ureter after ligating a branch of the renal artery.

A comparison was made between pathological specimens of hydronephrosis in the Pathological Institute in which the obstruction was at the ureteropelvic junction on the one hand and in the lower urinary tract or lower ureter on the other. From this it was found that in the early cases parenchymal compression was as conspicuous a feature in low as in high obstructions when the pelvis was extrarenal in type (Fig. 16). In the later stages if the pelvis was intrarenal situated, a corresponding cortical compression existed in both groups. The belief therefore that a so called pelvirenal hydronephrosis is a characteristic feature of low obstruction and that a predominantly pelvic dilatation is indicative of a primary neuromuscular disturbance of the renal pelvis is without support. Furthermore the contrast between the grossly funnel shaped dilatation following low obstructions and the globular ap-

pearance of the pelvis in vascular obstructions can be explained simply by the effect of the location of the blockage, for, as Braasch has pointed out, in the cases associated with accessory vessels, the dilated pelvis in the early stages is likewise pyriform in shape.

Therefore, it would appear unreasonable to impute to so dubious a factor as neuromuscular dysfunction the mere, rounded contour of an extrarenal hypopelvis. Moreover, the fact that improvement followed relief of obstruction at the ureteropelvic junction in the series of cases herein reported is sufficient proof that such dysfunction, in these cases at least, could have played no rôle.

RESULTS OF CONSERVATIVE SURGICAL PROCEDURES

Group A Accessory renal vessels the only demonstrable cause of obstruction, 11 cases. It is evident from a study of Figures 2 to 10 that anatomical improvement in the kidney occurred in each of the 9 patients submitting to postoperative urography. In 6 cases, the improvement was marked, in 2, moderate, and in 1, slight. In 1 case (B.U.I. 17344) no postoperative urogram was obtained. Of the 6 patients showing marked reduction in size of calyces and pelvis, two had normal function before operation. In the 4 others, the renal function, which had been found impaired on admission, was markedly improved. All but one (B.U.I. 19905) had sterile urine on admission. The 2 patients showing moderate improvement in the pyelogram also had sterile urine on admission. One showed moderate improvement in renal function, and the other had no test of function made after operation. The 1 patient (B.U.I. 4632) whose postoperative pyelogram revealed only slight improvement, had bacteriuria on admission, but division of the obstructing vessel resulted in marked improvement in renal function and disappearance of the infection. There was complete relief of symptoms in every case.

Group B Accessory renal vessels associated with stricture at the ureteropelvic junction, 8 cases. In this group the anatomical improvement as revealed by urogram, was marked in 3 cases, moderate in 2 and slight in 2. There was no postoperative record in 1 case. Of the 3 showing marked improvement, two had a considerable increase in renal function, and one, a moderate increase. All had sterile urine before operation. Of the 2 patients with moderate structural improvement, one had a considerable increase in renal function with disappearance of the pre-existing infection. In the other case, the function

was normal and the urine sterile before operation. In the 2 patients with slight anatomical improvement, one showed a marked increase in renal function but the other had a normal function on admission, at which time the urine of both was reported sterile. In 7 of these patients the symptoms were completely relieved. One patient (B.U.I. 26210) with bilateral hydronephrosis, had no symptoms referable to the left kidney. Plastic operation on this side was carried out because the urogram showed considerable dilatation of pelvis and calyces.

An investigation of the various conditions influencing the postoperative result, following complete relief of the obstruction, revealed several interesting facts. With one exception (B.U.I. 19905) cases of severe renal infection or advanced hydronephrosis with marked cortical atrophy were subjected to nephrectomy. This indicates that the success of conservative surgery would be expected to vary indirectly with each of these two conditions, although newer technical procedures are reducing still further the number of nephrectomies. In general, the best results were obtained in the older patients in both Group A and Group B. The duration of the symptoms *per se* was of little significance, the important factor seemed to be the relation of the duration to the completeness of obstruction, which, in turn was reflected in the degree of cortical compression. This, and not the mere size of the pelvic sac, was the significant feature.

CONCLUSIONS

A primary disturbance of the neuromuscular activity of calyces and pelvis resulting in dilatation localized above the ureteropelvic junction has never been observed in the Brady Urological Institute. The predominance of calycal or of pelvic dilatation depends more upon the original situation of the renal pelvis than upon the actual location of the obstruction. Accessory vessels at the lower pole of the kidney are frequently found associated with obstruction in the region of the ureteropelvic junction. In some of these cases the underlying cause is stricture, which, when present, is probably a primary pathological entity.

In certain cases of hydronephrosis accessory renal vessels are the chief cause of the obstruction, which is precipitated, usually in early adult life, by the effect of one or more subsidiary factors, of which the mechanism of renal growth is possibly one of the most important. Surgical intervention designed to eliminate obstructive contact is indicated. Success depends largely

upon severity of infection and extent of cortical destruction

INTRACRANIAL SOLITARY CHONDROMA

JERZY CHOROBSKI, M D, JERZY JARZYMSKI, M.D, and ERNEST FERENS, M D,
Warsaw, Poland

INTRACRANIAL chondromas, i.e., true progressive neoplasms composed of cartilage, appearing in tissues not normally containing cartilage (v Rindfleisch), are of very rare occurrence¹ The large treatises on the neoplastic disease mention the tongue, the tonsils, the subcutaneous tissue, the skin of the neck, the thyroid, the salivary and the mamillary glands, the diaphragm, the uterus, the testicles, the bladder mucosa, and the corpus vitreum, but wholly omit the intracranial cavity as the possible site of those heterologous neoformations

It seems worth while, therefore, to add to the list of intracranial chondromas summarized below, one personal observation, inasmuch as it presents some interesting features. There was a definite history of trauma 6 years preceding the appearance of symptoms caused by the tumor The parietofrontal chondroma developed at the very region of a previous skull fracture Contrary to almost all of the cases found in the literature, presenting usually a clear cut picture of a brain tumor, the clinical syndrome of our patient, consisting of headaches, vomiting, psychic and emotional changes, dilatation of the right pupil, right lower facial paresis, and attacks of rotation of the head to the right, was none too easy to interpret The huge neoplasm had caused most probably an almost complete obliteration of the cerebrospinal fluid spaces of the brain. The tumor was free from any gross attachment to the surrounding structures

REVIEW OF THE LITERATURE

Hirschfeld (1851) was probably the first to record an intracranial tumor of the chondroma group Diagnosed as such by Robin, the small cartilaginous nodule found at autopsy in a woman about 35 years old, had grown out from the base of the skull in the left medial fossa, centrally to the gasserian ganglion The clinical history was not given Pirket's (1881) tumor, mentioned by Alpers (1935), was an autopsy finding It meas-

ured 15 centimeters in diameter and was attached to the dura mater. Nixon (1892) reported a case found at operation—a "cartilaginous tumor" partially removed in a patient 28 years old The tumor was connected with the superior longitudinal sinus and compressed the superior part of the right motor area of the brain The skull overlying the tumor was distinctly thickened. In Letterer's (1920) first autopsy case, a man of 27 years, the chondroma was located between the two sheaths of the tela choroidea of the third ventricle The tumor, the size of a cherry, was attached to the fornix His second case was that of an epileptic who had, in addition to a left temporal glioma, a chondroma embedded in the plexus choroideus of the left lateral ventricle It too was the size of a cherry and was attached to the plexus with a small pedicle Huebscher (1922), according to Bruett (1931), found at autopsy on a woman, who died from tuberculous meningitis, a small chondroma located at the border of the frontal and parietal bones The tumor was cystic in the center.

With Neuman (1927) begin the modern records of the surgical removal of intracranial chondromas His patient, a 22 year old male, had a tumor in the left temporoparietal region, producing cephalalgia, vomiting, and transitory loss of consciousness, for 6 months The very large chondroma had apparently no attachment either to the dura mater or to the falx cerebri or to the base of the skull to which it was said to extend Sillevs Smitt (1929) records a case of a man, aged 29 years, operated upon by Laméris This patient suffered with headaches, vomiting, somnolence, papilledoma, progressive loss of vision, and a right spastic hemiparesis The symptoms started after some psychic difficulties The chondroma weighing 128 grams, was located in the left parietal region and produced an endostosis which was visible on x-ray examination It was attached to the dura mater which, in turn, could not be separated from the overlying bone The 65 gram chondroma which was removed by Petit-Dutaillis from a man of 23 years and reported with Guillain, Bertrand, and Schmite (1930), and which caused headaches, papilledema, and left sided Jacksonian seizures, was connected with the pachymeninx in the right frontoparietal region In

¹We are excluding from the present review all of the cases characterized by a more or less generalized chondromatosis with occasional intracranial localization of the cartilaginous neoformations

From the Neurosurgical Division of the Neurological Clinic J. Piłsudski University, the Institute of M. Nencki, T.N.W. and the Institute of Traumatological Surgery

dema, bilateral central scotoma, and a left spastic hemiparesis. Roentgenograms showed "a light intracranial shadow." Alpers (1935) reports a case of a recurring osteochondroma removed twice. The 49 year old man was operated on for the first time in 1921 because of Jacksonian seizures starting in the right lower extremity. An osteochondroma was found to grow out from the falx cerebri. Seven years later the patient was again operated upon for the relief of right hemiparesis; the x-ray pictures indicated in the left parietal region, slightly anterior to its previous location, a recurrence of the partly calcified neoplasm. Microscopically, the tumor proved to be also an osteochondroma.

All of these benign tumors (with the exception of the invading chondroma of Froment, Wertheimer, and Dechaume and of the fibro-osteochondroma of Jakob and Pedace) were hard, elastic, rounded, lobulated, and encapsulated tumors, often reaching great size. The milky-opaline surface of the neoplasms made their cartilaginous nature quite obvious on inspection. Men seem to be much more frequently afflicted with these tumors than do women. The average age of the patients was 30 years, the youngest being 16, the oldest 64 years. The left side of the skull was affected 9 times, the right only 4. In the other patients the tumor was located centrally or its site was not stated. The parietal region of the brain seems to be the most common site of the chondromas (Fig. 1), 10 out of the total 25 tumors were encountered hereabouts. The frontal region was involved three times, the third ventricle, the lateral ventricle, and the motor region, each harboring one neoplasm, the base of the skull was the site of the tumor in 5 other tumors. In 4 instances the neoplasm was attached to the falx cerebri, in 3 instances it was connected with the dura mater of the convexity of the brain, in 1 with the superior longitudinal sinus, in 1 with the fornx of the third ventricle, in 1 with the plexus choroideus of the lateral ventricle, in 5 with the base of the skull, and in 4 no attachment to the surrounding tissues was noted.

As to the duration of the symptoms from their onset to the time of operation or autopsy the shortest period was 4 months, the longest, 7 years. The most frequent complaints noted in the case histories are a more or less advanced hemiparesis and epileptic attacks of the Jacksonian type, together with signs of increased intracranial pressure. The last were lacking in only 1 case (Verbrugghen and Learmonth). An endostosis overlying the tumor was seen in 3 cases. In 3 instances the neoplasm was revealed

Fig. 2 The appearance of the removed chondroma. Tumor weighed 220 grams. Two-thirds natural size.

by shadows of calcification. In 1 case the symptoms appeared 8 years after trauma (Oppenheim), in 1 subsequent to some psychic difficulties (Sillevis Smitt). In other reports no mention is made about any possible inciting agents of the disease. In 9 of the 25 recorded benign tumors the diagnosis was made at autopsy and in 16 instances at operation. Two patients died after operation (Nixon and Froment, Wertheimer and Dechaume), and 14 were cured by the total removal of the tumor. In Alpers' patient, the osteochondroma recurred twice.

REPORT OF CASE

S. F., aged 31 years, farmer, married, was admitted to the Neurosurgical Division on May 1, 1937. In September, 1931, he was hit by a heavy stone in the right parietal region. After the accident he did not lose consciousness but complained of severe headaches, nausea, and vertigo. There was bleeding from the right ear and nose. The x-ray pictures of the head showed a closed, depressed fracture in the right parietal region, from which three linear fractures were seen to descend toward the base of the skull. Two days after the accident, during which the patient complained only of cephalalgia, he was operated upon in the County Hospital in Skierniewice (Dr. Witkowski), and all the depressed bone fragments were elevated and removed. The dura mater was found to be severed but the inspected part of the brain appeared normal. The patient left the hospital 9 days later, feeling entirely well.

In June, 1936, patient's home was burned and he became depressed. He complained of attacks of severe headache localized chiefly in the left half of the skull, occurring at first rarely, then once a week, sometimes accompanied by vomiting. One and a half months before admission he started to be at times jocular, at times irritable and ready to cry for no reason at all. According to the family, several times, during periods of cephalalgia, he had some attacks of rotation of the head to the right, no seizures being observed. On admission patient was very apathetic and slow but oriented as to the time, place, and current events. When in the hospital he urinated several times in the ward and was frequently found to wet his bed involuntarily.

Fig 3 Photomicrograph showing the stellate cells containing peculiar vacuoles. The other cells in process of atrophy and degeneration. The homogenous hyaline matrix staining pale rose.

There was nothing pathological in internal organs neurologically only some weakness of the lower branch of the right facial nerve and a dilatation of the right pupil was noted. Otherwise the examination as well as the laboratory findings (the cerebrospinal fluid, blood and urine) were essentially negative. Roentgenograms of the skull showed in the right parietal region a fairly well defined loss of bone substance 8 centimeters long and 2.5 centimeters wide. On palpation the bottom of this bone defect felt rather hard and rugged and it was thought that it was probably filling out by still uncalcified new bone formation.

To establish the diagnosis ventriculography was attempted on May 4, 1937. Several attempts to puncture the cellula media of the right lateral ventricle was unsuccessful.

Fig 4 Photomicrograph showing cells the cytoplasm of which extends into processes entering the amorphous matrix.

Fig 5 Photomicrograph showing the transition of the chondrocytes into compound granular corpuscles seen here in the perivascular space of a small blood vessel.

The left ventricle was reached at normal depth but only two cubic centimeters of the cerebrospinal fluid could be withdrawn and the same amount of air introduced. However during the procedure the restless and loudly crying patient pushed out apparently all of the injected air from the ventricles. For the x-ray plates showed no air inside the skull. The same day an encephalogram was made 30 cubic centimeters of air being injected in 5 cubic centimeter portions. But just before the completion of the procedure the air rushed back through the needle and none entered the skull. The next day encephalography was repeated (50 cubic centimeters of air being introduced) but for the second time the result was negative practically no air entering either the ventricles or the subarachnoid spaces of the brain.

Although we were at a loss how to explain these unusual difficulties in introducing air both into the ventricular and the subarachnoid system we decided to explore the region of the skull fracture. Our assumption was that the patient's headaches, his psychic and emotional disturbances might be due to a subdural hematoma situated over the right cerebral hemisphere causing the discrete paresis of the right oculomotorius (dilatation of the pupil) and compressing the right lateral ventricle. By pushing the contralateral (left) cerebral hemisphere toward the wall of the skull the hematoma could thus produce the homolateral (right) lower facial weakness and the attacks of rotation of the head to the right.

Accordingly on May 5, 1937 a right frontoparietal osteoplastic flap was turned down with the skull defect at its base. A ventricular needle introduced through the very tense and non-pulsating dura mater encountered just below the uncovered pachymeninx a hard resistance. Our first impression was that we might be dealing with a depressed bone fragment left here unintentionally at previous operation but we soon found that it was a huge tumor. The wholly encapsulated and lobulated neoplasm, almost as large as one's fist, was easily enucleated (1 or 2). It occupied the parietofrontal region; it was located para sagittally in the parietal region and extended toward the base of the skull in the frontal region. The tumor had no attachment either to the dura mater or to the falx cerebri. No blood vessels of any importance were seen to connect it with the surrounding cerebrum. The cortex was dry and

Fig 6 Photomicrograph showing a large blood vessel with a widely dilated perivascular space growing from the perichondrium between two lobules of the chondroma. The perivascular space loaded with compound granular corpuscles

anemic, and the non-pulsating brain, which was pushed laterally and backward, showed no tendency to fill out the large cavity resulting from the enucleation of the neoplasm. During the removal of the tumor the patient—slightly shocked by the procedure—had a generalized epileptic attack but otherwise went through the operation quite well.

Except for a left motor and sensory hemiplegia, which developed immediately after the extirpation of the tumor and subsided 4 days later, the postoperative course was uneventful and the patient left the hospital on May 26, 1937, entirely free of signs and symptoms. Unfortunately we lost track of him and cannot report his present condition.¹

¹The case was presented before the Warsaw Neurological Society, May 26, 1937.

Fig 7 Photomicrograph demonstrating the collagenous area of the chondroma

Microscopic examination revealed the tumor to be a chondroma of the hyaline variety, although here and there some collagenous areas are also present. No elastic fibers were demonstrable in the matrix with special stains. In some places the amorphous hyaline matrix was very young, and showed a definite affinity to hematoxylin, in other sections it stained with eosin. As a whole there was great variation in the density and intensity of the eosinophilic staining of the matrix. With the Van Gieson method it became brown in some areas, like adult cartilage. In sections where the matrix was well formed the cells, varying greatly in size and shape, were usually round, oval, or fusiform, and lay in distinct capsules, singly or twofold. The cells were often gathered into large or small groups. In sections with imperfect formation of matrix, the staining was pale-rose, the cells were also stellate and contained commonly peculiar vacuoles, which resembled those described by Virchow as "physaliden" (Fig 3). In some places the cartilage capsules, which were not always very distinct, were either empty or wholly absent and the cells lay then directly in the matrix. In such areas there were

Fig 8 Cross section of the chondroma showing multiple areas of degeneration leading to the formation of small cysts and cavities

Fig 9 Photomicrograph demonstrating the so called asbestos transformation of the homogenous matrix

also cells with cytoplasm which extended into long processes entering the interstitial tissue. Often fat granules were seen in the cells, some of which had the appearance of compound granular corpuscles. The latter (Fig 5) were found especially in the widely dilated perivascular spaces of the blood vessels which issued from the perichondrium and extended into the interior of the tumor with the connective tissue septa (Fig 6). Such septa divided the chondroma into single cartilaginous lobules. The thick or thin collagenous bundles formed either a dense network running in all directions or they were gathered together into distinctly oriented fibers (Fig. 7).

The perichondrium was composed of bundles of connective tissue fibers more or less closely twisted and applied each to the other. The border line between the perichondrium and the cartilaginous matrix was often not very distinct, the cells under the perichondrium being flattened and running in a plane parallel with the surface of the

Fig 10 Photomicrograph showing one of the cavities formed by confluence of cell lacunae. The arrows indicate some of the enlarged lacunae opening into the cavity

Fig 11 X-ray picture of the removed chondroma showing foci of calcification. They were invisible on roentgenograms of the skull made before the operation

tumor. Here and there one had the impression of the presence of intermediate forms between the perichondrial fibroblasts and the cartilage cells. The regressive changes were leading to the formation of cysts of various sizes which were visible to the naked eye when the tumor was cross sectioned (Fig 8). Such cysts were filled out either with a serous or a mucin like material. Under the microscope the processes of degeneration were found in different stages and in different forms. For instance the usually homogenous matrix was fibrillated, softened and rarefied (the so called asbestos transformation, Fig 9) or it was a cavity which was either empty or contained some uncolored material. Such cavities were not necessarily the result of softening, because they could have been produced by the confluence of cell lacunae which had become irregular and enlarged (Fig 10). The calcification—as seen also on X-ray pictures of the removed tumor (Fig 11)—was limited to the most superficial layers of the neoplasm; the lime salts being deposited in the matrix in form of homogeneous masses.

We maintain our assumption that the discrete signs on the side containing the verified lesion were most probably caused by the huge chondroma which pushed the other hemisphere toward the wall of the skull. We also maintain that the difficulties encountered in introducing the air both into the ventricular and the subarachnoid system were due to a serious obliteration of the cerebrospinal fluid spaces by the tumor and the compressed brain.

The not infrequent homolateral involvement of the pyramidal tract in the presence of a brain tumor and of a subdural hematoma is at present a well known fact. Of the several possible causes of such an involvement we will mention only two, viz., notching of the contralateral crus cerebri by the free margin of the tentorium and compression of the contralateral cerebral hemisphere toward the wall of the skull. In this connection we would refer to the detailed reports of Gould (1928) and of Kernohan and Woltman (1929).

However, the presence of a cartilaginous tumor inside the cranial cavity raises the question as to origin. Such tumors lie free of any gross connections with the surrounding structures, and are more or less finished products of abnormal growths, so that it is not surprising that the origin of the growth cannot be positively determined. As in our case so it has been with many other chondromas reported in the literature. Many explanations have been given as to the source of such intracranial tumors.

For the majority of chondromas developing in the soft tissues it is generally seen in embryonal cartilaginous cell groups misplaced by dysontogenesis. If this hypothesis as to the etiology of some cartilaginous tumors located elsewhere, is accepted, as it usually is, there is no good reason that the hypothesis should not hold good at least for some intracranial chondromas.

Since the base of the skull at first is entirely formed of cartilage, the origin of chondromas situated here may be explained on the ground that some cartilage cells left during the developmental period retained their embryonal character and gave rise to chondroma formation. This explanation looks plausible *prima vista*. However the vault of the skull is commonly considered to be composed of membranous bones so that such a hypothesis rests on less firm ground. Looking closely to the problem—at least as regards the higher vertebrates—it would seem that, since the ontogenesis of the human skull repeats in many details its phylogenesis, it is perhaps permissible to look for the source of the chondromas in persistent embryonal cartilage rests, even when growths are located on the roof of the cranium. According to Dursy (1869) some portions of the cranium *primordiale* regress in later stages of development and are replaced by membranous bones. Such is the case with the part replaced later by the parietal bone but some of its cartilaginous portion fails to disappear completely. It merges with the membranous part so that the permanent parietal bone is finally composed of both the cartilage and dermal elements. Therefore the dermal origin of the vault of the skull is by no means absolute. Minot (1884) is of the same opinion and maintains that at the time when the cartilaginous skull is stretching and growing upward it comes in close contact with the dermal frontalia, parietalia, and interparietalia, so that when they finally ossify the permanent bones contain some cartilaginous elements. Bonnet (1891) supports these opinions, inasmuch as he showed that the membranous skull contained some cartilaginous foci. Koelliker (1893), who demon-

strated cartilage in the squama of the temporal bone, a finding confirmed later by Gaupp (1901), asserts that the membranes from which later some parts of the frontal, temporal, and parietal bones, some parts of the nasal bone and of the vomer are formed, may be considered as belonging to the perichondrium of the primordial cranium or as its continuation.

In connection with the data quoted pointing toward the possible dermomembranous origin of the parietal bones it might be worth while to re-emphasize the frequent occurrence of chondromas around that exact region of the skull (Fig. 1).

Most of the tumors reported were closely attached to the dura mater. It is, of course, a well known fact that foci of superfluous cartilage are found in the periosteum of skeletal bones. It is true that contrary to the bony plaques not infrequently found in the dura mater and in the arachnoidea and to the arachnoidal inclusions encountered in the dura mater, no cartilaginous foci—embryonal or adult—have heretofore been reported as present in the meninges. This might be due to the lack of careful search for them. Theoretically, however, the growth of dural chondromas, as well as of those attached to the falx cerebri and to the superior longitudinal sinus from embryonal cartilaginous rests misplaced from the bones of the skull into the dura mater, is perhaps possible also in other sites than near or at the base of the skull. The same is true for the chondromas reported as lying grossly free in the cranial chamber, i. e., not connected either with the skull or with the dura mater, tumors which in our opinion are of leptomeningeal origin, and in which some discrete attachment to the arachnoidea is easily overlooked during removal of an often very large tumor. The presence of aberrant embryonal cartilaginous rests in the leptomeninges might be explained as follows. The young vascularized mesenchyme which will later build up the pia mater grows both from above—from the primitive falx—and from below—from the base of the skull. It is therefore possible that the budding young blood vessels included in the embryonal pia mater creeping over the entire brain may carry with them colonies of cartilage cells and deposit these cells as they proceed on their way. It is important, we feel, to note that with the exception of the 2 cases of Letterer (1920), in one of which the tumor was connected with the tela choroidea of the third ventricle, and in the other the growth was attached to the plexus choroideus of the lateral ventricle, none of the reported chondromas was really intracerebral.

Although imbedded in the brain substance, they were all extracerebral. As he noted cartilage like cells in the mesenchyme above the choroid plexus anlage in a 10 week embryo, Letterer (1906) considered his case of chondroma of the third ventricle to be the result of misplaced embryonic cartilaginous cells.

There is another way to explain the source of intracranial chondromas than by budding of the aberrant embryonal rests of cartilage. If it is true that common connective tissue tumors of the cranial cavity are derivatives of the pluripotential undifferentiated mesenchyme, then one is forced to the conclusion that at least some of the intracranial chondromas are the result of neoplastic growth of undifferentiated mesenchymal cells. As such cells are able to give birth to meningeal mesenchymatous, angioblastic, meningotheiomatous, psammomatous, osteoblastic, fibroblastic, melanoblastic, sarcomatous, and lipomatous neoforations (Bailey and Bucy, 1931), a chondroma closely connected with the meninges would be nothing but another variety of a 'meningioma,' and the plurivalent mesenchymal cells persistent in the meninges, would develop into chondrocytes (Maximow, 1934). The neoplastic budding of the embryonal mesenchyme instead of persisting (in adult meninges), may be misplaced by dysontogenesis, for instance, to the surface of the medullary canal and produce a chondroma in a place one would hardly expect to be the site of such a neoplasm. In fact Letterer (1920) explains his second case of chondroma on the ground that some remnants of mesenchymal cells of the dura mater were misplaced in the lateral ventricle and there formed a cartilaginous tumor. Indeed, he mentions the theory of Feré (1896), that the very young undifferentiated tissue is capable not only of growing in foreign tissues but of becoming differentiated into cartilage.

The fibroblast is also pluripotential however, and is capable of producing osteoblasts, osteocytes, and chondrocytes (Maximow, 1934). Beneke (1905) believed that cartilaginous tumors of the subcutaneous tissue of the mamillary gland of the bladder mucosa and of the corpus uterum are best explained by metaplasia of connective tissue. The ideas of Sillevs Smitt (1929) and of Bruett (1931) are very much the same. Smitt taking into consideration the fact that the outer layer of the dura mater represents the cranial endosteum and that all periosteum has the ability to form cartilage (cartilaginous callus), expresses the opinion that the dura mater might also under certain circumstances take up that

potential function and "running off the rails" produce a chondroma. This consideration of the potentialities of the dura mater is based on the results of some physiological experiments. Cohnheim and Mass (1877) introduced into the jugular vein of experimental animals particles of tibial periosteum, and found in the blood vessels of the lungs, 10 to 16 days later, that the inside of the periosteum was covered with layers of hyaline cartilage cells. Before then and after 40 days, however the result was negative. Koller (1886) demonstrated that not only the periosteum of the bone preformed in cartilage has under certain circumstances the ability to form cartilage but that the same is true also for the periosteum of bones preformed in skin (experiments on rabbits).

Guillam et al (1930), having established near the blood vessels of the tumor some stages of a rapid transition between the normal connective tissue elements, the fibroblasts and the neoplastic chondroblasts, believe that the chondroma resulted from the transformation of a connective tissue layer, probably the dura. Alpers (1935) believes that in his case the osteochondroma was derived from meningeal fibroblasts. The above view again link the intracranial chondromas with the meningiomas, Mallory (1920) and Penfield (1923) uphold the idea that the meningeal (arachnoidal) fibroblasts are the source of common meningeal tumors.

The explanation of the origin of the chondromas on one hand by budding of the embryonal cartilaginous rests left in place (chondromas attached to the base of the skull) or misplaced into the neighboring tissues and on the other hand by development of those tumors from persistent and aberrant foci of meningeal mesenchyme or from leptomeningeal fibroblasts (chondromas attached to the dura mater and to the leptomeninges) is only a part of the problem, the "why" of this budding is the rest.

The casual relationship between new growth formation and trauma, inciting to action a latent *genus loci*, has ever been a much discussed question. According to Borst (1902) the percentage of cases attributed to trauma ranges between 25 and 44.7 per cent. As is well known, trauma in addition to some irritative processes such as pachymeningitis is often thought to play an important rôle in the etiology of meningeal tumors. The presence of inflammation and trauma preceding the appearance of chondroma especially of the long bones is also a frequent etio-

Letterer (1920) calls his tumors hamartoblastomas. Penfield (1933) use the term hamartoblastoma.

logical finding. However, except for the case of Oppenheim, reported by Ewing (1934), in the reported intracranial chondromas, no injury to the head is mentioned as preceding the appearance of the symptoms. We feel that our case fulfills all the clinical and pathological requirements necessary to assume a causal relationship between the injury and the formation of the tumor: the microscopically verified tumor, of slow growing variety, developed in the very region of a severe skull fracture sustained 6 years previously by a man up to then apparently healthy. It is true that the tear in the dura mater at the time of the débridement was only 1 centimeter long and, as no further openings were made, not much of the underlying brain could be inspected. However, the patient before the accident was entirely symptomless, the brain pulsated and the portion seen at the operation appeared normal. We believe therefore that we are at least near the truth when we state that a causal relationship most probably existed between the skull fracture and the appearance of the chondroma.

Therefore, several possible explanations of the source of the grossly free lying chondroma are open to discussion. An injury causing fragmentation of the parietal bone might free some embryonal cartilaginous rests still remaining from the development of the bone, consisting perhaps of melting down of dermal and cartilaginous elements. The liberated colony of cartilage cells being thrown under the pachymeninx, may arrive in the meshes of the arachnoidea, and apparently finding suitable conditions for further growth and behaving here "as the wild beasts which escaped their cages" (de Quervain) produce a chondroma. Or, a fragment of fractured bone may cause a dormant embryonal cartilaginous or mesenchymal cell colony misplaced or persistent in the leptomeninges to bud and to form a cartilaginous new-growth. Finally, the same bone fragment might incite the leptomeningeal fibroblasts to give origin to a chondroma. Any one of those possibilities may play a rôle in the formation of a chondroma, but none can be proved decisively to be the cause, as unfortunately the only two elements at our disposal to judge the problem on are (1) the trauma and (2) the fully grown cartilaginous tumor.

SUMMARY

- 1 The rare occurrence of solitary intracranial cartilaginous tumors is emphasized
- 2 The salient clinical features of the 25 cases recorded in the literature, including 16 pure chondromas and 9 mixed but not pluridermal cartilaginous new-growths, are briefly reported.

3. One personal observation of a solitary chondroma of the right parietofrontal region in a man aged 31 years is presented. The tumor appeared at the exact site of a depressed skull fracture sustained by a man healthy until 6 years ago, when he sustained the injury which produced headaches, vomiting, vertigo, psychic and emotional disturbances, a right lower facial paresis and dilatation of the right pupil. The patient is said also to have suffered attacks of rotation of the head to the right. The psychic and emotional changes and the dilatation of the right pupil could easily be explained by the presence in the right half of the skull of a huge neoplasm, weighing 220 grams, seriously compressing the frontal lobe and the right oculomotor nerve. The homolateral signs (attacks of rotation of the head and the lower facial weakness) were probably the result of the chondroma pushing the left cerebral hemisphere toward the contralateral wall of the cranium. The difficulties of introducing air both into the ventricular and subarachnoid system, encountered in our case, were probably also the result of spatial changes inside the skull caused by the expansive and slow growing chondroma. The tumor was completely enucleated and the patient left the hospital cured.

4. The several possible explanations of the origin of intracranial chondromas—including the presented case—are discussed and their speculative character is pointed out. The tumors growing out from the base of the skull or closely connected with the other bones of the cranium (especially at or around the parietal region) are probably best explained by tumor-like budding of cartilaginous rests persistent there from the early development of the skull. Young mesenchyme or the fibroblasts of the pachymeninges and leptomeninges may be the source of the chondromas attached to the dura mater of the convexities, falx cerebri, or the superior longitudinal sinus and of those which are described as lying free from any gross connection with the surrounding tissues but which, in our opinion, are most likely connected with the leptomeninges. No truly intracerebral chondromas have been reported. Trauma may be said to be the provocative agent in producing these abnormal growths.

ACUTE PUTRID ABSCESS OF THE LUNG

III. Roentgenographic Features

ARTHUR S W TOUROFF, M.D, F A C S, and HAROLD NEUHOF, M D, F A C S,
New York, New York

ACUTE anaerobic (putrid) pulmonary abscess is a primary suppurative disease of the lung, the diagnosis of which is based essentially upon fairly characteristic clinical manifestations and roentgen features. Although the symptomatology of the disease has been the subject of previous discussion (4), little has been written concerning the roentgenographic findings. As a result, a general lack of appreciation of the significance of a number of roentgenographic features of the disease seems to exist. Our purpose in presenting the subject in some detail, at this time, is to emphasize the value of the roentgenogram not only in establishing the diagnosis of acute putrid pulmonary abscess but also in serving as a guide to the prognosis and treatment of the disease.

Roentgenograms in cases of acute putrid abscess of the lung fall into two general groups: first, those disclosing a well defined cavity containing fluid and air, and, second, those disclosing essentially an area of pulmonary infiltration. Films disclosing a cavity of fair size containing a fluid level are also to be seen in such diseases as a putrid necrosis complicating lobar pneumonia, aerobic (non-putrid) pulmonary abscess, tuberculosis with cavitation, necrotic pulmonary neoplasm, small encapsulated pyopneumothorax, partially empty pulmonary cyst, pulmonary infarction with cavitation, and pulmonary cavitation due to infection by higher bacteria (especially streptothricosis and leptothricosis). Films disclosing essentially an area of fairly dense pulmonary infiltration, as noted in the second group of cases of acute putrid pulmonary abscess, are also to be seen in a variety of pulmonary diseases, the most common of which are the pneumonias due to various organisms, tuberculosis, localized bronchiectasis, pulmonary neoplasm, infarction of the lung, etc. Thus, it is obvious that the diagnosis of acute putrid pulmonary abscess cannot be made by roentgenography alone, and that in the final analysis the symptomatology of the patient must constitute the basic criterion of diagnosis. Roentgenography, however, is a diagnostic method of prime importance, and one which is essential for corroboration of the clinical diagnosis. Furthermore, for pur-

poses of accurate localization of the lesion it is indispensable. Finally, it serves as a most reliable guide to the progress and prognosis of the disease. Since the clinician is charged with the responsibility not only of establishing the diagnosis but also of making the decision as to the type of therapy and the time when it is to be instituted, it is essential that he be thoroughly acquainted not merely with the clinical manifestations of the disease but with its roentgenographic features as well.

In order to avoid any misunderstanding of the term "acute abscess," we arbitrarily designate as acute cases those of not more than 6 weeks' duration from the time of onset of pulmonary manifestations (2). The observations about to be recorded are based upon a study of more than 150 such cases. Sixty-five of these have been subjected to operation, at various times within the aforementioned 6 week period, by methods which we already have described (2). These cases are of particular value for purposes of discussion because the actual pathological findings, as disclosed at operation, have been correlated directly with pre-operative roentgen findings. Thus in each case, not only the correctness of pre-operative diagnosis but also the accuracy of interpretation of finer details of roentgenograms have been determined. Prior to our advocacy of operation in the acute stage of putrid abscess of the lung (2), there was little opportunity to study the pathological features of this stage of the disease or to correlate them with the early roentgenographic findings. As a result of our experience with these surgically treated cases, however, we not only have learned much concerning the pathology of acute abscess of the lung, but also have come to appreciate the significance of certain roentgenological findings which formerly appeared to be of little moment. Since correct interpretation of the details of the roentgenogram is based essentially upon a knowledge of the pathological features of the disease, a brief description of the pathology of acute pulmonary abscess now will be presented.

PATHOLOGY

Acute putrid abscess of the lung, the result of known or assumed aspiration of anaerobically in-

fectured material begins in and distal to one of the smaller bronchi at the site of arrest of such aspirated particulate material. An intense destructive inflammation occurs almost immediately in the involved bronchus and its tributary bronchioles and alveoli. The result is a localized gangrenous bronchopneumonia involving part or all of a bronchopulmonary segment (1). Necrosis and liquefaction of the structures in the involved area soon supervene, and result in the formation of a localized abscess containing foul pus, pulmonary sloughs and detritus. Abscess formation (cavitation) occurs early, and usually is present within a week to 10 days of the onset of infection. The lesion invariably is situated superficially within one of the lobes of the lung. As a result, early and pronounced overlying adhesive pleuritis occurs. This is present in all cases and constitutes a constant pathological feature of the disease. Depending upon the site of the abscess, the visceral pleura overlying the lung in the involved area is agglutinated to the thoracic parietal pleura, to the diaphragmatic pleura, to the mediastinal pleura, or to an adjacent lobe. Thus, the typical acute putrid abscess as noted at operation is a solitary cavity, varying from 1 to 3 inches in diameter, situated within the lung only a short distance beneath the visceral pleura. The walls of the cavity consist of infiltrated, compressed pulmonary tissue, usually covered by adherent detritus and presenting the mouths of one or more eroded bronchi. The contents of the cavity at any given time, depend upon the degree of necrosis and liquefaction which already has occurred and also upon the degree of spontaneous drainage and aeration which has taken place through the communicating bronchus or bronchi. At a very early stage the involved area is occupied by pulmonary tissue which is undergoing necrosis but still merges with the relatively more normal tissue at its periphery. At a later stage, the involved tissue begins to liquefy and becomes demarcated at various points. In these areas it becomes separated from the wall of the abscess cavity. Subsequently the slough separates completely and itself liquefies entirely or in part. With the onset of initial liquefaction, spontaneous drainage and aeration through the communicating bronchi occur in varying degree. These phenomena depend not only upon the fluidity of the contents of the cavity but also upon the patency of the bronchi which open into the cavity. Bronchial patency is determined by the degree of inflammatory swelling of the bronchial mouths and the degree of their obstruction by exudate. If drainage and aeration via the bronchial tree are adequate and the anaerobic infection is controlled,

the lesion may heal spontaneously. If not the lesion becomes chronic in the vast majority of cases. Since our paper deals specifically with acute putrid abscess of the lung, the pathological features of the subacute and chronic phases will not be described.

FACTORS RESPONSIBLE FOR ROENTGENOGRAPHIC FINDINGS

Various gross pathological changes, which occur within the involved pulmonary area during the acute stage of the disease, have their counterpart in changes which are to be noted in the x-ray film. In general the roentgenographic features depend upon a combination of the following circumstances: (1) the size of the lesion, (2) its location, (3) the degree of infection present, (4) the degree of liquefaction which has occurred, (5) the degree of spontaneous drainage and aeration which has taken place via the bronchial tree, (6) the presence or absence of extension of the lesion beyond its original limits, (7) the extent and intensity of the overlying pleural reaction, (8) the presence or absence of perforation of the lesion into the pleura together with the degree and extent of the accompanying pleural response, (9) certain factors which are concerned with roentgenographic technique. Since each of the factors is variable, it is evident that combinations of them will result in roentgenograms with widely varying details. It is roentgenographic differences may exist not only between one case of acute putrid pulmonary abscess as compared with another but also between serial films in individual cases. All other factors remaining constant the time interval between the onset of infection and the taking of the roentgenogram is the factor chiefly responsible for the varied roentgen findings. Thus if comparisons are to be made between the findings in various cases it is essential that the films which are to be compared be taken at corresponding times following the onset of the disease.

In the individual case, time is also the factor largely responsible for the changing roentgen picture. For example in the earliest phase evidence of cavitation is not to be noted in the roentgenogram. As necrosis and liquefaction progress however evidence of cavitation in one form or another generally appears. As will be pointed out later the time at which typical evidence of cavitation is noted varies considerably, and in some instances may be delayed far beyond the usual period.

While it is not our intention to discuss the treatment of acute putrid abscess of the lung, it is proper to stress the dangers of prolonged observation of patients pursuing an unsatisfactory clinical

ical course, in order to await the appearance of "typical" evidence of cavitation. Serious complications, which increase the morbidity and the immediate and ultimate mortality, may result from such undue delay of therapy. If the clinician realizes that "typical" evidence of cavitation is not the *sine qua non* of roentgen diagnosis and has a knowledge of the various roentgenographic features of the disease and their significance, he is in a position to corroborate the clinical diagnosis at an early stage and therefore to begin his therapeutic efforts promptly. As we have shown elsewhere (2, 3), operative treatment is especially important in the early stages of cases which are not progressing satisfactorily.

ROENTGENOGRAPHIC EXAMINATION

Films are taken upon admission of patient to the hospital and, if the clinical progress is satisfactory, at weekly intervals thereafter. If the clinical manifestations indicate an unfavorable course, or if the initial films suggest that early operative intervention may be desirable, films are taken more often. If, at any time, there is a rise in temperature, sudden cessation or marked diminution of expectoration, recurrence of pain in the chest, dyspnea, or the appearance of new or untoward physical signs or symptoms, immediate roentgen examination is imperative.

Films are taken routinely with the patient in the erect posture, placed carefully in the postero-anterior and then in the lateral position. Although slight rotation of the body out of the *exact* postero-anterior or lateral position as a rule makes little difference from the standpoint of diagnosis, it may result in inaccurate localization of the lesion. Since we are not concerned in this article with methods of localization, this phase of roentgenography shall not be discussed, but will be the subject of a separate communication in the near future.

There are several reasons for taking films routinely with the patient in both the postero-anterior and lateral erect positions. Postero-anterior films reveal the details of the vast majority of lesions clearly and in accurate proportions. Certain details not visible clearly in the postero-anterior view often are noted readily in the lateral view. At times single or multiple small fluid levels, visible when the patient is in the postero-anterior position, may not be seen with the patient in the lateral position (Figs. 11 and 12), and vice versa (Figs. 13 and 14). Very frequently accentuation of the interlobar fissures, the significance of which will be discussed later, will be indistinct or not seen at all in the postero-anterior film, while in the

lateral film it will be clearly discernible (Figs. 12 and 14). The details of lesions lying behind or in front of the heart or hilus of the lung may be more distinct in the lateral than in the postero-anterior film. On the other hand, lesions lying on either side of the heart, or immediately lateral to the hilus of the lung, or in the paravertebral region, may be more readily visible in postero-anterior than in lateral films. Finally, films taken with the patient in the erect position, in contrast with those taken in the recumbent or semi-recumbent position, are essential for the demonstration of fluid levels. Recumbent or semi-recumbent films are of little or no value for this purpose, because air situated above fluid cannot be demonstrated when the rays are directed in such a manner as to penetrate them in succession, that is from above downward.

The significance of a horizontal line of increased density, seen in the postero-anterior or lateral erect film and suggesting the presence of a fluid level, may have to be determined by a film taken with the patient in the lateral recumbent position, or in the erect position with the body well tilted to one side or the other. Under such circumstances the presence of a fluid level is established if the line under suspicion remains horizontal regardless of the patient's position. Oblique films, with the patient in the erect position, are of special value in those instances in which the area under suspicion tends to be obscured in the routine postero-anterior or lateral film. Thus, the details of a lesion lying in front of or behind the heart, or in close proximity to the sternum or vertebral column, are frequently clarified in an oblique film. Oblique films are occasionally of value when the lesion lies along the extreme lateral border of the chest, and thus tends to be obscured by the superimposition of the anterior and posterior curvature of the ribs. When the lateral film discloses a posteriorly situated lesion, certain details not entirely clear in the customary postero-anterior view may be more readily discernible in the anteroposterior position. With the patient in the latter position, the lesion lies closer to the film, there is less diffusion of the rays, and its image therefore is clearer. We do not employ stereoscopic films and wish again to emphasize that simple postero-anterior and lateral films taken with the patient in the erect posture, have sufficed for purposes of diagnosis, localization, and determination of the progress of the lesion, in the majority of instances.

ROENTGENOGRAPHIC FINDINGS

We now proceed to the presentation of roentgenographic findings in acute putrid abscess of the

lung. These are usually readily explainable on the basis of a consideration of the pathological changes, as described in previous paragraphs.

1 *The typical case.* The earliest roentgenographic feature, to be noted in the typical case, is the appearance of a small area of pulmonary infiltration. The latter is indistinguishable from a patch of bronchopneumonia of the usual variety, except that as a rule it is more sharply circumscribed, its margins more rounded, and its limits more clearly defined (Fig. 2).¹ The infiltration usually becomes visible within a week of the onset of infection. The next phase consists of an increase in the density and in the extent of the infiltration. The third phase begins with the onset of visible evidence of necrosis and cavity formation (Fig. 3). At this time, striking changes usually are to be noted in the roentgenogram. These consist in the occurrence of one or more small areas of increased illumination (diminished density) within the pre-existing area of infiltration, and are produced by softening and liquefaction of small foci within the area of gangrenous bronchopneumonia. As liquefaction continues, these multicentric areas of softening tend to coalesce. Frequently their coalescence can be followed in serial roentgenograms until the typical unilocular cavity is produced (Fig. 4). Usually the major portion of the pre-existing area of pneumonic infiltration becomes progressively excavated and as a rule only a thin rim of infiltrated and compressed pulmonary tissue remains peripherally as the "wall" of the abscess cavity (Figs. 5, 6, and 7). Within the cavity, a horizontal level of fluid surmounted by air is seen. With changes in the position of the patient, the fluid maintains its horizontal level. In the average case the diameter of the cavity varies from 1 to 3 inches, and the width of the surrounding pulmonary infiltration from $\frac{1}{4}$ to $\frac{1}{2}$ an inch (Fig. 9).

If drainage and aeration are adequate, the cavity becomes evacuated completely, the existing infection subsides and disappears, the surrounding narrow zone of pulmonary infiltration is absorbed, and the cavity disappears. Subsequent films then reveal limited fine pulmonary fibrosis, which either remains visible permanently or in time disappears completely. In general a lesion which heals spontaneously is usually of comparatively small size or is represented by an area of infiltration of comparatively slight density. Also as a rule, it passes fairly rapidly through the various phases of evolution and regression. Thus

in our experience, cases of acute purulent abscess of the lung which heal spontaneously usually regress completely or show a definite tendency toward regression well within the six week (acute) period. If by that time the tendency toward spontaneous resolution is not well established, the chances of its occurrence at a later date become increasingly remote. Accordingly we have found a sharp decrease in the number of cases which subside spontaneously, and a corresponding increase in morbidity and mortality during the subacute stage (6 to 10 weeks). During the chronic stage spontaneous subsidence practically never occurs.

2 *Variations.* A not uncommon variant from the typical picture as described is one in which the lesion is unusually large. As stated previously, the average acute abscess varies from 1 to 3 inches in diameter. In some cases the lesion exceeds this size and on not a few occasions we have noted abscesses 4, 5, and even 6 inches in diameter. Excavation in these cases proceeds as rapidly and at times even more rapidly than in the typical cases (Figs. 5, 6, and 7). Because numerous bronchi in the involved area undergo necrosis, large abscesses often drain and ventilate fairly freely. They therefore appear in the roentgen film as large air-filled cavities containing comparatively small amounts of fluid and surrounded by zones of pulmonary infiltration of varying width. Not infrequently, because of its large size, the differentiation of such a lesion from perforated abscess with associated encapsulated pyopneumothorax is extremely difficult or impossible. While large abscesses conceivably may subside spontaneously at times the patients usually have been so toxic and the uncertainty of the coexistence of a complicating putrid pyopneumothorax so great that we have been unwilling under such circumstances to defer operation.

Although pulmonary cavitation as stated previously occurs early in cases of purulent abscess, the typical roentgenographic evidence of cavitation, namely a circular area of rarefaction with fluid level, varies considerably in the time of its appearance. Thus, in some cases the cavity becomes visible in the roentgenogram almost as soon as cavitation occurs, while in others it may not be visible for days or even weeks. In still other cases a cavity may not be seen during the acute stage, and finally in others a cavity may never be noted even in the subacute or chronic stage. Likewise the amount of fluid to be noted within the cavity varies considerably.

3 *Fluid levels and cavities.* As indicated in the section on pathology, the presence or absence of a cavity containing fluid and air in the roentgeno-

FIGURES 1, 2, 3, and 4 illustrate the evolution of an acute purulent abscess of the lung in a single case. Fig. 1, roentgen film, 1 week before the chest was opened; Fig. 2, roentgen film, 2 weeks before the chest was opened; Fig. 3, roentgen film, 3 weeks before the chest was opened; Fig. 4, roentgen film, 4 weeks before the chest was opened. The patient died of the abscess. We are indebted to Dr. William L. W. for the use of these films.

gram is an accident which depends upon the degree of spontaneous drainage of fluid secretion through the communicating bronchi, and its re-

placement by air. If drainage is free, the cavity on x-ray examination contains little or no fluid. On the other hand, if the communicating bronchi are

Fig 3 W R Same case as in Figures 1 and 2. Seven days later. Increase in density and extent of pulmonary infiltration (sixth to eighth ribs), and beginning cavitation beneath sixth rib.

Fig 4 W R Six days after Figure 3. Large area of dense pulmonary infiltration (fifth to eighth ribs), containing a cavity with small fluid level. Film indicative of inadequate spontaneous drainage. Unsatisfactory clinical course.

Fig. 5 J. R. Early phase in the development of a large abscess of lung. Infiltration extends from the ninth rib downward. Enlarged hilar glands are present. This is a typical case.

Fig. 6 J. R. Eight days later. Pulmonary infiltration replaced by a large cavity containing fluid and air. Limited pulmonary infiltration about cavity. Irregular cortex of cavity indicating early peripheral extensions.

completely obstructed by inflammatory edema or by detritus, none of the contents of the cavity can escape and no air can enter. Under such circumstances the shadow cast by the filled cavity merges with and is indistinguishable from, that of the

surrounding pulmonary infiltration. Thus in some cases the typical roentgenographic evidence of cavitation may not be visible despite the actual existence of a large cavity within the lung (Fig. 8). In other words, at times the presence of 'premonitory' infiltration may indicate not an absence of cavitation but an abscess cavity completely

Fig. 7 J. R. Same case as in Figures 5 and 6. Lateral view (same time as Figure 6). Sharp limitation of lesion and minimal surrounding pulmonary infiltration.

Fig. 8 M. F. Dense pulmonary infiltration in right paravertebral area without evidence of cavitation. At operation a large abscess was encountered.

Fig 9 M K Well defined abscess of average size Small fluid level indicating free drainage Moderate surrounding pulmonary infiltration

Fig 10 M K Same case as Figure 9 One day later Cavity filled with pus because of inadequate drainage Increase in density of entire lesion

filled with pus and detritus. Between the extremes of free drainage on the one hand and total absence of drainage on the other, all gradations and variations in the degree of spontaneous drainage exist.

After spontaneous drainage and aeration have begun, the roentgen evidence of the existence of a cavity may vary from a tiny fluid level surmounted by a small bubble of air (Fig 13) to an air filled cavity containing either no fluid or a small amount of fluid (Fig 9). It should be emphasized that the patency of the communicating bronchi may vary considerably from time to time and that a lesion which is draining well at one time may drain poorly or not at all at a later date. The result of such a sequence is a roentgenogram disclosing a cavity containing a well defined fluid level, followed by one in which the cavity apparently has diminished considerably in size or has disappeared in the midst of the surrounding pulmonary infiltration (Figs 9 and 10, 15 and 16). If spontaneous drainage and aeration become re-established at a later stage, the cavity reappears, its size then depending upon the degree of drainage and aeration.

Other roentgenographic variations are to be noted at times in cases in which spontaneous drainage and aeration are inadequate. A fairly common type is one in which a cavity of small or moderate size is surrounded by an extensive zone of dense infiltration (Figs 4, 13). In another type, multiple small areas of increased illumination (diminished density), with and without contained fluid

levels, are to be noted within an area of extensive infiltration (Figs 11 and 17). And finally, as stated previously, a common type is one in which only dense infiltration alone is visible (Figs 8, 10, and 16).

4 *Spread of infection* If drainage remains poor or ceases entirely, the lesion either remains unchanged in extent for a variable period of time or else commences to enlarge. In the latter instance, there is first an increase in the extent of the infiltration. This may occur in concentric fashion or may take place at one or more points at the periphery of the original lesion. As fresh invasion of pulmonary parenchyma occurs, the newly involved area undergoes pathological changes which are identical with those of the primary lesion (Figs 16 and 17). Not infrequently, some drainage and aeration of the entire involved area may occur as the result of the erosion of a previously uninvolved bronchus (or bronchi), and as a result an irregular multilocular cavity consisting of the original abscess together with the recent extensions may become visible in the roentgenogram. The ultimate fate of such a lesion depends apparently, as in the first instance, on the degree of evacuation and aeration via the communicating bronchi.

In addition to spread of pulmonary infection by direct extension from the original site into the surrounding uninvolved pulmonary tissue (Figs 16 and 17), new infection may occur by the mechanism which we have termed "spillover." The latter type of spread results from the aspiration of anaerobically infected pus, derived from the bronchi

Fig 11 A J Large abscess of right lung 1 week after onset. Multiple areas of rarefaction (with and without fluid levels) within the zone of pulmonary infiltration. Film indicative of incomplete liquefaction. Septic clinical state.

Fig 12 A J Lateral view (same time as Figure 11). Details of lesion are not seen. Accentuation of oblique and transverse interlobar fissures. Abscess lies in apex of lower lobe close to the junction of these fissures.

draining the abscess cavity, into previously uninvolvement bronchi. As the result of such inoculation of new bronchopulmonary segments gangrenous bronchopneumonia similar to that which occurred at the onset of the original abscess, is to be noted. These "spillover" lesions may occur within the same lobe, adjacent lobes, or the opposite lung. If "spillover" infection occurs within the same lobe, it may be indistinguishable roentgenographically from spread by direct extension because of the proximity of the old and the new lesions.

Spillover infection to other lobes or to the opposite lung, is readily recognized by virtue of its distance from the original lesion (Fig 18). From the clinical and roentgenographic standpoint the fate of the fresh spillover lesion varies in accordance with certain circumstances which were detailed in preceding paragraphs. Unfortunately spillover infection frequently involve such a large area that the patient often succumbs from the toxic effects of fresh gangrenous bronchopneumonia before the occurrence of extensive cavitation.

5. *The associated pleural reaction.* A roentgenographic feature of interest in cases of acute putrid pulmonary abscess is the associated pleural reaction. We are now discussing specifically only cases of acute abscess which have not perforated into the pleura. It was indicated previously that adhesive pleuritis occurs invariably directly over the site of an acute abscess. The adhesions are situ-

ated most commonly between the lung and the thoracic parietes but occasionally between the lung and the diaphragm or mediastinum. At times the situation of the lesion may result in the formation of adhesions only between two adjacent lobes. The pleuritic response is dependent upon the irritative effect of the abscess the most superficial portion of which lies close to the overlying visceral pleura. Other factors being constant the extent of the pleuritis is proportionate to the size of the lesion. By the same token adhesions will be most dense in the area in which the lesion most nearly approaches the surface of the lung. Thus in cases in which a well defined cavity surrounded by comparatively little pulmonary infiltration is visible on x ray examination the pleural reaction as disclosed at operation usually does not extend far beyond the limits of visible cavitation. On the other hand when a comparatively small cavity exists in the midst of a wide zone of pulmonary infiltration the pleural reaction extends not only over the site of visible cavitation but also approximately to the limits of the pulmonary infiltration (Fig 17).

At times the pleural reaction appears to be unusually dense and to extend well beyond the

Fig 13 M W Area of dense pulmonary infiltration in axillary segment of left lung Solitary cavity, apparently small Film indicative of inadequate drainage

Fig 14 M W Lateral view (taken at same time as Figure 13) Multiple cavities containing fluid levels, not visible in postero-anterior view (Fig 13) Accentuation of upper part of interlobar fissure and widening of lower part Pulmonary lesion in upper lobe facing fissure

area of pulmonary involvement This is most apt to occur when the abscess offers roentgenographic evidence of inadequate spontaneous drainage, as shown by the existence of dense pulmonary infiltration alone or by infiltration containing single or multiple small areas of increased illumination with or without small fluid levels Dense and extensive pleural reaction is to be regarded seriously, as not infrequently it is an indication of impending or actual perforation of the lesion into the pleura When spontaneous drainage and aeration are inadequate, peripheral spread of infection is particularly apt to occur, and the thin shell of lung overlying the abscess becomes invaded by the advancing infective process Under such circumstances, rapid spread of the adhesive pleuritic reaction may be assumed While it is not our purpose in this paper to describe the general roentgenographic features of perforated abscess, attention should be called to the fact that under certain circumstances localized perforation of a pulmonary abscess into the pleura may exist without producing significant changes in the roentgenogram Thus, in cases in which there is roentgenographic and clinical evidence of inadequate spontaneous drainage and aeration via the bronchial tree, and the overlying pleural reaction is dense and extensive, perforation into the existing pleuro-pulmonary adhesions may have occurred Since the bronchi which open into the abscess cavity in such cases are not widely patent (as evidenced by absence of a fluid level within the area of infiltration), a small empyema rather than a pyopneumo-

thorax (which is the usual roentgen sign of perforation of abscess of the lung into the pleura) is produced. Because of the extent and density of the pre-existing pleural reaction, such small empyemas may not be recognizable in the x-ray film Thus, as reported in a previous communication (3), actual local perforation into the pleura which was not known to exist before operation, was found at operation in several instances On the other hand, at times pleuritic response may be so well marked that local perforation into the pleura may be suspected yet be absent at operation

6 *Interlobar fissures.* Another interesting and significant roentgen finding, in certain cases of acute abscess of the lung, is the accentuation of interlobar fissures As stated previously, putrid pulmonary abscess, because of its situation superficially within a lobe, is accompanied regularly by reaction in the overlying pleura When a pulmonary abscess lies in close proximity to one of the fissures, the overlying pleural reaction may occur exclusively within the fissure and agglutinate the surface of the involved lobe to the surface of an adjacent normal lobe In such unusual cases, at operation, adhesions between the lung and tho-

racic parietes usually are absent or minimal. The occurrence of pleural reaction within one of the

Fig. 17 S-M Same case as in Figures 15 and 16. One week after Figure 16 was taken. Further spread of disease indicated by increase in density, extent of pulmonary infiltration and pleural reaction. Original cavity not visible. Several new areas of rarefaction in lowermost part of infiltrated area.

fissures is indicated roentgenographically by the presence of a line of opacity occupying the position of the fissure in question. Such opaque lines are not seen in normal pulmonary fields.

The degree and extent of fissural accentuation as noted in the x-ray film is directly proportional to the degree and extent of fissural pleuritis. A pulmonary abscess of the upper or lower lobe facing a point along the lower part of the long (oblique) interlobar fissure, usually is associated with accentuation of the lower part of the fissure only. A lesion facing the upper part of the fissure is accompanied by accentuation of this portion of the fissure and frequently by accentuation of the lower portion as well as the result of downward seepage of exudate (Fig. 14). On the right side a lesion of the upper or middle lobe facing a point along the short (transverse) fissure usually is associated with accentuation of this fissure. Finally, both the oblique and transverse fissures may be accentuated by a lesion lying at a point close to the junction of the fissures within either the upper, middle or lower lobe (Fig. 12). In all cases of irritative accentuation the fissure appears as a thin well defined line of increased density. In some instances it is represented by a more dense and somewhat wider line indicative of more severe pleuritic reaction. This occurs commonly in cases in which an abscess of one lobe has perforated across the sealed-off fissure into an adjacent lobe.

or in cases in which such perforation is imminent. In still other cases, the interlobar fissure may be represented by a fairly wide zone of density indicative of interlobar effusion or exudate (Fig 14). This may be the result of impending or actual perforation of a pulmonary abscess into the fissure, in cases in which the lobes have not become firmly agglutinated. Although accentuation of the fissures may be visible in both the postero-anterior and lateral films because of limited superimposition of pulmonary tissue, it is best seen in the lateral film. Thus fissural accentuation not visible in the postero-anterior film may be seen readily in a lateral film taken at the same time.

ROENTGENOGRAPHY AS AN INDEX OF THE COURSE OF THE DISEASE

After the diagnosis of acute pulmonary abscess has been established, the clinical manifestations and the roentgen findings continue to be an index of the progress of the lesion. There are times, however, when the evidence gained from these two sources appears to be in conflict. The question then arises, which is to be considered the more important and upon which the greater reliance is to be placed in the evaluation of the status of the patient. For example, in the majority of "typical" cases of acute putrid abscess, the symptoms become ameliorated as spontaneous drainage and aeration are established. Thus at the end of 2 to 3 weeks, the temperature is apt to be lower and the sputum not infrequently diminishes in amount. At that time the sputum may become less foul, may be foul only at intervals, or may become entirely odorless. If the x-ray film reveals diminution in the size of the cavity and in the extent of infiltration, the assumption that improvement is taking place is warranted. On the other hand, if the roentgenogram reveals increase in the size of the cavity and persisting or increasing pulmonary infiltration, the mildness of the clinical manifestations must be disregarded. This dictum cannot be emphasized too strongly, since some of our patients with chronic abscess of the lung previously had been discharged by their physicians as cured in the acute phase of the disease, although roentgenograms taken at that time revealed persisting pulmonary infiltration. Thus, "cure" cannot be considered to have taken place, regardless of the subsidence of clinical manifestations, unless roentgen evidence of pulmonary infiltration has disappeared completely.

At times, clinical manifestations may become more severe concomitant with apparent roentgenographic improvement. Under such circumstances, the observer may be unable to decide

Fig 18 P M Acute "spillover" abscess of right upper lobe following recent operation upon subacute abscess of left lower lobe. Infiltration in right upper lobe containing a cavity with fluid level just above sixth rib. Residual infiltration at site of operation in left lower lobe.

which of these criteria to utilize in evaluating the patient's status. We wish to state that such a discrepancy can be due only to an error of roentgen interpretation. The mistake which usually is made is the assumption of improvement on the basis of disappearance of a cavity in the roentgen film despite the persistence of pulmonary infiltration. As stated previously, this sequence is common when spontaneous drainage and aeration become inadequate, for under such circumstances the cavity within the lung, which seemingly disappears, merely becomes invisible because it is filled with secretion (Figs 9, 10, 15, and 16). Proof that the lesion has become "shut-off" from the bronchial tree often is offered by alteration of the clinical manifestations. Thus, the sputum may decrease sharply in amount and lose its foul odor entirely or in part. The temperature, however, is apt to be higher, the pulse rate to increase, and the patient to look and feel more ill. If peripheral spread of the lesion follows, there is apt to be a recrudescence of thoracic pain and of hemoptysis. Thus, when the clinical course is unsatisfactory, the very existence of an apparent discrepancy between clinical symptomatology and roentgenography should lead to the suspicion of an error in interpretation of the roentgen film.

A consideration of the relative value of these two criteria of progress of the lesion leads therefore to the conclusion that roentgenography, when the findings are interpreted correctly, is as reliable as, and at times more reliable than, the symptomatology. From the standpoint of reliability in

instances in which the question of cure is considered we can only state again that experience has demonstrated on numerous occasions that, regardless of the complete absence of clinical manifestations no patient can be considered cured until all pulmonary infiltration has disappeared.

SUMMARY AND CONCLUSIONS

This contribution is based upon observations made in a series of more than 150 cases of acute putrid pulmonary abscess. In 65 cases operation was performed in the acute stage of the disease. Thus there was ample opportunity to correlate operative findings with pre-operative roentgenograms.

The diagnosis of acute putrid pulmonary abscess rests both upon clinical features and roentgenographic findings. The disease *cannot* be diagnosed solely by roentgenography. The latter is, however, a diagnostic method which is absolutely essential for corroboration of the clinical diagnosis. Roentgenography is the most important method for accurate localization of the lesion. It also serves as an index of the course and prognosis of the disease.

The pathological features and the factors responsible for the varied roentgenographic appearances in acute putrid pulmonary abscess are presented.

Methods of roentgenographic examination with special reference to demonstration of the pulmonary lesion are described.

In the evolution of the typical case of acute putrid pulmonary abscess early roentgenograms reveal only the presence of a limited area of pulmonary infiltration. The latter increases in extent and density in the second stage. Rarefaction

within the involved area occurs in the third stage. The fourth stage is one of progressive excavation of this area. The cavity contains air and fluid and is surrounded by limited pulmonary infiltration.

Among the roentgenographic variants which are discussed are: Unusually large size of the abscess; rapid increase in size of the lesion; variations in the time of onset of cavitation; absence of evidence of cavitation; early multilocularity; wide spread pulmonary infiltration with and without cavitation; sudden disappearance of cavities; extensive pleural reaction; evidence of spread of infection by direct extension or by "spillover."

The pleural reaction accompanying acute pulmonary abscess and its variations are described with special reference to roentgenographic aspects. The significance of accentuation and other abnormalities of the interlobar fissures are discussed.

The greater reliability of roentgenography as compared with clinical manifestations as an index of the course of acute pulmonary abscess, is stressed. Emphasis is placed upon the necessity of correct roentgen interpretation when apparent roentgenographic improvement is noted in the presence of an unsatisfactory clinical course.

OPERATIVE MANAGEMENT OF FIBROMYOMAS IN THE UTERUS AT TERM

CARL P. HUBER, M A, M.D., F A.C.S., Indianapolis, Indiana
H. CLOSE HESSELTINE, M S, M D, Chicago, Illinois

PREGNANCY is infrequently accompanied by fibromyomas of the uterus, and these tumors require operative interference even less often during pregnancy, labor, and the puerperium. Active controversy concerning the choice of myomectomy or hysterectomy for those requiring treatment after viability of the fetus and in the puerperium is well illustrated by the conflicting statements in the literature. Therefore, this present study was undertaken to evaluate better the relative merits of each

LITERATURE

In several large series of pregnant patients the frequency of fibroid tumors varies from 0.3 per cent (2) to 1.4 per cent (10) with the average incidence being near 0.5 per cent (1-4, 7, 10). In the majority of such cases the fibroid does not interfere with the usual course of pregnancy, delivery, or the puerperium. Many times the nodules are findings which are accidentally discovered when the uterus is palpated during labor or the puerperium. The size, position, type, and number of tumors are the significant factors.

Submucous, large subserous, and intramural fibromyomas are often responsible for sterility and for an increased incidence of complications in pregnancy. Abortion and premature labor may result. However, an equally serious problem is offered by the fibroid tumor which is of sufficient size or so located that it may produce obstruction to the passage of the fetus through the birth canal. Less than one-half of the fibroids complicating pregnancy are of this type but they, nevertheless, offer a distinct problem in the management of parturition. Degenerative changes or infection in the tumor are also of serious import.

The usually accepted plan for treatment of fibroids during pregnancy consists of careful observation without interference unless symptoms of sufficient magnitude arise. In such instances, myomectomy may be done before fetal viability, for one or a few readily accessible nodules if the product of conception remains undisturbed. Abortion occurs frequently subsequent to this type of

operative interference. Hysterectomy is a preferable procedure for multiple and inaccessible tumors, for unsatisfactory hemostasis following myomectomy, or for a seriously damaged uterus.

At the end of gestation obstetricians generally agree that the following possibilities must be considered in deciding the method of delivery:

(1) Even if the birth canal is unobstructed and vaginal delivery seems probable, the fibroid may be associated with inadequate or faulty uterine contractions enough to prolong labor dangerously.

(2) The tumor may offer unrecognized obstruction to the passage of the fetus. For these reasons, the early part of labor should be considered in the light of a trial labor and not as a commitment to vaginal delivery.

(3) The presence of the fibroid tumor increases the frequency of vaginal operative interference.

(4) Complications of the third stage of labor are more frequent as has been shown by Campbell's report of postpartum hemorrhage (600 cubic centimeters) in 31.7 per cent and adherent placenta in 9.7 per cent of his series.

(5) Although vaginal delivery may be accomplished without difficulty, degenerative changes in the fibroid may still necessitate operative interference during the puerperium. Necrosis was present in 75.8 per cent of fibroid tumors in 82 pregnant patients (Campbell). This is almost ten times greater than the incidence of 7.8 per cent, in the non-pregnant state.

When cesarean section is the method used for delivery it may be done alone, combined with myomectomy, or followed by hysterectomy. When it is the only procedure the risk of postpartum hemorrhage and necrobiosis persists, and the fibroid still remains as a source of morbidity. Myomectomy in conjunction with cesarean section may remove the more prominent tumors, but others may develop subsequently. A more immediate danger is hemorrhage through inadequate or unsatisfactory hemostasis and infection in the operative site. Removal of the uterus should decrease the danger of infection and at the same time prevent further trouble from enlarging fibromyomas. Of course, extirpation of the uterus excludes future childbearing.

ANALYSIS OF DATA

Controversy is evidenced by conflicting recommendations in the choice between myomectomy and hysterectomy at the time of cesarean section. In order to obtain a better evaluation of these two types of therapy pooled data were used to eliminate errors in individual smaller series. To obtain a balanced report, it was deemed advisable to use only those in which a series of cases was published as the numerous isolated case reports almost invariably represent a favorable termination which might thus give a false value. The 10 reports meeting these requirements, published since 1920, are presented in Table I. Due to the improvement in pre-operative and postoperative care and management in recent years it was believed that earlier studies might well be excluded. These quoted reports offer a significant number of cases and also contain adequate information concerning the associated mortality. In addition, operative procedures in the immediate puerperium are included. Including the report from the Chicago Lying in Hospital department of obstetrics and gynecology. The University of Chicago, 8 of the 11 sources have cared for 182,543 obstetric cases. The total deliveries covered by the 3 other reports is not given but certainly represents a proportionately greater number. In this pooled group the fibroid was of sufficient significance to warrant abdominal delivery in 131 cases. In 23 additional instances operative treatment of the fibroid tumor subsequent to vaginal

delivery was necessary during the course of the puerperium.

Cesarean section alone was done in only 18 cases, all of which are reported by 3 of the authors (3, 4, 6) listed in Table I. No deaths are recorded. The one death (3) not definitely assigned to the separate procedures may have been in this group as noted in Table I. It is interesting to note that in over 115 000 cases analyzed by the 8 remaining authors (1, 2, 5, 7-10) cesarean section alone was not done.

Cesarean section was followed by hysterectomy in 59 cases. In this group there was one death recorded and in the one instance indicated in Table I it could not be determined whether the recorded mortality was in the hysterectomy group or subsequent to myomectomy. Even if we assume that both of these deaths occurred in the hysterectomy series, the maximum mortality percentage would be 3.4 per cent.

Myomectomy was performed in conjunction with cesarean section in 39 cases. Five deaths are definitely recorded in this group and if the designated case occurred in this group, the total is raised to 6. The mortality rate is then at least 15.4 per cent and may have been as much as 15.4 per cent.

The difference in the mortality in these two groups is so great that the probable error in relatively small series does not account for the variation. In addition, it is a fair assumption that myomectomy was done on those patients

whose tumors appeared least difficult of removal. It seems only just then to conclude that at the time of cesarean section hysterectomy is a safer procedure than myomectomy.

Further evidence for this statement is found in the fact that 13 hysterectomies were done in the puerperium without mortality whereas one fatality occurred in 10 myomectomies.

In the 20,895 patients who have been delivered at the Chicago Lying-in Hospital (Table II) from May 25, 1931 to January 1, 1938, 10 patients have had fibroid tumors of a nature to interfere with delivery, or an incidence of .05 per cent. In this group Porro cesarean section was done 8 times and cesarean followed by myomectomy in 2 instances. The 1 death occurred in the myomectomy group.

A consideration of morbidity in the two groups shows that in 4 of the 8 Porro cesarean sections the temperature was above 100.4 degrees on 2 or more days postpartum. This was true of both cases in which myomectomy followed cesarean section. In the hysterectomy group 2 of the morbid patients had evidence of pulmonary embolism and both recovered. In one of the others there was marked necrosis of the tumor and in the fourth the operation was performed after 16 hours of labor.

Both of the patients upon whom myomectomy was performed had definitely septic courses with chills and fever. The patient who recovered had a uterine infection.

The patient who died was a 33 year old primipara upon whom an elective cesarean section was done at 39 weeks

because of the presence of a large fibroid (10 by 12 by 8 centimeters) situated deep in the pelvis arising from the left and posterior uterine wall. Laparotrachelotomy was performed under local infiltration anesthesia (novocain $\frac{1}{2}$ per cent) until the birth of the baby after which general anesthesia (cyclopropane) was used. The fibroid tumor was removed easily without entering the uterine cavity. The incision was readily closed. After operation the patient developed evidence of infection, ran a septic course, and died on the tenth day after operation. Necropsy disclosed a generalized peritonitis with evidence of intra-uterine infection extending through the myomectomy incision.

In addition, hysterectomy subsequent to vaginal delivery was performed once during the puerperium.

The hysterectomy in the puerperium was performed 36 hours after delivery because of extreme pain over the uterus, an elevation of temperature to 100 degrees, and a white blood count of 30,000. The delivery had been without incident following a normal labor and was accomplished by low forceps with episiotomy. Necrosis was present in a large intramural fibroid.

A condensed summary of all the operative procedures is presented in Table III. When one considers the inadequacy of cesarean section alone as a therapeutic measure in this situation, one feels that it is indicated only in the rare instance in which there is a definite contra-indication to more

TABLE III

Operation	Number	Mortality	Per cent
Cesarean only	18	0-1*	0-5.5
All hysterectomies	72**	1-2*	1.4-3.4
All myomectomies	49**	6-7*	12.2-14.3

*One undesignated death may have occurred in any of the 3 groups.

**An additional 15 cases as noted in Table I had either hysterectomy or myomectomy—unstated.

extensive operative treatment. The results in the hysterectomy group are definitely superior to those in the myomectomy series. This study, therefore, indicates that when abdominal operation is indicated hysterectomy is the better procedure for treatment of the fibromyomas. On the other hand, the mere presence of fibromyomas does not necessitate either hysterectomy or myomectomy.

CONCLUSIONS

In the treatment of the pregnant patient with uterine fibromyomas the following management is advised:

1. There should be careful observation during the course of pregnancy without interference unless symptoms of sufficient magnitude arise.

2. Natural delivery should be allowed to go on unless the size, number or location of tumors produces obstruction to the passage of the fetus.

3. Trial of labor should be permitted in doubtful cases.

4. When operative interference prior to delivery is indicated by necrosis in the tumor by

obstruction to the birth canal, or by failure of normal uterine mechanism, it should consist of cesarean section with hysterectomy.

5. If operative interference becomes necessary during the puerperium, hysterectomy is also the procedure of choice.

6. Myomectomy with cesarean section carries an appreciably greater mortality and therefore its employment is generally contraindicated.

7. Fibromyomas *per se*, do not necessarily indicate either hysterectomy or myomectomy.

JEJUNOPLASTY

For Obstruction Following Gastro-Enterostomy or Subtotal Gastric Resection

CARL L. HOAG, M.D., F.A.C.S., and JOHN B. DE C. M. SAUNDERS, F.R.C.S. (Ed.),
San Francisco, California

OBSTRUCTION following gastro-enterostomy or subtotal resection of the stomach with gastrojejunal anastomosis occurs in a relatively small percentage of cases, but when it does it is a serious and frequently fatal complication. Almost every experienced surgeon with an accurate and retentive memory can recall such patients of his own, and others whom he has seen in consultation. It is noteworthy that nearly every senior house surgeon, notwithstanding that he has had special training and expert supervision, is likely to have one or more patients with this fatal complication. In one of our leading hospitals there have been only 1 or 2 exceptions to this record covering a period of 20 years. Graham reported 3 fatal cases following gastro-enterostomy and one other after a gastroduodenostomy. Moreover, such highly skilled surgeons as Marshall and Kiefer, of the Lahey Clinic, have largely abandoned the postcolic anastomosis in favor of the antecolic route following gastrectomy, apparently because of the frequency of obstruction. No percentages are recorded. The data available in our vital statistics on this subject are of little value, as the cause of death is often attributed to the original condition, commonly ulcer or cancer, or to the secondary complicating factors, such as paralytic ileus, peritonitis, pneumonia, myocardial failure, etc., when death was, in fact, the result of obstruction. The contention so frequently advanced, that obstruction would not occur if the operation had been done properly, is beside the question. None will deny that experience makes all complications less common. Not infrequently, however, the "master surgeon" has attained his enviable state of skill and balanced judgment through such bitter experience and disappointment.

CAUSES OF OBSTRUCTION

Obstruction after posterior gastro-enterostomy may be due to one or more of the following causes:
An improperly placed stoma. A gastro-enteros-

tomy may function perfectly if made in any part of the stomach. Considering the many ways in which this operation is done it is truly remarkable, not that an occasional one fails to function, but that most of them function so well. We agree with Eusterman and Balfour that the position of choice for the stoma in a posterior gastro-enterostomy is in the most dependent portion of the stomach and nearly at right angles to the longitudinal diameter. When the operation is completed the distal jejunum should be in contact with the greater curvature and point toward the left hip. While the anastomosis is being made and the stomach is turned upward, this loop points toward the left shoulder (Fig. 1A). Because the operation is usually done through a midline incision and because the greater portion of the stomach lies well toward the left side, it is not uncommon for the surgeon to find that his anastomosis is located much nearer to the pylorus than he had anticipated.

A stoma which is too small or which, because of its small size and narrow attachment to the stomach, produces an acute angulation of the jejunum. The stoma may have been made too small originally or may have become so either because the stomach was dilated at the time of operation and later contracted, or because an unusual amount of tissue was inverted at the suture line during the anastomosis. With a wide stoma more gut is actually in contact with the wall of the stomach and the openings in the proximal and distal loops are further apart and more like a letter "U" than a letter "V" which makes it less likely that one loop will become distended and compress or obstruct the other.

The idea that "dumping" or too sudden emptying of the stomach may occur with a large stoma has been effectually exploded by the uniformly excellent function seen after subtotal gastrectomy in which the width of the entire end of the stomach is used. It is the small, not the large, stoma that gives trouble.

One other personal observation made upon experimental animals seems important, namely, that the stoma may be such a dense fibrous ring that it neither expands nor contracts to any extent.

From the Departments of Surgery and Anatomy, University of California Medical School.
Read before the sixty-seventh annual session of the California Medical Association, Pasadena, May 10, 1938.

extensive operative treatment. The results in the hysterectomy group are definitely superior to those in the myomectomy series. This study, therefore, indicates that when abdominal operation is indicated, hysterectomy is the better procedure for treatment of the fibromyomas. On the other hand, the mere presence of fibromyomas does not necessitate either hysterectomy or myomectomy.

CONCLUSIONS

In the treatment of the pregnant patient with uterine fibromyomas the following management is advised:

1. There should be careful observation during the course of pregnancy without interference unless symptoms of sufficient magnitude arise.

2. Natural delivery should be allowed to go on unless the size, number or location of tumors produces obstruction to the passage of the fetus.

3. Trial of labor should be permitted in doubtful cases.

4. When operative interference prior to delivery is indicated by necrosis in the tumor, by

obstruction to the birth canal, or by failure of normal uterine mechanism, it should consist of cesarean section with hysterectomy.

5. If operative interference becomes necessary during the puerperium, hysterectomy is also the procedure of choice.

6. Myomectomy with cesarean section carries an appreciably greater mortality and, therefore, its employment is generally contraindicated.

7. Fibromyomas *per se*, do not necessarily indicate either hysterectomy or myomectomy.

between the end of the stomach and the side of the jejunum so that distention of the stomach with food or gas tends to open up the stoma and attached jejunum as a part of its wall, and at the same time thrusts the whole anastomosis downward in the abdomen instead of compressing it. On the other hand, the extensive disturbance of normal relations, the opportunity for the soiling of and trauma to large areas of peritoneum, the possibilities of leakage either at the duodenal stump or along the suture line, make obstruction from adhesions possible.

Patients developing obstruction can be divided into 4 groups: (1) Those who develop gastric retention immediately after operation but who are eventually relieved by continued gastric lavage, showing that the obstruction was due to edema and swelling, (2) those who still have obstruction after from 7 to 14 days of conservative treatment, indicating that the obstruction is mechanical in character, (3) those who have been able to take food satisfactorily during the early part of their postoperative period and subsequently develop signs of obstruction. In such patients the obstruction is usually mechanical due to adhesions but occasionally may be adynamic in character, and (4) those who show weeks or years after operation either complete or incomplete obstruction caused by a marginal ulcer or its complications.

Patients in groups 2 and 3, having acute mechanical obstruction, obviously will require emergency surgery if their lives are to be saved. Of patients in these 2 groups, requiring secondary operation, it is not improbable, considering all cases, that 3 out of 4 fail to survive. The reason for such a high mortality is the fact that the surgeon does not know the exact cause of the obstruction before operation and frequently cannot determine it even when the abdomen is opened. He, therefore, has no plan of procedure to follow. Investigation by x-ray shows that the stomach fails to empty but no reason is obvious because the barium cannot pass further than the stoma. Too frequently the abdomen is opened and the stoma is exposed, after considerable dissection, palpated and found to be open and apparently satisfactory. The patient's condition will not allow an extensive operative procedure, so the surgeon, perplexed and uncertain in his own mind, does nothing more or reluctantly performs the usual entero-anastomosis below the stoma, or does an ileostomy, and hurriedly closes the abdomen. The patient may appear to be relieved but frequently continues a downward course and dies. At autopsy little evidence may be found to explain the cause of death. This failure to make a diagno-

sis is due to the fact that at no time was it possible to observe the bowel during peristaltic effort.

An entero-anastomosis would seem to be a logical procedure for relieving such an obstruction, but actually it has been disappointing both as an emergency measure and as a means of permanent relief. Ileostomy has been even less satisfactory, associated, as it frequently is, at this level with digestion of the abdominal wall and infection. As a rule, little is accomplished by either method because the obstruction actually exists at the point of the anastomosis which must be changed to restore normal function. Operations which heretofore have accomplished this have been too severe and time consuming for a patient already depleted by starvation and a recent operation.

A NEW JEJUNOPLASTY. I. FOR RELIEF OF ACUTE OBSTRUCTION

We propose a plan of procedure in these cases of acute obstruction—original in its purpose and application, as far as we know, but old in principle—which will relieve the obstruction at the point where it actually occurs with a minimum amount of surgery and at the same time will permit direct inspection of the gastric stoma.

As soon as the abdomen is opened and inspected for possible obstructive adhesions at a distance from the anastomosis, the anastomosis is identified and the jejunal loops are used for a jejuno-plasty to be made adjacent to the stoma and patterned after the principles of the Finney pyloroplasty. The loops of the jejunum are drawn downward from their attachment to the stomach, and their apposed serosal coats are sutured together for about 2 to 4 centimeters (Fig. 1 B). A central point for starting this line of suture may be chosen directly opposite the stoma or at either end, depending upon whether or not it seems advisable to shorten the proximal loop (Fig. 5). After the viscera are carefully packed off, an inverted "U" shaped incision is made around this suture line which opens both arms of the bowel (Fig. 1 C). When the edges are drawn apart, the stoma in the stomach can be directly inspected and palpated (Fig. 2 A). Having determined that the stoma is adequate, that no ulcer or faulty mechanics exist, the opening in the jejunum is closed by completing the technique used for a Finney pyloroplasty (2, 4) or some modification of it (5) (Figs. 2 A, 3). In this procedure the septum between the jejunal loops has been moved from 2 to 4 centimeters from the gastric stoma, and the original double barreled structure has been converted into a single barrel, the size now being that of the entire opening (Fig. 4). In fact,

with peristalsis for weeks or perhaps months after it is made.¹

A loop which is too long or too short for the changing position of the stomach In the gastro-enterostomy of earlier times the proximal loop was made so long that, becoming filled and dilated it would empty itself intermittently into the stomach with the production of the corresponding periods of nausea and vomiting, the so called "vicious circle." Once this error was recognized and short loops were recommended they were frequently made too short with much the same result (1). The stomach has no fixed position. It is usually empty, contracted, and high in the epigastrium when seen on the operating table. When it is filled, however, it may sag of its own weight and lie in the pelvis although the mesocolon usually limits the mobility of the stomach after such operations. If the proximal loop is too short the stomach may drag upon or twist it and prevent its emptying.

A mesocolon which fails to stretch when the stomach fills and its walls straighten out This condition allows the anastomosis to be drawn up into or through the mesocolon. The importance of the transverse mesocolon in the success or failure of a gastro-enterostomy is still not appreciated by many surgeons. Ordinarily the mesocolon is thin and pliable and accommodates itself to the changing positions of the stomach. Frequently however it is naturally short, thick, and boardlike, or has become so from fatty deposits or from inflammation. If the wall of the stomach, with the anastomosis is drawn through an opening in such a mesocolon, what may be the result? Unless the opening is unusually large and the projecting stomach is sutured firmly around it, the anastomosis may be pulled up and become obstructed when the stomach fills and its wall attempts to straighten out. This can be demonstrated on the operating table by filling the stomach with water and then blowing it up with air or gas, or demonstrated in the laboratory by drawing the side of a rubber balloon through a hole in a board or rubber mat and then inflating it. This type of mesocolon is commented upon by Balfour (1) as being unsuitable for the operation of posterior gastro-enterostomy. If trouble is to be avoided here the opening in the mesocolon must be made unusually large and the stomach drawn well through it and firmly fixed in this position.

Inadequate fixation by suture of the stomach to the mesocolon If thorough fixation is not accomplished a part of the anastomosis or a distal loop

of the intestine may work its way through the opening into the lesser peritoneal cavity and become obstructed.

Adhesions about the stoma due to leakage or trauma to the peritoneum If the surrounding peritoneum has been soiled or traumatized adhesions may form which, as time goes on, become firmer and more obstructive in character. Adhesions of this type are commonly the cause of the obstructions which appear late in the period of convalescence.

Pressure on the 2 loops of the jejunum by the middle colic artery An obstruction of this type was recently reported by McCaughan and Corghin who pointed out that, if the opening in the mesocolon is made to the right of the middle colic artery, this artery may produce obstructive pressure upon the jejunum.

Marginal or jejunal ulcers at or near the stoma The swelling and edema accompanying such ulcers and the contraction which follows may produce partial or complete obstruction. We have attempted to check the occurrence of acute ulcers in normal dogs on a normal diet. Observations were made in a small series from 7 to 28 days after gastro-enterostomy. We found ulcers in those cases only in which continuous non absorbable sutures had been used. These continuous sutures obviously caused the ulcers.

Adhesions distal to the anastomosis If the bowel becomes fixed in adhesions associated with the abdominal closure, or elsewhere, its contents may back up and induce hyperperistalsis which will give all the signs and symptoms of an obstruction at the stoma.

It should be noted that all of these causes of obstruction except the last one, namely, adhesions at a point distal to the anastomosis are operative in the area of the anastomosis itself.

With an anterior gastro-enterostomy the mesocolon is eliminated as an element of trouble, only to have the long loop of the jejunum required for this anastomosis substituted for it. An entero-anastomosis may prevent an obstruction but it also eliminates the alkaline duodenal content as a factor in the prevention of a marginal ulcer.

Obstruction following subtotal gastrectomy may arise from the same group of causes with the exception that, if the entire end of the stomach is used as a stoma the opening is usually so large that there is little tendency for acute angulation of the jejunum. Many surgeons, however, remove the lesser curvature entirely and reserve only a small opening adjacent to the greater curvature for the anastomosis. Even with this smaller opening, obstruction is less frequent than it is after gastro-enterostomy because the union is made

¹ Experimental observations will be published as they are made on the factors which play a part in the rigidity of the stomal ring.

Fig 1 A, Stomach and posterior gastrojejunostomy B, Center point selected and the jejunum on either side of the anastomosis drawn parallel and united by running peritoneal sutures—the outer suture line C, Horseshoe shaped incision following the lumen of the gut and encircling the suture line

hesions could be followed only by their reformation and further obstruction. A jejunoplasty was performed without further loss of time. The two arms of the jejunum forming the anastomosis were drawn taut, the peritoneum was sutured together, and a "U" shaped incision was made opening the lumen of the gut. The stoma was found to be adequate and not ulcerated. The jejunum, however, was densely adherent in the mesocolon for a distance of at least 4 centimeters. Recovery was uneventful and the patient is now well except for the fact that he has an abdominal hernia.

CASE 4 (Illustrating Group 3) Mr W K, 34 years of age, entered the hospital on December 18, 1934, complaining of the symptoms of duodenal ulcer of 18 years' duration for which a gastro-enterostomy had been done elsewhere 9 months before. The duodenal ulcer was cauterized at the same time. He was put on a medical regimen until November, 1935, when he again entered the hospital because of pain, weakness, fainting, and hematemesis.

A second operation, a Billroth II subtotal resection, was done on December 20, 1935. Inasmuch as his gastro-enterostomy was working satisfactorily and there was no marginal ulcer present, a subtotal resection of the stom-

ach, including the duodenal ulcer, but leaving the gastro-enterostomy, was performed. Two weeks later signs of obstruction appeared which eventually became complete, as no barium would pass the gastro-enterostomy stoma.

A third operation, a jejunoplasty, was done on January 25, 1936, 36 days after the second operation. Exploration showed that the stomach had rotated in such a manner that the loops of the jejunum were twisted and obstructed at the stoma apparently due to the loss of the gastrohepatic ligament after the gastrectomy. A jejunoplasty was immediately done, the patient made a satisfactory recovery and emptying of the stomach was again normal. He was relieved for a time but about a year and a half later began to show symptoms of a marginal ulcer.

The fourth operation, a radical subtotal gastrectomy (Mayo-Pólya), was done on October 14, 1937. A marginal ulcer was found on the posterior wall of the jejunum adjacent to the stoma. The patient made an uncomplicated recovery and is in excellent condition at this time with a total gastric acidity of only 13. It is still too early to know what may happen next. If he should develop another ulcer, inasmuch as there is no more stomach to resect, it may be visualized if necessary through another jejunoplasty.

a miniature secondary stomach has been created with its 3 openings more widely separated from each other. This cavity is similar in position and size to the pouch produced by the gradual dilatation and hypertrophy of the jejunum which is so frequently found in patients who have a gastro-enterostomy or a subtotal resection of long standing. The continuity of the jejunum has been restored so that its contents may pass directly downward, may bathe the gastric stoma, or may pass into the stomach. If any twist or compression of the jejunal loops existed it has an opportunity to straighten out. If the new suture line becomes covered by adhesions there is little likelihood of obstruction. In fact it is our practice to reinforce the anterior suture line with omentum.

This operative procedure does not require the time nor inflict the trauma incident to the breaking up of adhesions to expose the anastomosis from without. The adhesions are divided as the gut is split by the "U" shaped incision, which will naturally expose the stoma as it is carried to completion. The procedure can be completed with no more shock and with as much dispatch as an ordinary entero-anastomosis and has the obvious advantage of direct inspection of the stoma and the adjacent mucosa. It should be much more valuable and carry no greater operative risk than the usual entero-anastomosis.

CASE 1 (Illustrating the obstructions of Group 2) Mr. H. W. S., 37 years of age, had a history of a duodenal ulcer for 5 years or more and had been on medical treatment for 2½ years. X-ray examinations showed the crater of an ulcer on posterior wall near pylorus with about 30 per cent retention of barium meal after 6 hours. Patient had had no bleeding but had had a good deal of pain and persistent vomiting. After rest in bed and gastric lavage daily for 1 week operation was performed on September 17, 1930.

The duodenum was found firmly fixed posteriorly by an ulcer which was attached to the pancreas. A short loop posterior gastro-enterostomy was done in the usual manner. The operation offered no difficulties. The mesocolon was not unusually thick or short. The patient showed no signs of leakage or peritonitis after the operation. He was unable to take any great amount of food or liquid from the beginning and continued to vomit except when his stomach was kept clear by the use of the Connell suction apparatus. At the end of 9 days barium did not pass and it was evident that the gastro-enterostomy had failed to function for some unknown reason.

Secondary operation for obstruction was performed on September 27, 1930, which was the tenth postoperative day. When the abdomen was opened there were few adhesions; the distal loop was free and the gastro-enterostomy opening was in excellent condition. The stoma seemed adequate from without and there was no kink or obstruction evident. Something radical had to be done but what? Every patient that I had seen with a similar condition including 2 of my own had eventually died. Pondering this problem I noticed that the 2 arms of the jejunum forming the gastro-enterostomy lay side by side. The thought suddenly occurred why not a Finney pyloroplasty? If that

procedure would relieve obstruction at the pylorus why should it not achieve the same result here? It was the answer to a serious and as yet unsolved problem.

The two arms of the jejunal anastomosis were quickly sutured together and opened by means of an inverted U incision as here described. When the stoma was opened it proved to be surprisingly small, only about half the size of the original opening. This condition was probably the result of contraction of the somewhat dilated stomach and overlapping of the suture line. There was no sign of perforation or ulcer. The second part of the operation which we have designated as a jejunoplasty was immediately completed.

The patient was able to take fluids the next day and made an uneventful recovery. He had excellent relief from the original symptoms. He was not heard of again for about 2 years when he was operated on elsewhere for a ruptured appendix and died of general peritonitis. At post mortem showed a well functioning gastro-enterostomy opening which could not be distinguished from that frequently seen long after the usual gastro-enterostomy. The duodenal ulcer had healed.

CASE 2 (Illustrating Group 2) Mr. C. H. P., 35 years of age, entered the hospital on September 1, 1930, with a history of persistent vomiting and loss of weight. X-ray examination showed an almost complete pyloric block with a small niche on the lesser curvature which was diagnosed as a probable carcinoma. Exploratory laparotomy on September 27, 1930, showed the stomach to be extensively infiltrated with carcinoma which extended to the lesser curvature. No metastases were found. Because of condition and age of patient a gastro-enterostomy was done high up on the posterior wall. He continued to vomit and nothing passed through the gastro-enterostomy opening.

On October 10, 1930, the abdomen was opened and a jejunoplasty as herein described was done. The patient's stomach began to empty immediately and he made an excellent recovery. He was discharged on November 4, 1930.

CASE 3 (Illustrating the obstructions of Group 1) Mr. J. F., 62 years of age, after medical treatment for a duodenal ulcer for a number of years had suffered repeated severe hemorrhages which could not be controlled by a well conducted medical regimen. At operation on November 6, 1934, the stomach was found to be large and atonic, the pyloric end was densely adherent posteriorly and could not be freed. About 6 centimeters beyond the pylorus there was a large indurated mass with much surrounding inflammatory reaction. Because of the recurring hemorrhage it was deemed advisable to exclude this ulcer by performing a subtotal resection of the Mayo-Robey type. The duodenal end was closed in the usual manner and a gastro-jejunal anastomosis was done by the postcolic route. The mesocolon was found to be short, thick and very heavy and bled easily. It was thought that an adequate opening had been made in the mesocolon but it was fat and friable and a number of vessels bled, requiring ligatures. The entire opening of the stomach was anastomosed to the jejunum about 4 inches from the ligament of Treitz. The mesocolon was carefully sutured to the stomach. The operation was completed without difficulty and the convalescence was excellent.

He was taking food satisfactorily until the tenth day when he suddenly started to vomit. For the next 3 days he vomited everything given him. A small barium meal failed to pass through the stoma.

An emergency operation was performed on the thirteenth postoperative day. When the abdomen was opened numerous adhesions were found both in the duodenal region and about the stoma. The adjacent jejunum was covered with adhesions which made it appear to be a part of the mesocolon. It seemed apparent that separation of the ul-

his patient from a situation which otherwise would have cost him his life

II JEJUNOPLASTY AS AN APPROACH TO MARGINAL ULCERS, OR FOR ENLARGING OR CLOSING THE GASTRIC STOMA

Although this jejunoplasty was originally designed to relieve the acute obstructions occurring after gastrojejunal anastomoses, we were immediately impressed by the excellent exposure of the gastric stoma and the adjacent jejunum which it afforded. The occurrence of marginal ulcers with their sequels has been the most serious complication of gastric surgery. When ulcers occur and cannot be controlled by a proper medical regimen, the surgeon has the choice of 3 alternatives: (a) He may deal with the ulcer locally and continue to do so as necessary. (b) He may adopt a more radical procedure and do a subtotal gastrectomy. (This course is advocated by a majority of American and European surgeons.) (c) He may retrace his operative steps by closing the gastric stoma, provided the pylorus is open, and return his patient to the original status particularly if, in the meantime, the original lesion has healed. (This is the

Fig 4 View of anastomosis from within the stomach a, Before the jejunoplasty b, After the jejunoplasty, showing how the septum has been split down restoring the continuity of the jejunal lumen and creating a potentially larger stoma

procedure of choice in England and Scotland where subtotal gastrectomies are seldom done except for cancer.)

If the surgeon is inclined toward conservatism or if more radical surgery is contra-indicated for any reason, we believe that this jejunoplasty, as an approach to the stoma, has many advantages over any other with which we are familiar.

Gastrojejunal ulcer. If an ulcer is present it can be dealt with by excision or cauterization without

Fig 5 Sketch showing how the selection of a central point for starting the jejunoplasty will permit changing the length of the short loop and the resulting change in the lumen of the gut A, Central point using equal length of both proximal and distal jejunum, both shortened an equal amount B, Length of short loop not changed by reflecting the distal jejunum against it C, Maximum shortening of proximal loop by using it entirely for the jejunoplasty

Fig. 2 A Outer edge of the incision retracted showing the stoma, inner catgut interlocking suture line completing the posterior wall B Inner catgut suture line carried to the anterior wall, completing the closure by use of the Connell stitch

Someone will raise the question as to the viability of that strip of jejunum which lies between the inverted U shaped incision and the gastro jejunal anastomosis. The question of the circulation of this strip was uppermost in our minds and formed the basis of a large number of operations upon experimental animals. Occasionally there was some cyanosis in this strip but we found no necrosis or leakage. As the strip is cut off from its original blood supply, however, we recommend

that the anterior suture line be routinely reinforced with the omentum as a precautionary measure. The posterior suture line is still in contact with its mesenteric vessels and obviously has a good circulation. By reinforcing the anterior suture line there is little danger of further obstruction such as might occur after reinforcing a gastroenterostomy anastomosis, because the lumen of the gut then lies in the plane parallel to the line of sutures.

Will this jejunoplasty influence the hazard of marginal ulcer? We think it unlikely, because the procedure simply increases the lumen of the jejunum and makes the anastomosis what it should have been originally.

The relief afforded to this group of patients with acute obstruction is most striking. Pinched and depleted by the loss of 2000 cubic centimeters or more of duodenal secretions daily and kept alive only by intravenous medication before operation, they may be found reading the paper or smoking a cigar (as happened in one of our cases) on the day after. This sudden change for the better emphasizes again the importance of the duodenal secretions. We can recommend this procedure without reservation for these acutely obstructed patients who heretofore have proved so troublesome and in whom the mortality has been so high. It has been called the 'fire escape' of the gastric surgeon, a way out, by which he is able to rescue

Fig. 3 A Completion of outer peritoneal suture line by continuing it from the posterior wall B Sagittal section of stomach, stoma, and jejunum before jejunoplasty C, After jejunoplasty

Fig 10 Complete closure of the gastric stoma from within the gut (Approach and closure as in Figs 1, 2, and 3) A, Mucous membrane covering the rim of the stoma excised exposing a wall made up of (1) muscularis mucosa of the stomach, (2) combined muscle of the stomach and jejunum, and (3) mucous membrane of the jejunum B, Muscularis mucosa detached from around the stoma and everted into the stomach by the Connell stitch of catgut C, Muscular layer closed with interrupted silk in the direction in which the stoma was originally made These stitches approximate but do not penetrate the firmly attached jejunal mucosa which falls together as the muscle is approximated, and usually does not require a separate suture

ulcer, it can be enlarged with the greatest of ease as a final step in completing the jejunoplasty. In addition the surgeon does not have to make this decision until the lesion has been removed and he has had an opportunity to appraise the size of the repaired opening. If he wishes to enlarge it a vertical incision is made from the superior margin of the original inverted "U" incision across the stoma into the stomach as far as is necessary for the size desired (Fig. 7). A new center is then chosen for closing the entire incision so that the divided ring can be separated by interposing gastric or duodenal tissues between its ends (Figs 8, 9), taking more tissue in each stitch on the longer side.

CASE 5 Mr A A, 37 years of age, first entered the hospital in 1924 and a posterior gastro-enterostomy was performed because of a densely adherent duodenal ulcer. He had some relief but returned 6 months later with a marginal ulcer. He was treated conservatively and improved.

A second operation was done in 1929. The old gastro-enterostomy stoma was partly obstructed by a marginal ulcer and there was evidence that the duodenal ulcer still persisted, so a subtotal resection (Mayo-Pólya) was done. In November, 1931, the patient returned with a second marginal ulcer and was treated medically with varying degrees of relief. In January, 1938, he returned with severe pain, having a 90 per cent retention, not only in that part

of the stomach which still remained but also in the closed duodenal stump.

In February, 1938, gastrojejunoplasty was performed. Laparotomy showed dense adhesions about the stoma, colon, and jejunal loops. These loops were distended both distad and proximad to the anastomosis. The stoma was exposed by doing the first portion of the jejunoplasty. The opening was found to be very small and contracted and there was a very small marginal ulcer on the posterior rim. This ulcer was destroyed by the cautery. The stoma was enlarged by carrying the incision from the inverted "U" incision in the jejunum across the stoma into the stomach for about 4 centimeters. This combined line of the jejunum and stomach was then closed by staggering the edge of the incision and interposing gastric tissue between the divided ends of the stomal ring, or a "gastrojejunoplasty." Convalescence was uneventful and there is no retention. It is, of course, too early to determine the final result.

Closure of the stoma In certain cases in which the gastro-enterostomy is unsatisfactory because of recurring marginal ulcers and in which the pylorus is open, it may be desirable to restore the original continuity of the bowel rather than to attempt to deal with the lesions locally, or subject the patient to a subtotal gastrectomy. In such an event, this approach permits complete closure of the stoma from inside, without the necessity of detaching the jejunum from the stomach or of resecting the jejunum and doing an anastomosis.

Fig 6 First part of the jejunoplasty complete as an approach for the removal of a marginal ulcer

disturbing the anastomosis and what is more important without the usual danger of narrowing the stoma. The additional room gained by virtue of the jejunoplasty more than offsets any narrowing that may occur by removing the ulcer (Fig 6)

Fig 10 Complete closure of the gastric stoma from within the gut (Approach and closure as in Figs 1, 2, and 3) A, Mucous membrane covering the rim of the stoma excised exposing a wall made up of (1) muscularis mucosa of the stomach, (2) combined muscle of the stomach and jejunum, and (3) mucous membrane of the jejunum B, Muscularis mucosa detached from around the stoma and everted into the stomach by the Connell stitch of catgut C, Muscular layer closed with interrupted silk in the direction in which the stoma was originally made These stitches approximate but do not penetrate the firmly attached jejunal mucosa which falls together as the muscle is approximated, and usually does not require a separate suture

ulcer, it can be enlarged with the greatest of ease as a final step in completing the jejunoplasty. In addition the surgeon does not have to make this decision until the lesion has been removed and he has had an opportunity to appraise the size of the repaired opening. If he wishes to enlarge it a vertical incision is made from the superior margin of the original inverted "U" incision across the stoma into the stomach as far as is necessary for the size desired (Fig 7). A new center is then chosen for closing the entire incision so that the divided ring can be separated by interposing gastric or duodenal tissues between its ends (Figs 8, 9), taking more tissue in each stitch on the longer side.

CASE 5 Mr A A, 37 years of age, first entered the hospital in 1924 and a posterior gastro-enterostomy was performed because of a densely adherent duodenal ulcer. He had some relief but returned 6 months later with a marginal ulcer. He was treated conservatively and improved.

A second operation was done in 1929. The old gastro-enterostomy stoma was partly obstructed by a marginal ulcer and there was evidence that the duodenal ulcer still persisted, so a subtotal resection (Mayo-Pólya) was done. In November, 1931, the patient returned with a second marginal ulcer and was treated medically with varying degrees of relief. In January, 1938, he returned with severe pain, having a 90 per cent retention, not only in that part

of the stomach which still remained but also in the closed duodenal stump.

In February, 1938, gastrojejunoplasty was performed. Laparotomy showed dense adhesions about the stoma, colon, and jejunal loops. These loops were distended both distad and proximad to the anastomosis. The stoma was exposed by doing the first portion of the jejunoplasty. The opening was found to be very small and contracted and there was a very small marginal ulcer on the posterior rim. This ulcer was destroyed by the cautery. The stoma was enlarged by carrying the incision from the inverted "U" incision in the jejunum across the stoma into the stomach for about 4 centimeters. This combined line of the jejunum and stomach was then closed by staggering the edge of the incision and interposing gastric tissue between the divided ends of the stomal ring, or a "gastrojejunoplasty." Convalescence was uneventful and there is no retention. It is, of course, too early to determine the final result.

Closure of the stoma In certain cases in which the gastro-enterostomy is unsatisfactory because of recurring marginal ulcers and in which the pylorus is open, it may be desirable to restore the original continuity of the bowel rather than to attempt to deal with the lesions locally, or subject the patient to a subtotal gastrectomy. In such an event, this approach permits complete closure of the stoma from inside, without the necessity of detaching the jejunum from the stomach or of resecting the jejunum and doing an anastomosis.

The stoma is pushed forward by the hand of the assistant which may be placed behind the stomach or even in the lesser peritoneal cavity if necessary. After the first part of the jejunoplasty has been completed, the mucous membrane around the rim of the stoma is excised with curved scissors. The free edge of the muscularis mucosa is detached around the entire circumference of the opening and everted into the stomach with a Connell stitch. This is best done by using fine gastro-enterostomy catgut and everting it by a double row of sutures. Following this the muscle layer of the ring is closed with interrupted silk in the direction in which it was originally made. This stitch includes the entire muscle layer and approaches but does not penetrate the jejunal mucous membrane. It may approximate the jejunal mucosa so well that a third line of sutures (catgut) may not be required for this layer (Fig. 10). The second portion of the jejunoplasty is then completed in the usual manner. We wish to emphasize the importance of having the assistant push the anastomosis well up into the field so that it is readily accessible and will permit this closure with a minimum of traction and trauma. While the closure of the stoma offers no unusual technical difficulties, it is suggested that those interested in mastering the details of this technique may find it advantageous to try it out on the cadaver or experimental animal.

It should also be pointed out that whenever the stoma is to be closed a longer anastomosis of the jejunal loops is necessary to prevent the swollen tissues about the closed stoma from encroaching upon the lumen of the jejunoplasty. *In all other conditions except this one in which the stoma is closed and the neutralization of acid ceases to be a factor, the anastomosis should be made as short as is consistent with the correction of the mechanical difficulties (usually 2 to 3 centimeters) so that the alkaline duodenal secretions will continue to bathe the stoma and minimize the hazard of a marginal ulcer.*

In virtue of our limited experience with these procedures we do not at this time desire to leave the impression that we are advocating them as a substitute for subtotal gastric resection in the treatment of marginal ulcer, except when the more radical operation is contra-indicated or when a marginal ulcer has occurred after subtotal resection.

CONCLUSIONS

1. Obstruction following gastro-enterostomy or subtotal resection of the stomach may be caused

by (1) an improperly placed stoma (2) one that is too small in itself or because of its narrow attachment angulates the jejunum (3) a jejunal loop which is either too long or too short for the changing positions of the stomach (4) a mesocolon which fails to stretch when the stomach wall straightens out and causes the anastomosis to be drawn into or through it (5) herniation resulting from an inadequate fixation of the mesocolon to the stomach (6) pressure of the middle colic artery on the jejunal loops (7) adhesions about the stoma (8) marginal ulcers or their sequelae and (9) adhesions about the gut distal to the stoma.

* A new jejunoplasty adjacent to the stoma has the distinct advantage of (1) relief of the obstruction at the anastomosis where it actually occurs (2) direct inspection of the stoma from within, (3) formation of a miniature stomach in which duodenal secretions continue to bathe the stoma, (4) re-establishment of the direct continuity of the jejunum (5) a potentially larger stoma and (6) a minimum amount of surgery.

In the acute obstructions we are convinced that the mortality rate can be easily reversed. Whereas an estimated 75 per cent of patients requiring re-operation previously have died it is possible with this procedure to save 75 per cent or even a greater number.

3. This jejunoplasty may be used in chronic obstructions as an approach for (1) the resection of marginal ulcers (2) increasing the size of the stoma—a gastro-jejunoplasty, and (3) permanent closure of the stoma and restoration of the original continuity of the gut.

The authors wish to thank Dr. Henry Seale, Dr. H. Glenn Bell, Dr. Leon Goldman, Dr. Harold Lindner, and Dr. Harry Benteen for their generous assistance in carrying out the clinical and experimental investigations associated with this problem.

FRACTURES OF NECK OF THE FEMUR TREATED WITH SMITH-PETERSEN NAIL

Analysis of 78 Cases During 1937

STANLEY M LEYDIG, M D, Saint Louis, Missouri

FROM January 1, 1937, to January 1, 1938, 166 fractures of the hip were admitted to St Louis City Hospital, 88 were trochanteric fractures, and 78 were fractured necks of the femur. Further classification seems unnecessary as in our experience of previous years there has not been any difficulty in securing bony union of extracapsular fractures, while the contrary has been true of displaced intracapsular fractures. No differentiation is made between subcapital or central intracapsular fractures, as the difficulty in treatment and prognosis of these types has been similar. Fractures at the base of the neck in which the neck is split off from the shaft are not included in this report and were classed with the trochanteric fractures. Impacted fractures of the neck of the femur, which in our experience have usually united, are classified separately. The average age of patients with fracture of the neck of the femur was 66 years and the average age of those who expired was 68.

Of the 78 cases, 14 were impacted fractures of the neck of the femur. These fractures united in all cases, and such has been our result in previous years, regardless of the type of treatment. Seven of the impacted fractures were treated in the body spica casts, 4 were nailed with the Smith-Petersen nail, 1 was treated in a Hodgen splint, and 2 were treated with bed rest only. All are now walking and apparently have bony union, with the exception of 2 cases that were nailed. These also will probably unite but have not been under observation a sufficient time.

Of the 64 cases with displaced intracapsular fractures of the femur, 10 were moribund on admission and remained so until their death. In these cases, the fracture was treated only by traction and immobilization in sand bags. Six cases were treated in body spica casts, 3 united and 3 went on to non-union, with complete absorption of the neck of the femur. The remaining 48 cases were reduced and nailed with the Smith-Petersen nail (7). Of the 52 patients with fractures that were nailed, including 4 cases of impacted fracture, there were 13 patients who expired during the course of the year. Of this number, 3 gradu-

ally terminated in uremia, 1 died of pneumonia several weeks after operation, 2, of cardiac decompensation, 1, with pulmonary embolism, 1, apparently of too much morphine before operation ($\frac{1}{2}$ grain of morphine), 1, of carcinoma of breast (pathological fracture), 1 of delirium tremens, 2, of wound infection with septicemia, and 1, of femoral thrombosis with ensuing gangrene. I believe that in only 8 of this group was there any expectancy of sustaining life for long. The 5 remaining probably would have expired within the year had the fracture of the hip not occurred. The fractures were nailed only to facilitate nursing care and add to the patients' comfort, as these cases lived from 3 to 7 weeks after operation.

If these 5 cases were not considered, there would be 8 deaths out of 47 cases, and the mortality would be 17.2 per cent. Two patients expired because of wound infection which was a direct result of the operation.

These results represent the work of 2 surgeons, Dr Norman Johnson, who handled 15 cases, and the author, who took care of 37 cases, with the exception of 3 or 4 cases done by the visiting surgeons, Dr J Albert Key, Dr Peter J Heinbecker, and Dr Avery P Rowlette, to whom we are indebted and grateful for their interest.

The percentage of union is difficult to determine at this time, as 6 months should elapse before one can say that bony union will not result, and in some cases several years must elapse, as 2 cases which were reported as non-union by Dr. Avery P Rowlette, et al, in 1936, have since united, after being under observation for 2 years. Of 39 living patients, including 4 impacted cases, 23 are able to walk without support. Six cases are unable to walk even with crutches, 3 of these cannot walk because of their senescent condition, but the other 3 could not walk before the fracture occurred, due to atrophic arthritis, chorea, and hemiplegia, 4 would not return for re-examination and 6 are too recent to determine prognosis.

Of the 23 patients walking, 10 show absorption of the neck of the femur, which is nearly complete in 2 instances, although bony union appears to be present (Fig 6). Of the 3 patients who could not

The stoma is pushed forward by the hand of the assistant which may be placed behind the stomach or even in the lesser peritoneal cavity if necessary. After the first part of the jejunoplasty has been completed, the mucous membrane around the rim of the stoma is excised with curved scissors. The free edge of the muscularis mucosa is detached around the entire circumference of the opening and everted into the stomach with a Connell stitch. This is best done by using fine gastro-enterostomy catgut and everting it by a double row of sutures. Following this the muscle layer of the ring is closed with interrupted silk in the direction in which it was originally made. This stitch includes the entire muscle layer and approaches, but does not penetrate the jejunal mucous membrane. It may approximate the jejunal mucosa so well that a third line of sutures (catgut) may not be required for this layer (Fig. 10). The second portion of the jejunoplasty is then completed in the usual manner. We wish to emphasize the importance of having the assistant push the anastomosis well up into the field so that it is readily accessible and will permit this closure with a minimum of traction and trauma. While the closure of the stoma offers no unusual technical difficulties it is suggested that those interested in mastering the details of this technique may find it advantageous to try it out on the cadaver or experimental animal.

It should also be pointed out that whenever the stoma is to be closed a longer anastomosis of the jejunal loops is necessary to prevent the swollen tissues about the closed stoma from encroaching upon the lumen of the jejunoplasty. *In all other conditions except this one in which the stoma is closed and the neutralization of acid ceases to be a factor, the anastomosis should be made as short as is consistent with the correction of the mechanical difficulties (usually 2 to 4 centimeters) so that the alkaline duodenal secretions will continue to bathe the stoma, and minimize the hazard of a marginal ulcer.*

In virtue of our limited experience with these procedures we do not at this time desire to leave the impression that we are advocating them as a substitute for subtotal gastric resection in the treatment of marginal ulcer except when the more radical operation is contra-indicated or when a marginal ulcer has occurred after subtotal resection.

CONCLUSIONS

1 Obstruction following gastro-enterostomy or subtotal resection of the stomach may be caused

by (1) an improperly placed stoma (2) one that is too small in itself or, because of its narrow attachment, angulates the jejunum, (3) a jejunal loop which is either too long or too short for the changing positions of the stomach, (4) a mesocolon which fails to stretch when the stomach wall straightens out and causes the anastomosis to be drawn into or through it, (5) herniation resulting from an inadequate fixation of the mesocolon to the stomach, (6) pressure of the middle root artery on the jejunal loops (7) adhesions about the stoma, (8) marginal ulcers or their sequelae and (9) adhesions about the gut distal to the stoma.

2 A new jejunoplasty adjacent to the stoma has the distinct advantage of (1) relief of the obstruction at the anastomosis where it actually occurs (2) direct inspection of the stoma from within, (3) formation of a miniature stomach in which duodenal secretions continue to bathe the stoma (4) re-establishment of the direct continuity of the jejunum (5) a potentially larger stoma and (6) a minimum amount of surgery.

In the acute obstructions we are convinced that the mortality rate can be easily reversed. Whereas an estimated 75 per cent of patients requiring operation previously have died, it is possible with this procedure to save 75 per cent or even a greater number.

3 This jejunoplasty may be used in chronic obstructions as an approach for (1) the resection of marginal ulcers (2) increasing the size of the stoma—a gastro-jejunoplasty and (3) permanent closure of the stoma and restoration of the original continuity of the gut.

The authors wish to thank Dr. Henry Sears, Dr. H. Glenn Bell, Dr. Leon Goldman, Dr. Harold Linder and Dr. Harry Benteen for their generous assistance in carrying out the clinical and experimental investigations associated with this problem.

Fig 5 Our own devised nail driver and impactor. The flange rests against the shaft and is prevented from slipping by the 4 sharp pins that protrude. The flange is at an angle of 125 degrees to the cylinder which corresponds to the angle which the neck of the femur makes with the shaft. The nail is placed in the cylinder and the plunger is inserted. The set screw is then turned tightly against the plunger. Thus the force of each blow is divided against the nail and against the impactor, so that the fragments are impacted as the nail is driven.

ing This procedure is done in our fluoroscopic room and necessitates taking only 4 x-ray plates, an anteroposterior and lateral view after reduction, and again after the nail has been started.

Fig 7 Tray with all instruments used. A, Impactor and nail driver. B, Nail extractor.

Fig 6 Illustration of aseptic necrosis around the nail, and absorption of the neck with bony union. Patient has only a slight limp, walks without support, and has no pain.

It rarely takes over 45 minutes for both the reduction and completion of operation.

We have done several cases by direct visualization with an incision from the anterosuperior spine down to below the trochanter, cutting the tendon of the tensor fascia lata, and opening the capsule. This method impresses us as being a rather extensive surgical procedure and only applicable to the more vigorous cases.¹

In one such operation it was noticed that while driving the nail the head displaced slightly inward, and impaction of the reduced fragments was difficult to maintain. After the nail had been driven

¹Since the preparation of this paper an interesting article on the same procedure has appeared in *SURGERY, GYNECOLOGY AND OBSTETRICS* for January, 1939, by W. R. Cubbins, J. J. Callahan, and Carlo S. Scuderi.

Fig 8 The nail was inserted about $\frac{1}{8}$ inch too far and after observation for a year some necrosis of the acetabulum was seen at the point of the nail. The patient can walk without support and has had no pain.

Fig 1 Section through femur with nail in place. Patient expired 2 weeks after operation of delirium tremens

walk before they fractured their hip. 2 showed complete absorption of the neck of the femur, with non union of the 3 that never walked without crutches after their fracture. 2 showed complete absorption with non union, and the third has united. Thus of 27 known living patients 14 or 51 per cent showed some degree of absorption of the neck of the femur.

Of 35 living patients that had displaced intra capsular fractures that were reduced and nailed the reduction was considered good in 27 cases, and only 5 of these showed absorption of the neck of the femur not over three fourths of an inch, and in these cases the nail was accurately placed (Figs 1, 2). There were 8 cases in which the reduction was imperfect; absorption was complete in 6 of these patients and marked in the 2 others (Figs 3 and 4). Whenever absorption of the neck was observed it had occurred within 4 months of the operation. There were no cases in which absorption occurred if the reduction and the nailing were accurate, provided the patient was not bedridden and was able to use crutches. The average number of hospital days per patient was 22 days.

Fig 2 Good reduction of fracture and accurate nailing

The method used in nailing was the same as that described by Dr J. Albert Key, the so called blind method in which reduction was done under local anesthesia by the Leadbetter maneuver and the Smith Petersen nail inserted through a 6 inch incision over the trochanter after inserting a drill and checking the position by portable x ray in the operating room.

During the past few months we have modified the technique, and now drive the nail with our own devised impactor through an incision 1½ inches long, without previously inserting a guide such as the drill. The smaller incision decreases the chances of wound infection, shortens the time of the operation, and lessens the amount of blood

Fig 3 Only fair reduction and nailing of fracture

Fig 4 Imperfect reduction with complete absorption of the neck after 10 months although bony union is present

Of the patients who survived 51 per cent showed some degree of absorption of the neck, and whether early weight bearing is a factor in absorption and is to be advised will have to be decided in the future

Accurate reduction, and accurate nailing with early weight bearing on crutches has been our desire. It is interesting to note that when these 3 conditions have been fulfilled, the fracture has healed with apparent bony union and good function

TABLE I—FRACTURED NECKS OF THE FEMUR FROM 1931 TO 1936 AND THOSE IN 1937

	1931-1936	1937
No of fractures	166	64*
Average age in years	63.8	66.0
Mortality per cent	25.9	28.2
Average age of deaths	71.2	68.0
Average no. of hospital days	83.0	22.4

*This number does not include 14 impact cases

in as far as necessary there was a slight separation of the fragments which was not improved by further impaction although rays taken after operation showed good approximation. This has undoubtedly occurred before with the blind nailing method, and it was this observation that led us to devise our own type of nail driver which impacts the fragments as the nail is being driven (Fig. 5). We make an attempt to get the patients up on crutches as soon as possible after operation and encourage them to place their affected extremity on the floor, bearing a slight amount of weight. After 3 months they have usually discarded 1 crutch and after 5 months they are walking with a cane, which most of them prefer using for several months longer. We remove the nail after 1 year and find that it is easily extracted.

The following chart is a comparison of fractured necks of the femur at City Hospital from 1931 to 1936 and 1937.

Among many objections now heard concerning the use of the Smith Petersen nail is the presence of metal being a cause of local bone absorption (6) and delayed union (1). Aseptic necrosis around the nail was seen in only 3 of our patients and was without ill effect (Fig. 6). The amount of metal in the Smith Petersen 3 flanged stainless steel nail is no more than if multiple Kirschner wires or several pins (5) were used, and the type of nail which we use is no more expensive. We do not feel that an array of various sized nails is necessary and have only 2 nails on our sterile tray (Fig. 7) a $3\frac{1}{2}$ inch and a 4 inch nail and by varying the point of insertion below the trochanter, we have had very little difficulty in inserting the nail at the correct distance. In 1 case the nail was inserted too far and after observation for a year there was some slight absorption of the acetabulum at the point of the nail (Fig. 8) but the patient has always walked without pain and uses no support.

Various devices have been used in an attempt to answer the problem of the nail backing out due to absorption of the bone around it (2). Some have resorted to fixing the head of the nail to the cortex of the shaft of the femur with a pin. If

TABLE II—COMPARISON OF TWO METHODS OF TREATMENT USED FOR FRACTURED NECKS OF FEMUR

Method	1935-36 2-71	In Smith Petersen (37 cases)
No of cases	30	4*
No of months observed	8	4
Mortality—no and per cent	6-20	13-27
Traced or re-examined	20	38
Non union	7	4
Bony union—no and per cent	13-43	19-51

*This number does not include 4 impact cases

**If 6 deaths be subtracted the average would be 58 per cent

†If 25 deaths be subtracted the average would be 89.4 per cent

even slight absorption of the neck should occur the nail would then tend to hold the fragments apart, making non union inevitable unless the nail worked through the head into the acetabulum with obvious possible complications. In only 3 of our cases has the nail worked out and in each instance was easily reinserted. Two of these cases have healed with bony union and the other is too recent to determine the prognosis.

CONCLUSION

Although a longer period of observation would be desirable, one can determine the prognosis in fractures of the neck of the femur treated by the Smith Petersen nail much earlier than formerly as a long period of observation was necessary in cases treated with the Whitman cast, or subcutaneous pinning. Furthermore, our report is offered at this time because of the present wide practical interest in internal fixation of fractures of the neck of the femur and also because of the difficulty in following up our patients over a longer period as a large number of them have no permanent residence throughout the year.

These statistics show that much is yet to be desired in results with the Smith Petersen nail but it must be remembered that these cases come from an underprivileged group and their poor general condition has contributed to an undesirable result in many cases.

Before 1935 internal fixation of intracapsular fractures had not been attempted in this hospital and patients were treated in a Whitman spica cast with very few cases of union resulting. Internal fixation with the 2 pin method used in 1935 to 1936 showed a marked improvement and resulted in 58 per cent union in patients who survived (6). The Smith Petersen nail has increased bony union to 89.4 per cent in patients who survived and has cut the average number of hospital days per case to almost a fourth of what it had been previously.

ment of that period. This would be true unless the student had learned how to learn either in school or subsequently. Why not in the medical school? In the program of graduate training in surgery at the University of Chicago, the candidate after completion of the interne year is required to spend a year in research, either alone or in association with a member of the staff. It is not our thought that any considerable proportion of these men will become professional investigators or occupy academic positions, but rather that they will benefit from the experience as part of the educational process. The beginner makes many mistakes, and he draws conclusions not warranted by the evidence, but he learns by the experience, he becomes aware of many pitfalls, and he is better able to evaluate what he reads. It is unfortunate that all students cannot be given this advantage. The program is expensive. It consumes much of the teacher's time and energy and there is considerable waste of material. Possibly not all students are sufficiently capable to warrant the expenditure of effort and money. But where it can be done, let it not be discouraged. Medicine is not static and the method of its progress should not be kept secret.

LESTER R. DRAGSTEDT

INTRAVENOUS ANESTHESIA

THE increasing usefulness of intravenous anesthesia for many types of operations has never been as apparent as it has recently. The criticism of the method in the past was often well deserved, as most of the agents employed were essentially unsuitable and in some instances dangerous. The longer-acting barbiturates, so many of which enjoyed a brief but extensive use, were soon seen to have many disadvantages as anesthetic agents. The evolution of

the so called ultra-short-acting barbiturates opened up the field of intravenous anesthesia as we know it today and has provided us with a method which has proved safe, satisfactory, and essentially free from complications, when the agents are administered by experienced persons for suitable types of operations. In other words, intravenous anesthesia now has a definite place among the various anesthetic methods. The barbiturates that have proved most satisfactory in this field are evipal soluble (sodium n-methyl-cyclohexenyl methyl barbituric acid) and pentothal sodium (sodium ethyl-1-methyl butyl barbituric acid). While the action of these drugs is similar, most authorities feel that pentothal sodium, owing to its increased potency over evipal soluble, provides a superior anesthesia and that the awakening of the patient is usually attended by somewhat less excitation and other post-anesthetic effect than when evipal soluble is employed. Preliminary medication with morphine, atropine, and a barbiturate is of advantage in all but the most brief operative procedures. The intermittent or fractional method of injection has proved to be the safest method of administering these drugs, and no set dose should be computed. Individual tolerance of the patient for a barbiturate is a most variable factor. A free airway should be maintained at all times, either by support of the patient's jaw when required, or by the introduction of an artificial airway. Perhaps the most important single factor to be observed when administering barbiturates intravenously is never to administer a dose which causes prolonged respiratory depression. The amounts of the drug necessary to induce anesthesia and those subsequently required to maintain it serve as a reliable guide to the patient's tolerance. As an aid to the observation of the respiratory functions, the movements of a cotton or paper "butterfly" which

ON MEDICAL EDUCATION

IN a recent charming book¹, Dr Arthur I Hertzler makes the following statement about medical teaching and teachers: 'I give place to no man in the appreciation of the medical researcher, but his problems are not for the medical student. Researchers should be quarantined both for their own good and for the good of the student. I speak sympathetically because I have dabbled in the border lines myself, but I have never mentioned them to my students. The fact should be recognized that the average doctor never does catch up with what the researcher is doing. We doctors should be spared the agony of the scientific delivery room and should be allowed to hold the baby only after the nurse has him all polished up and dressed.' This is, as I understand it, a picturesque statement of the position held by many that the student learns best by the didactic method and should be spared the agony of thinking

for himself. It assumes furthermore that the scientific babies finally do become dressed and polished and that the clothes will not later (after graduation) need to be changed.

Mr Dooley was a bartender on Archer Avenue in Chicago during the early years of the century and was wont to discuss many things with his friend, Mr Hennessy, which were recorded for a larger audience by Finley Peter Dunne. On the subject of education, Mr Dooley had this to say: "Childher shud den't be sint to school to larn, but to larn how to larn. I don't care what ye larn thum so long as 'tis onpleasant to thum. 'Tis thraimin' they need, Hinuss." I prefer the philosophy of the sage of Archer Avenue to that of the famous "horse and buggy doctor" of Halsted, Kansas. I believe that only the man who knows by experience the method of original investigation, its difficulties and disappointments, and the tentative character of its conclusions, is qualified to teach science, at least at the graduate level. Only the investigator can really appreciate the basis in fact for the opinion that passes as knowledge. Once this opinion becomes sanctified by inclusion in a textbook and clarified and elaborated in subsequent textbooks based on the first, it forms part and parcel of common knowledge and its position becomes almost unassailable.

I have sometimes had occasion to glance at notes prepared for lectures to medical classes twenty years ago and to reflect on the status of our knowledge at that time and today. I am appalled at the thought that some may be working now with the equip-

INTRAVENOUS ANESTHESIA

THE increasing usefulness of intravenous anesthesia for many types of operations has never been as apparent as it has recently. The criticism of the method in the past was often well deserved, as most of the agents employed were essentially unsuitable and in some instances dangerous. The longer-acting barbiturates, so many of which enjoyed a brief but extensive use, were soon seen to have many disadvantages as anesthetic agents. The evolution of

the so called ultra-short-acting barbiturates opened up the field of intravenous anesthesia as we know it today and has provided us with a method which has proved safe, satisfactory, and essentially free from complications, when the agents are administered by experienced persons for suitable types of operations. In other words, intravenous anesthesia now has a definite place among the various anesthetic methods. The barbiturates that have proved most satisfactory in this field are evipal soluble (sodium n-methyl-cyclohexenyl methyl barbituric acid) and pentothal sodium (sodium ethyl-l-methyl butyl barbituric acid). While the action of these drugs is similar, most authorities feel that pentothal sodium, owing to its increased potency over evipal soluble, provides a superior anesthesia and that the awakening of the patient is usually attended by somewhat less excitation and other post-anesthetic effect than when evipal soluble is employed. Preliminary medication with morphine, atropine, and a barbiturate is of advantage in all but the most brief operative procedures. The intermittent or fractional method of injection has proved to be the safest method of administering these drugs, and no set dose should be computed. Individual tolerance of the patient for a barbiturate is a most variable factor. A free airway should be maintained at all times, either by support of the patient's jaw when required, or by the introduction of an artificial airway. Perhaps the most important single factor to be observed when administering barbiturates intravenously is never to administer a dose which causes prolonged respiratory depression. The amounts of the drug necessary to induce anesthesia and those subsequently required to maintain it serve as a reliable guide to the patient's tolerance. As an aid to the observance of the respiratory functions, the movements of a cotton or paper "butterfly" which

is fastened by adhesive tape over the patient's mouth and nose, will add to the safety of the method.

Some of the literature on the usefulness of intravenous anesthesia may be confusing to many readers, as it is so often contradictory. The wave of enthusiasm for many new methods has been very well demonstrated by writers in this field. The more ardent enthusiasts recommend the method as being practically ideal for almost every type of operation while some go to the other extreme and condemn it whole heartedly. Neither of these conceptions gives the reader a true picture of the present status of intravenous anesthesia. Many justifiable criticisms in the past have arisen from the use of unsuitable drugs or faulty methods of administration, and from choosing the method for patients or operative procedures in which its use should have been contraindicated. Generally speaking, the method is most applicable for short and minor surgical procedures ranging from fifteen to thirty minutes especially in cases in which the operative procedure does not involve the respiratory passages or the peritoneal cavity. In certain selected cases its use may be preferable for intra abdominal operations but in many of these instances a safer and more satisfactory anesthesia is obtained if an abdominal wall block is used as a supplement to intravenous anesthesia. When it is used to induce anesthesia prior to the administration of local regional or inhalation anesthesia an apprehensive patient may be spared much mental strain or physical discomfort. It may frequently be useful to supplement local or spinal anesthesia when the effect of the latter is beginning to wear off. For certain operations requiring the use of the electrocautery, intravenous anesthesia may be preferred to an inflammable or explosive inhalation anesthetic agent. Complications following the use of

intravenous anesthesia are rare. Phlebitis along the course of the vein employed or other irritative effects rarely if ever occur when 2.5 per cent solutions of pentothal sodium have been employed. Remote untoward effects and complications are conspicuously absent. Elderly and debilitated patients tolerate this type of anesthesia well, although much smaller doses usually are required. Most anesthetists agree that the method should not be used for operations in the vicinity of the pharynx, operations in which it will be difficult to maintain a free airway, in cases in which the blood and secretions may act as a potential obstruction to the airway, in operations in which profound and continuous muscular relaxation is desired, as in extensive intra abdominal operations, and in cases in which the patients are young children. A sulphur containing barbiturate, such as pentothal sodium, is not felt to be a safe anesthetic agent when a patient has been receiving another sulphur containing preparation, such as sulfanilamide unless the latter drug has been withheld for twenty four to forty eight hours.

A question which frequently arises is the advisability of employing intravenous anesthesia in private practice either in the home or the doctor's office. If the narcosis is to be brief not exceeding five minutes and if the physician insists that the patient lie down until the effects of the drug have completely worn off its use in the office may be permitted. Even when a patient appears to have completely recovered from the anesthetic, he should not be permitted to return home unless accompanied by a responsible person. Intravenous anesthetics should be administered with the patient in the prone position. Facilities for administering oxygen and carbon dioxide should be available, as these agents are most reliable in combating excessive respiratory depression caused by a barbiturate. Thus, with

the type of intravenous anesthesia available today, we have a method whose merits and safety have become established. The method of administration is comparatively simple and does not involve the use of complicated apparatus. Despite this fact, the method is safe only in the hands of those experienced in its use.

The importance of a thorough knowledge of the effects of the barbiturates and the method of administration cannot be stressed too strongly. Such knowledge will, of course, tend to increase the value and safety of this new method of anesthesia.

THE SURGEON'S LIBRARY

REVIEWS OF NEW BOOKS

THE excellent book *Fractures of the Jaws* by Ivy and Curtis which now appears in revised edition will be a valuable addition to the library of not only the general practitioner but of the specialist as well. Its simple practical language not only deals with the simple problems but by directing easily applied treatment facilitates the management of the more difficult complications which do at times arise. It is comprehensive and concise and directs the application of well known and proved methods avoiding

controversial topics which are apt to confuse the operator who in the course of his practice encounters an occasional jaw fracture.

The book will appeal to the specialist as it offers many suggestions by which the experienced operator can improve his own methods of treatment. The chapter on radiography technique will be invaluable to the operator who in the smaller centers is obliged to make his own radiograms or is at least obliged to direct the making of them. The chapter on dietary management is especially valuable to the operator who has no trained dietitian at hand who can assume charge of the case.

EXCISION OF THE SUPERIOR HYPOGASTRIC PLEXUS (PRESACRAL NERVE) FOR PRIMARY DYSMENORRHEA

JOE VINCENT MEIGS, M.D., F.A.C.S., Boston, Massachusetts

FROM 1898 till 1924 attempts were made to relieve pain in the pelvis by section or excision of sympathetic nerves. Periaarterial sympathectomy was attempted by Leriche with some measure of success. In December, 1924, Cotte first performed the operation known as "presacral neurectomy." His patients' relief of pain was immediate and satisfactory so that in 1925 he reported his operation and its success. Since then many reports in foreign and domestic journals testify to the soundness of Cotte's operation. There have been few admitted failures and no report of sequelæ from excision of this part of the pelvic sympathetic system. The mortality is said to be almost nil and the operation reported as easy. Cotte emphasized certain definite types of cases that might be expected to be relieved by his operation and it is obvious from perusing the literature that few have deviated from his original standards. He reported in 1930 that the presacral nerve is one that spreads out exclusively in the pelvis and vaginal regions and that resection of this plexus of nerves is a cure for "plexalgia hypogastrica." This last term includes dysmenorrhea, dyspareunia, causalgia of the vagina, pelvic neuralgias, and pruritis vulvæ. It is definitely of no use for lumbar pains

From the Surgical Service of the Massachusetts General Hospital.

(ovarian dysmenorrhea) or ovarian intermenstrual crises. But for pain referred to the uterus and radiating to the anus, coccyx, and urinary bladder, a properly done operation should be followed by a 100 per cent relief.

Various names are connected with the attempt to solve the problem of pelvic pain and a few follow Jaboulay, 1898; Ruggi, 1899; Leriche, 1921; Cotte, 1925. These men all contributed to the ground work of the operative procedure while Latarjet and Bonnet named the main nerve branches of the sympathetic system of the pelvis the "presacral nerve." Hovelacque re-named this nerve area and more properly called it the "superior hypogastric plexus." Later Elaut, Fontaine, and Herrmann, in 1932, contributed studies both anatomical and experimental to the problem.

In 1933, Davis undertook careful studies of the nerves themselves removed at operation for relief of pain. Cotte first suggested the possibility of an inflammatory process in the region of the pelvic sympathetic nerves as the reason for pelvic neuralgias, and the work of Davis substantiates it. One reason, among many others, suggested for pelvic neuralgias and for dysmenorrhea is that mild inflammatory processes are found affecting the connective tissue and the nerves themselves with degeneration occurring in the ganglion cells.

It must be acknowledged that certain dysmenorrheas are psychic or physical, and the better the condition of the patient's psyche and the better her physical condition the less likely she is to be bothered with pain. Nevertheless the number of patients relieved of true dysmenorrhea by either psychiatrists or hygienists is small. They may make it easier for the patient to bear her pain but they do not, except in a few instances, relieve it. The gynecologist should be on the watch for patients who do not have a typical story of true dysmenorrhea, for the operation will not help them and failure discourages the patient's physician. If it is evident that a patient has no complexes and that her physical condition is satisfactory and the dysmenorrhea is *uterine dysmenorrhea*, then real relief of from 75 to 100 per cent can be expected by removal of the plexus.

Before subjecting any patient to the operation, it is suggested that other methods of treatment be tried first, such as psychiatry; improvement in hygiene, the use of simple drugs, such as aspirin, antispasmodics, such as atropine or belladonna; and dilatation of the cervix. The use of morphine and its derivatives should not be considered. No doubt in the near future there will be reports on the use of hormones but all except huge doses of estrin with its probable effect upon ovulation have proved failures in our hands. It will have to be decided by the individual doctor and patient whether the surgical removal of the nerve is more hazardous than a possible disturbance of the pituitary gland by large doses of estrin. It is better in most instances to advise dilatation of the cervix before an abdominal operation inasmuch as this simple procedure does relieve 25 to 50 per cent of cases for an indefinite period. The presence of a thick muscular band about the internal os, similar to the band about the pylorus in pyloric stenosis of children must be considered. If such a band is felt on rectal examination, it can be split by cutting posteriorly in the cervical canal against the finger in the rectum. This method of longitudinal section of the internal os is important and if the cervix is exceptionally tight the incision should enlarge the os and give relief from pain. The use of

the stem pessary is a real possibility as it may be accompanied by a great deal of success and surely the dangers are not too great. This form of treatment can be tried by those who have no objection to it. If at operation a retroversion or flexion of the uterus is found, it is much better to do a suspension and also a neurectomy than it is to find after the suspension that the patient is not relieved of her pain.

ANATOMY OF THE NERVES

"The superior hypogastric plexus is a sympathetic plexus and the preganglionic fibers come from the lowest thoracic and upper lumbar levels of the intermediolateral columns. The cells send their axones out over the lower white rami of the thoracolumbar outflow to the lumbar and pre-aortic ganglia. The postganglionic neurones originate in the sympathetic trunks, as well as in the pre-aortic ganglia, to form a plexus descending along the abdominal aorta. At the level of the inferior mesenteric artery there are two small ganglia and from these a plexus descends the artery to innervate the sigmoid and rectum. The remainder of the descending sympathetic fibers form the superior hypogastric plexus at the bifurcation of the aorta. This plexus divides at the bifurcation of the two common iliac arteries to form two hypogastric nerves that run into the hollow of the sacrum to join the inferior hypogastric plexus. Sensory neurones from the posterior root ganglia in the same segments of the cord run directly into the superior and inferior hypogastric plexus" (White). In other words, from the celiac, semilunar, splanchnic, and mesenteric ganglia sympathetic fibers course down either side of the aorta (the intermesenteric nerves) and often crossing and recrossing the aorta are joined by branches from the lumbar ganglia (Fig 1). At the region of the root of the inferior mesenteric artery as it arises from the aorta a plexus is found known as the inferior mesenteric plexus. Some of the nerves making up this plexus follow the inferior mesenteric artery to supply the sigmoid and rectum, and others course down over the bifurcation of the aorta to form the superior hypogastric plexus. This plexus lies in the triangle bounded by the two common iliac

meters If this injection is done bilaterally and 5 to 10 cubic centimeters of 2 per cent procaine deposited through each needle, it will result in anesthesia of the superior hypogastric plexus If this preliminary test could be carried out in all patients with severe dysmenorrhea there ought to be no failure (except for inexpert surgery) and cases not suitable for this type of surgery would be excluded

THE OPERATION

The operation itself has been reported as both easy and fairly difficult After doing over 30 I believe that it is not difficult but that it requires considerable patience and painstaking dissection As it is often said to be combined with the operation of abdominoperineal resection for carcinoma of the rectum by various surgeons it would seem easy to do I believe that it cannot be satisfactorily done if combined with any long and difficult operation such as abdominoperineal resection for carcinoma of the rectum, for it should take about an hour to do the neurectomy well Success depends upon the removal of all nerve fibers, even the very small ones, and if they are not entirely removed recurrence of pain may be expected The operation is done with the patient in Trendelenburg position and the incision is made from about the symphysis to just above the umbilicus (In women who have had children a midline incision is made but in those with no children a paramedian incision is best) The pelvic organs are carefully inspected for evidences of pathology, and it is especially important that evidences of endometriosis be sought for, since this entity is so often accompanied by acquired dysmenorrhea The intestines are well walled off and the posterior peritoneum from the bifurcation of the aorta into the true pelvis is exposed This peritoneum is picked up with forceps just below the bifurcation and a small incision is made into it With scissors the loose areolar tissue of the retroperitoneal space is dissected off the under surface of the peritoneum The opening in the peritoneum is from 10 to 15 centimeters in length It is well to place three or four silk stay sutures along the edge of the peritoneum to be used as retractors As the tissue on the right side is

Fig 1 This drawing shows the origin of the superior hypogastric plexus (presacral nerve) from sympathetic fibers coursing along the aorta arising from the splanchnic, semilunar, and other higher ganglia and from the lumbar ganglia Notice that the branch from the fourth lumbar ganglion passes under the common iliac arteries and not over the bifurcation of the aorta, as most of the plexus does This is a very important technical point

released the right common iliac artery is exposed Gently with scissors or with small bits of gauze held in hemostats the areolar tissue, connective tissue, and nerves are freed from their connections with the common iliac arteries from the bifurcation of the aorta to the bifurcation of the iliacs The large left common iliac vein is located directly posterior in the triangle Great care must be used for a tear in this vein might be disastrous Occasional small venules arise from it that are easily torn and these should be clamped and tied The right common iliac vein is not seen as it lies to the outer side of the right common iliac artery A piece of tape is then threaded under the mass of tissue to be removed and traction made upon it The dissection is carried up to the bifurcation of the aorta or just above it, and the tissue is clamped and the proximal part is tied This mass of tissue is then pulled downward and carefully dissected free as far down as the bifurcation of the common iliac arteries on both sides Here the plexus is clamped and removed and the distal end is tied The triangle should now be bare from the bifurcation of the aorta to the bifurcation of the common iliacs (Fig 2) The left iliac vein is clear of all small fibers as is the periosteum and the perichondrium of the fifth lumbar vertebra The right ureter

arteries and originates at the bifurcation of the aorta and ends at the bifurcation of the common iliac arteries to become the right and left hypogastric nerves. Some fibers follow the common iliac arteries and are intimately connected with them. The left common iliac vein forms the back wall of the triangle and the nerves are often in close association with it. It must be remembered that from under the common iliac arteries branches of nerves from the fourth lumbar ganglia come to join the plexus. All other nerves cross over the bifurcation of the aorta but these two branches are under and must be remembered when doing the dissection. Low down the superior hypogastric plexus lies directly upon the peritoneum and perichondrium of the fifth lumbar vertebra and just above the vertical middle sacral artery. The two hypogastric nerves are joined lower down in the pelvis by parasympathetic fibers of the second, third, and fourth sacral ganglia and make up the inferior hypogastric plexuses. These nerves supply the uterus and bladder and end in the uterus in the great plexuses of Frankenhaeuser.

PHYSIOLOGY OF THE NERVES

It has long been considered that the pelvic nerves were motor and carried no sensory fibers, but the success of presacral neurectomy and the great relief of pain increase belief in the presence of sensory fibers. Learmonth's observation supports this view. With a patient under spinal anesthesia he noted that handling the superior hypogastric plexus with forceps caused crushing pain in the bladder. The sympathetic fibers cause vasoconstriction and inhibition of the musculature of the sigmoid, rectum and bladder and cause ejaculation and contraction of the involuntary sphincters of the bladder. The parasympathetic works in opposition to the sympathetic nerves and causes vasodilatation and release of the various sphincters. It is, therefore, possible to conceive of a better blood supply to the uterus and a release of muscular tone both in the body and the cervix by excision of the superior hypogastric plexus. This alone might account for certain pain relief, but the fact that section of these nerves does not alter (to any great degree) the menstrual function, does not inter-

fere with delivery, does not produce atrophy or cause any disturbances of motor function of the bladder seems to Fontaine and Herrmann to be supportive proof that the genital nerves of the sympathetic systems are sensory rather than motor in nature. The hypogastric plexus carries pathways of sensation from the genital tract to the medullary centers, and excision of this plexus is therefore sound in the treatment of uterine or cervical pain.

Thus we have a system of sympathetic nerves that course through the superior hypogastric plexus and that carry vasoconstrictor fibers to the blood vessels of the uterus and cause contraction of certain sphincter muscles. The nerves also carry afferent sensory impulses to the higher centers. Excision of such a plexus therefore should cause increase of blood supply lessening of spasm and interruption of pain impulses to higher centers. The parasympathetic in opposition to the sympathetic supply dilates blood vessels and releases sphincters, does not carry uterine pain, but does carry bladder pain. Thus removal of the superior hypogastric plexus seems to have a firm foundation physiologically.

Before the operation is described and the results in the two groups of patients are given, the type of cases chosen for the operation should necessarily be considered. In our experience (and it is only in cases of dysmenorrhea) it is essential that only those cases with a clear cut history of true primary dysmenorrhea should be considered. If there is any doubt as to the diagnosis, this operation should not be performed. In one of our cases we voiced the suggestion that the patient was not the right type and she has since had no relief of her pain and a subsequent delivery was more painful than ever. This should not be so. Flothow has discovered a test for checking the pain of dysmenorrhea by injection of a 2 per cent procaine into the region of the plexus. The second and third lumbar ganglia are injected. He inserts a needle at the level of the fourth lumbar interspace 7 centimeters from the midline at an angle of 45 degrees until the upper portion of the body of the fifth lumbar vertebra is encountered, then advances the needle over the anterolateral surface of the body of the vertebra for a distance of about 1.5 centi-

through the internal os. Following the operation, dilatation was continued in the office regularly but complete relief was never obtained. However, gradual improvement has occurred so that in April, 1938, the patient can do her daily work and does not remain at home as previously during her period. Nausea was completely relieved by the neurectomy but pain was not. A good deal of her later pain was in the form of backache which was not present before the operation. It is possible that the backache is due to the necessary stretching of the cervix. Incidentally this patient has had much less flow than usual and the period is of shorter duration since her operation. The third patient, Case 16, was operated upon in October, 1936. In January, 1937, she was considerably improved and felt pleased. In June, 1937, she regarded the operation as unsuccessful, with perhaps 10 per cent relief. In March, 1938, she had been having about 40 per cent relief for the past 6 months. She believes that she is now beginning to obtain some relief. She has had no treatment since the operation. This case cannot be regarded as a success.

One of the partial failures should not have had the operation at all as she did not have true dysmenorrhea. Another patient (Case 10), with only a slightly satisfactory result was operated upon in December, 1935. She was judged a questionable candidate for neurectomy before operation. In July, 1936, she stated that the operation was fairly successful giving her about 50 per cent relief. In December, 1936, she reported the operation as partially successful, still with 50 per cent relief. In 1937 she was operated upon again and a uterine suspension was done in another hospital. Following that she had a baby. The birth of the child was very painful and the neurectomy gave her no relief of pain during the delivery. In July, 1938, she reported 30 per cent relief. She has had severe headaches and nausea before her periods for the last year. This patient probably has had relief but will not admit it for she is very disappointed that she was not sterilized and that she has had another child. She is now anxious to be operated upon again; she wishes to be sterilized and hopes her uterus will be removed so she

TABLE I.—PRESACRAL NEURECTOMY ALONE

Case Year	Result
1 1930	No pain for 5 years. Recurrence of mild pain. Complete relief again.
2 1932	No relief. Dilatation and curettage done in July, 1933. Relief obtained. Pain returned 5½ years after operation.
3 1934	Complete relief.
4 1934	Complete relief.
5 1935	Complete relief. Married. Intercourse satisfactory.
6 1935	Complete relief for 2 years, then return of pain 3 years after operation. Relief again obtained. Married. Intercourse not satisfactory.
7 1935	No relief. Dilatation and curettage necessary later. Gradual improvement.
8 1935	Partial relief for 1 year, then return of pain. Relief again 2 years after operation.
9 1935	Complete relief at first. Three years after operation slight amount of pain recurred. Married. Intercourse not satisfactory. One child. Pain slightly less severe than average primipara.
10 1935	Fair amount of relief. Two years later suspension done. Intercourse not satisfactory. Child born. More pain than usual with delivery.
11 1936	Complete relief.
12 1936	Partial relief for a few months. One year later, complete.
13 1936	Complete relief. Married. Intercourse not satisfactory. One child. Rhythmic backache. No abdominal pain.
14 1936	Complete relief.
15 1936	Partial relief.
16 1936	Considerable improvement for a few months, then return of pain. Is beginning to obtain some slight relief.
17 1936	Complete relief of dyspareunia and dysmenorrhea.
18 1937	Complete relief.
19 1937	Some relief. Very much better in 1938. Subsequent endometrial biopsy caused no pain.
20 1938	Some relief. Getting much better.

can be sure she will have no more children. This case should not be regarded as a failure, but it is a failure as far as the patient is concerned.

Postoperative course. The postoperative course in all patients has been entirely satisfactory. None of them had more difficulty than in other abdominal operations. There have been no more postoperative catheterizations and no more difficulty with obtaining bowel movements than in any other abdominal operative procedure.

Fig. 2. At the end of the neurectomy the triangle bounded by the bifurcation of the aorta and a line drawn from the bifurcation of one common iliac to the other with the left common iliac vein and the vertebra as the back ground must be cleared of all nerve fibers.

has been bared for the whole distance. The left ureter is not always seen in this operation. Care should be taken to make sure that branches from the fourth lumbar ganglia that are found in the triangle under the common iliac arteries are identified and severed (Fig. 2). All suspicious fibers in the triangle should be removed and the area should appear as is shown in Figure 2. No shreds or doubtful pieces of tissue should be left. It is sometimes necessary to tie the middle sacral artery. All ties are of fine silk and the opening in the peritoneum is closed with a continuous suture of silk. Operations for other pelvic pathology should be done either before or after the neurectomy, depending upon which is the more important operation. If the section of the nerve is most important, plenty of time should be allowed for the procedure. It must not be hurried. There is no doubt but that all pelvic pathology should be removed and malpositions should be corrected as a part of the operation. Results from neurectomy alone are not so good as those done combined with necessary pelvic surgery. Occasionally the

operation is more difficult due to the position of the left mesocolon, usually it can easily be drawn aside but occasionally it crosses the field of operation in such a fashion as to render approach to the plexus impossible.

RESULTS

Results vary, both in the opinion of the patients and in the opinion of the surgeon (Table I). Patients often forget how much better they are on the whole and base their entire judgment on their feeling at their last period. A later letter or a later interview following a few easy periods discloses a change in the patient's judgment; the particular discomfort is gone and she is well again. Therefore, it seems wiser for the surgeon to present his opinion rather than to have the patient do so. In this series of 20 patients that had a presacral neurectomy without any other pelvic surgery, 15 of them, or 75 per cent, had a successful result. Two patients, or 10 per cent, had a partially successful result. Three cases were complete failures. The percentages of relief are as follows: four, 100 per cent, five, 90 per cent, one, about 80 per cent, four, 70 per cent, two, 50 per cent, one, 30 per cent, and the three others failures. In 1 failure Case 2 patient was operated upon in August, 1932. In July, 1933, dilatation was done to attempt relief of the same pain. Up to November, 1936, the relief, according to the patient, was about 90 per cent. Her periods were of shorter duration, one to two days late or early. In January, 1938, cramps started again commencing 2 weeks before the flow began. Examination of the cervix showed that it was open and could be easily dilated in the Out Patient Department up to a No. 16 uterine dilator. A letter from the patient in March, 1938, stated that the cramps were no different than before the operation and that the flow was of shorter duration. Another patient Case 7 was operated upon in July, 1935, and failure was due in the author's opinion to the fact that the cervix was so tight that the menstrual flow could not possibly drain well. Her dysmenorrhea was due to a mechanical block. It was necessary at a later date to dilate the cervix. One hour was spent before the finest cervical probe could be passed.

A third patient, Case 10, who has been reported as having an unsatisfactory result states that she had more pain than ever during her delivery. She had only a moderate amount of relief from the presacral neurectomy and from a later suspension of the uterus. This patient has a complex about pregnancy, and it is hard to credit her report about this delivery.

OTHER OPERATIVE PROCEDURES PLUS PRE-SACRAL NEURECTOMY

Seven patients had other operative procedures besides the presacral neurectomy. Of these 6, or 85.7 per cent, report complete relief. This is a very excellent report. One patient was not relieved, but she is so "mothered" by her mother who suffers every pain with her that it is impossible to state whether or not the operation was successful. Letters are received from her regularly every month and about 6 periods a year are painless, and 6 are painful. Her pain when present is said to be worse than it has ever been before. All 6 patients of this group who obtained relief claim it to be 100 per cent. In 3 there was a change in the periods—more regular in 1, slightly shorter duration and smaller in another, and irregular in a third. There was no change in 4. There were no urinary difficulties. Constipation was noted following the operation in one, and another had diarrhea. In 5 there have been no bowel symptoms.

In 6, there was postoperative bleeding. One patient's bleeding started 10 days following the onset of the last period. One went 38 days following the last period and a biopsy at operation showed a proliferative or estrin phase of endometrium. This patient may have had dysmenorrhea without ovulation, a rare occurrence. Two, or 28.6 per cent, of this group had a late change in periods.

Three of the patients had treatment before operation. One had emmenin, aspirin, and viburnum, the second, large doses of progynon, and the third, midol, progynon, and a dilatation. In 4 cases there is no record of the previous treatment. All patients were sent in by their local physicians and doubtless had had medication before coming to the hospital for surgery.

CONCLUSIONS

1 Resection of the superior hypogastric plexus or presacral nerve reduces uterine spasm and vasoconstriction. With these motor fibers there are others that are sensory and carry uterine pain to the central nervous system. Section of this nerve therefore should decrease spasm and permit dilatation of the blood vessels in the pelvis and uterus and should relieve pain sensation. To whatever cause one may attribute pain in dysmenorrhea, it is possible after consideration of the physiology of the nerves to expect relief from the section of them. This it certainly does in a large percentage of cases.

2 It is evident that this operation, which is eminently successful, depends upon proper choice of patients for operation. A patient with uterine dysmenorrhea referred to the region of the anus and coccyx and not into the lumbar or ovarian region, is likely to have relief. A patient with a questionable type of dysmenorrhea, especially the type that might be confused with ovarian dysmenorrhea, should obtain no relief.

3 The operation causes a change in menstrual habits in a considerable number of patients—more than has been reported by other surgeons. These changes are not serious, nevertheless they can be expected and the patient should be so warned.

4 The opinion of the surgeon is a better criterion of relief than the opinion of the patient, because as noted in the long follow-up of these cases, pains and sensations in the pelvis vary and the patient may interpret them incorrectly whereas the surgeon with the entire record at hand can better evaluate the end-result.

5 It is obvious that correction of all pelvic pathology is better than presacral neurectomy alone.

6 Backache is not always relieved. One patient who had complete relief of abdominal cramps still had backache during delivery. Backache apparently is not controlled by the superior hypogastric plexus.

7 Pregnancy is not interfered with inasmuch as out of 5 marriages 3 pregnancies occurred and were successfully terminated. One had absolutely no rhythmic abdominal pain.

Postoperative bleeding In 8, or 40 per cent of the patients, postoperative bleeding was noted directly following the operation. In one it occurred immediately following operation, in one 5 days later, in two, 4 days, in two, 3 days and in two, 2 days. All patients were a considerable time postmenstrual. One biopsy showed a secretory phase 25 days after the last period, which is normal. In 4 or 29 per cent, there was no postoperative bleeding. In one of these the endometrium was in the proliferative stage at the time of the operation. In 8, or 40 per cent there was no record as to whether or not there was any postoperative bleeding.

Change in catamenia Nine patients had a change in their menstrual periods following the operation. One was more frequent, 3 of shorter duration, 2 had less flow, and 3 became irregular. In 9 there was no change, and in 2 the result could not be ascertained.

Urinary changes In 5 patients there was definite difference in urination. One had less frequency than before. In two a mild cystitis developed due to catheterization. In one urgency persisted 7 years after operation. In one there was change but exactly what could not be determined. In 13 there were absolutely no urinary changes, and in 2 it was not recorded.

Changes in bowel habits Four patients complained of more constipation than before the operation. In 14 there were no bowel changes. In 2 patients this could not be ascertained.

Previous treatment Different types of treatment were given the patients before the presacral neurectomy was contemplated. Dilatation was done in 4, dilatation with suspension in 2, a suspension in 1, dilatation, suspension, and oophorectomy in 1 other. Hormones (proluton, progynon, antuitrin S) were given to 5 patients in sufficient amounts without help. In 6 medicines and various other types of treatment had been tried without success. In 2 patients a pessary had been used. These patients were not relieved by their treatment and therefore neurectomy was decided upon. In 5 patients no previous treatment is mentioned in these records. It is our policy not to operate on any patients who have not had previous treatment.

Four patients, or 20 per cent, obtained late partial relief. One had a nervous breakdown $1\frac{1}{2}$ years after operation and another following marriage. Six obtained no relief from their backaches. Inasmuch as the 3 patients who later became pregnant and gave birth to a child had backache it is evident that backache will not be relieved by presacral neurectomy and that the sensory nerves responsible for backache are different than those causing uterine dysmenorrhea. Four patients, or 20 per cent, had complete relief at first and later as learned from their letters, had only partial relief. Our first patient had a recurrence 5 years after operation only to have the pain disappear again 6 months later. Five, or 20 per cent, have had a late change in their periods. The change in periods is probably no greater than it is in a normal group of women, nevertheless these facts must be recorded.

Pathology In every instance the tissue removed showed nerve fibers. It is interesting to note the various findings of the pathology department—small nerve trunks, small sympathetic ganglion, nerve bundles and ganglia, lymph nodes, ganglion cells, clusters of nerve cells like sympathetic ganglion, etc.

Marriage and pregnancy Five married patients have been interviewed as to whether or not intercourse has been satisfactory. In 4, or 80 per cent it has not, and in 1, or 20 per cent, it has been. This is important because there may be some interference with the nerve supply of the vagina following this operation. Further accurate figures are necessary to prove this point, as in private practice only about 50 per cent of women have satisfactory intercourse. It is impossible to make a definite statement in regard to this important point. Five patients have married since the operation and 3 have had children. One with only 60 per cent relief from operation had a normal delivery. She and her doctor felt that her pains were slightly less severe than for the average primipara. One patient who had 100 per cent relief from dysmenorrhea had absolutely no abdominal pain of any kind during delivery but did have rhythmic backache. Here again it is evident that backache is not relieved as are uterine cramps by means of resection of the superior hypogastric plexus.

A CONSIDERATION OF CERTAIN TYPES OF BENIGN TUMORS OF THE PLACENTA

ANDREW A. MARCHETTI, M D, New York, New York

BENIGN tumors of the placenta are relatively rare. With R. Drummond Maxwell one may readily agree that outside of hospital practice and a university clinic they are seldom if ever seen. Interest centers chiefly about the pathological anatomy and especially the histological structure. The striking variability of the microscopic pattern has been and still is the source of a great deal of confusion in nomenclature. Today these tumors are more commonly known as chorio-angiomas. Though the histogenesis seems to be fairly well established, opinion is still at variance as to whether chorio-angiomas are true tumors or not, while clinically they do not appear to be as important as was formerly thought. It is a collection of 8 such tumors in the pathological laboratory of our clinic that prompts a report and further consideration of the subject, more especially with regard to the interpretation and differentiation of the various types into which these tumors may develop.

HISTORICAL BACKGROUND

The first benign tumor of the placenta found in the literature was reported by John Clarke, in 1798. His description and comment relating to the tumor leave little doubt that it was probably a chorio-angioma although he gave it no designation. The first instance of such a tumor in American literature did not appear until Emil Ries reported his observation in 1904. Virchow, in 1863, designated the tumor as *myxoma fibrosum chorii*, an appellation which frequently has been used by many who have been influenced and have followed this scientific luminary. From about 1880 to the present time it seems that every other additionally reported placental tumor falling into

this category has received a new or modified designation, so that an approximation of the number reveals that the same tumor depending upon its type and interpretation has inherited about 30 diverse designations. As far as it has been possible to determine, Beneke in 1900, first employed the term "chorio-angioma." Without enumerating the many others, we favor this term as being the one best suited to the tumor in the light of its histogenesis.

Reports of the occurrence of this tumor tend to show that it is comparatively rare. From earlier studies (Albert, Leopold, Kuehnell) the occurrence was noted once in from 7,000 to 9,000 deliveries. In the New York Lying-In Hospital, following 20,000 successive deliveries, the recognition of chorio-angioma was realized on 6 occasions or approximately a little less than once in 3,500 cases. It should be indicated, however, that 2 factors tend to make its appearance in the literature infrequent. Undoubtedly, there are some that are recognized but remain unreported, and in the second place, and of more importance, there are many which, because of their small size and their position deep in the substance of the placenta, are unrecognized and remain undiagnosed. Siddall lends support to the second circumstance by one of his studies. He hardened, sectioned, and carefully examined 600 placentas. Among them he found 6 instances of chorio-angioma, obviously demonstrating that had the placentas not been subjected to a very minute inspection they would have been discarded as negative.

In surveying the literature Szarthy, in 1934, collected 238 cases of chorio-angioma, the largest thus far reported. While the list of authors mentioned in the text appears only as references at the end of this paper, it should be pointed out that during the course of this study it was necessary to consult 195 references. Though we are aware that some may

but did have backache another had less pain, and a third patient, who was conceded to be a failure as far as the operation was concerned had no relief

8 Intercourse may be interfered with since only one of the five married patients had successful orgasm. However, the cases are so few that no definite statement can be made now

9 Occasionally pain recurs for a short time in spite of complete relief

10 There are no serious changes in bladder or bowel habits

11 Finally, it seems obvious that this operation which appears formidable, is apparently the best form of treatment for patients with true primary dysmenorrhea

Fig 5 Case 2 Illustration of a capsule consisting of a few if any connective tissue fibers and a single layer of syncytium-like epithelium $\times 120$

The color of the predominantly vascular tumor is a deep bluish-red, whereas that of the more cellular type is a grayish-red. On bisection, the cut surface simulates the appearance of the liver, spleen, or renal cortex, and may show a single or multilobular structure whose units are divided by fibrous connective tissue trabeculae. Often the combination and variation of the 2 types give the surface a mottled appearance.

The consistency of the tumor is uniformly firm approaching in many instances that of a fibroma. The vascular connection of the chorio-angioma with chorionic blood vessels or directly with those of the umbilical cord is established by the larger vessels of the tumor. Occasionally the communication between the tumor and the blood vessels of the umbilical cord is represented by a well defined vascular pedicle.

Microscopic appearance The great variety of microscopic pictures is such that it has caused a striking confusion in nomenclature. This is due to the variability in position, amount, condition, and degree of development of the blood vessels, and connective tissue elements which make up the various histological patterns seen in different chorio-angiomas or even in the same tumor.

All chorio-angiomas are well circumscribed. Some are encapsulated by a thin or thick layer of connective tissue fibers covered usually by a single layer of syncytium (Fig 4), others are

Fig 6 Case 3 Illustration of the so called pseudocapsule enveloping a chorio-angioma of the degenerated type $\times 120$

simply invested by a single layer of syncytium-like epithelium (Fig 5). The tumors which are not as well preserved or show different degrees of degeneration are bordered by a comparatively thick, partly hyalinized, fibrinoid tissue in which swollen, vacuolated, and degenerating chorionic epithelium is enmeshed (Fig 6). This is the pseudocapsule referred to by many writers. In reality it is formed by the agglutination of the degenerated epithelium of the adjoining and surrounding compressed chorionic villi to the surface of the tumor, the syncytial epithelial covering of which has in great part disappeared. Whether by their capsule or pseudocapsule, chorio-angiomas are always sharply demarcated from the surrounding placental tissue.

The most common type of chorio-angioma is characterized by the following components: a more or less loose groundwork of chorionic stromal cells, predominantly ovoid in shape, supports numerous small blood vessels and capillaries. These vessels, for the most part, are dilated and filled with blood cells and are generally lined with a single layer of endothelium (Figs 7 and 8). They are uniformly or diffusely distributed throughout the tumor, or arranged in clusters, or again may be confluent.

Fig 1 Gross specimen from Case 8 showing the chorio angioma on the fetal surface extending from the margin to the insertion of the cord

have been overlooked or entirely missed, we believe that these are almost fully representative of the bibliography on chorio-angioma. In a careful check every care was taken to avoid reduplication of case reports and to exclude those which apparently were incorrectly diagnosed. It was possible then to bring the total number from the literature to 209 instances. The addition of our own 8 cases produces a new total of 217 reported chorio angiomas.

PATHOLOGICAL ANATOMY

Gross appearance There is considerable variation in the size of these tumors. They may range from one, the smallest diameter of which measures about 0.5 centimeter, while another may have a diameter of 22 centimeters. The

Fig 3 Cross section through the chorio angioma of Case 5 representing the cellular type

Fig 2 Cross section of the placenta from Case 4 showing a well circumscribed chorio angioma of the vascular type. One also sees connective tissue trabeculae extending through the substance of the tumor

dimensions of the average sized chorio angioma will vary from about 2 by 3 by 3.5 centimeters to about 4 by 5.5 by 8 centimeters. Generally the tumor is solitary, but multiple ones have been described. The shape is usually round to oval, and may be nodular or lobulated, while the surface is usually smooth. The tumor is always invested by a capsule or, as some interpret it, a pseudocapsule and may be readily enucleated from the adjoining placental tissue.

Ordinarily the fetal surface is the site of predilection, however, many are located on the margins and others are found buried in the substance of the placenta. Some are found protruding from the maternal surface and a very few have been noted at the base of the umbilical cord entirely separated from the placenta proper.

Fig 4 Case 4. A capsule of connective tissue fibers covered by a single layer of syncytium. $\times 120$

Fig 10 A higher power from Case 5 showing the embryonal character of the cells $\times 235$

blood vessels and epithelial lining of the tumor, reduction in number, or absence of blood cells in the capillaries may give certain areas or the greater part of the tumor an areolar or myxomatous appearance (Fig 13). In addition, these may be accompanied by calcareous, fibrinoid, or hyaline changes.

In any of these 3 types we have failed to appreciate a sufficient preponderance of fibrous connective tissue such as would justify an adherence to the designation of fibroma in connection with these chorio-angiomatic tumors. A consideration of the histogenesis will tend to support this exclusion.

HISTOGENESIS

The resemblance of the components of chorio-angioma to the blood vessels and stroma of the normally developing chorionic villus unquestionably points to their origin from the chorionic mesenchyme, the common source of endothelial and connective tissue. That there is a close embryogenetic relationship between endothelium, connective tissue, and blood cells is fairly well established. One is able to note in the cellular or more immature type of chorio-angioma the process of transition from the embryonal type of mesenchymal cells into more adult types of endothelial and stromal cells.

Fig 11 A camera lucida drawing from an area in specimen from Case 5 illustrating collapsed capillaries and interstices lined with endothelial cells. The greater part of the cells, both endothelial and stromal, have a more immature appearance. One sees an endothelial cell in mitotic division $\times 750$

The proliferating endothelium assumes at once the predominant rôle. Ultimately the development and growth progresses to complete angioma formation with the stroma playing only a subordinate or accessory rôle. Beaufays describes and discusses this succession of developments very well in his report of

Fig 12 Case 4 An area illustrating transition from the cellular to the vascular type $\times 120$

Fig. 7. Case 2. A typical area of the mature or vascular type of chorio-angioma with practically all capillaries and blood vessels dilated and filled with red blood cells. $\times 120$.

ent so that a somewhat cavernous structure results. Fibrous connective tissue trabeculae carrying blood vessels of varying caliber are seen working their way through the substance of the tumor dividing it into lobules of diverse sizes. This description applies particularly to the predominantly vascular or the more mature type.

Fig. 8. A camera lucida drawing from a small area in Figure 7 illustrating the capillaries dilated with red blood cell and lined by a single layer of endothelium. One also notes the loose connective tissue groundwork and stromal cells. $\times 750$.

Fig. 9. Case 5. A typical area of the cellular or immature type of chorio-angioma. This is the type that has the fibromatous or sarcomatous appearance. $\times 120$.

A less common type is that which is composed of more cellular elements. Such tumors consist of an abundance of endothelial and chorionic stromal cells many of which are quite embryonal in character. The structure at once impresses one as being very compact. Closer scrutiny will disclose that many of the endothelial cells are lining interstices and small blood vessels which are obviously collapsed (Figs. 9, 10, and 11). Transition from these compact cellular areas to small isolated angiomatous areas with dilated capillaries filled with blood cells is noted (Fig. 12). This profusion of embryonal mesenchymal cells differentiated into young chorionic stromal cells and endothelium with occasional mitotic activity represents the more immature type of chorio-angioma. Beaufays has recently described and designated such a tumor as a mesenchymal angioma of the placenta. Between these 2 characteristic extremes it is obviously possible to obtain many combinations of the vascular and cellular constituents.

A third type is distinguished by various degrees of degeneration, a process which is naturally expected to be secondary to any primary growth. Interstitial edema swelling and vacuolization of stromal cells, degeneration and disappearance of the endothelial lining of the

demic inclinations. With the knowledge and criteria at present available we are of the opinion that one cannot say with any finality that benign tumors of the placenta are true tumors even though the greater number of writers are inclined to believe that they are

It is unnecessary to go into the details of some of the older theories which were advanced to explain the origin of chorio-angiomas. Most of them are now considered untenable. However, some mention of these theories does appear essential for the sake of completeness. Danyau and Goodhart speculated that their origin could be traced to organized blood clots. Albert and Dienst supported the idea that these tumors originated from vessels derived from the allantois. Many others considered an inflammatory basis as their source (Plauchu and Savy, von Mars, Lonnberg, Berglund, Le Page, Solowij). Chorio-angioma, the result of degeneration and necrosis, was advanced by Grafenberg and Hildebrand. Storch, Mertens, and Gueniot proposed that they originated as a result of hyperplasia of the chorionic villi. Finally among the many authors linking their origin to aberrations or disturbances of the maternal and fetal circulation such as stasis, increased tension, obstruction, hyperemia singly or in combinations, are Dienst, van der Feltz, Johnstone, Schindler, J. P. Maxwell, McDonald and Burnett, and Pitha.

Today the origin and formation of chorio-angiomas are explained in the following generally accepted manner. A group of blood vessels and stroma are thought to take on active proliferation and growth outside of the regular arrangement and restriction of the normally developing chorionic villi. Without the guidance of the chorionic epithelium covering the villi, the tumor forms in the chorionic surface plate or in some cases in the large trunk villi and develops independently of the normally developed surrounding tissue. Thus the tumor with its capsule is somewhat isolated and does not bear a physiological relation to the functioning portions of the placenta. Its growth is not limited.

Whether the anlage is congenital or whether it is a faulty tissue mixture depends upon whether one believes with Ribbert that it is a

true tumor, or with Albrecht and R. Meyer that it is a malformation or *hamartoma*.

TYPES

Fuller consideration of the histological structure of chorio-angioma, as described under the pathological anatomy, reveals that the tumor may be differentiated into various types. However, such a differentiation does not carry the implication that these forms may be classified as different tumors. They represent various phases of development in different or in the same chorio-angioma. Furthermore, this attitude lends understanding to the discussion of tumors which at first were misunderstood and were ultimately proven to be chorio-angiomas as well as to other conditions which have been incorrectly diagnosed as this tumor.

In the first place we should consider the cellular, more immature, or less differentiated type. Again may we refer to Beaufays' *angioma mesenchymale* of the placenta which we believe is a chorio-angioma with less differentiated manifestations of the more adult tumor and consequently of the same origin. This cellular type is the one that has been frequently and incorrectly designated in the past as sarcoma, fibrosarcoma, and angiosarcoma of the placenta. As yet a chorio-angioma with proven malignant changes remains to be reported. Cary's case of sarcoma of the placenta, examined and thought to be sarcoma by J. W. Williams and Welch, was later reconsidered by Williams and shown to be a chorio-angioma. However, malignant metastases to the placenta have been described on 3 occasions (the cases of Walz, Senge, and Markus). Lacassagne and Vignes have pointed out that the degree of proliferation of the endothelium makes one think of endothelioma. Frayman and Gorjajewa in 1928 reported a case of endothelioma placenta. The illustrations of this tumor convince us that in all likelihood it is a chorio-angioma of the cellular type. Because of its occasionally compact structure, this type has also been incorrectly diagnosed as fibroma of the placenta (Auvard, Kramer). On the other hand, there have been tumors designated as fibroma of the placenta which were later thought to be, and in one or two instances proved to be, submucous myoma of the uterus.

tion designated as angiecta is of the chorionic villi but often mistaken for chorio angioma $\times 120$

Fig 15 An area of a normal placenta inserted for contrast and comparison $\times 250$

the mesenchymal angioma. In the same paper he quotes Klinge's conception of the histogenesis of angiomas to give support to his argument. However, as he concludes that the mesenchymal angioma is a different tumor from the simple placental angioma because it has a different origin, we must beg to arrive at a different conclusion. By simple placental angioma we interpret him as meaning chorio angioma. If our interpretation is correct the tumor he describes has the same origin as the chorio angioma and we consider it merely a manifestation of the immature cellular type.

The hypothesis that chorio angiomas may represent phases in the development of the hydatidiform mole or chorio epithelioma as pointed out by Virchow, Valeri and Storch is now considered wholly untenable. The mole and chorio epithelioma are tumors of epithelial origin and pre eminently associated with malignancy, 2 characteristics which contrast decidedly and unquestionably exclude any relationship to chorio angioma.

ORIGIN

It is desirable to introduce the subject of the origin of chorio angioma with a brief discus-

sion of whether an angioma is a true tumor or not. Indeed, this is a controversial point among pathologists which still remains unsettled. There are 2 prevailing points of view. The first, and one which seems to be accepted generally, is Ribbert's idea that it is an independent growth originating from a rudiment predetermined to form blood vessels. The second is the conception championed by Albrecht and supported prominently by R. Meyer, that angiomas are the result of fetal displacement or malformation of tissue. Albrecht differentiates these displacements and perverted formations as *hamartomas* and when they assume the form of a tumor R. Meyer distinguishes them as *hamartoblastomas*. Hinselmann enjoys a little play in antithesis when he calls chorio angioma the antipode of hydatidiform mole. The former is a malformation caused by an excess of development or *Excessmissbildung* whereas the latter is a malformation resulting from arrest of development or *Hemmungsmissbildung*.

The unchallenged conception and definition of a tumor is still to be sought and further discussion of this subject is left to the investigator with more profound philosophic and aca-

or fetus was certainly not affected by the presence of a chorio-angioma. Among them, it is true, there was an infant considered premature, but she was born of a mother with a toxemia of pregnancy, a complication that is known to affect the size of a baby in many instances. In these cases also, hydramnios and premature rupture of the membranes were not noted in a single instance. With the possible exception of hydramnios and the extremely rare possibility of dystocia, it may be concluded from the evidence we have at hand that chorio-angioma is clinically insignificant.

CASE REPORTS

Six of the following 8 cases were collected during the last 5 years; the 2 others were found in the older material preserved in our pathological museum.

CASE 1 B R, (Berwind No 32551, P-223), white, secundipara, age 22. The last menstrual period occurred on March 2, 1932, expected date of confinement was December 9, 1932. There was a normal antenatal course, and a spontaneous delivery without a history of premature rupture of the membranes of a normal, female, living infant weighing 4,060 grams on December 3, 1932. Duration of labor was 3 hours and 10 minutes, blood loss 150 cubic centimeters, puerperium was normal.

Placenta The placenta weighed 775 grams and was 2 by 16 by 17 centimeters in size. On the maternal surface and extending into the substance of the placenta, a fibrous, well circumscribed nodule measuring 2.5 by 4 by 4 centimeters was found. The tumor was readily enucleated from its bed and on bisection the cut surface was grayish-red in color. Microscopic examination revealed a well encapsulated chorio-angioma of the cellular variety. For the most part the texture of the tumor appeared compact. Here and there, along the periphery especially, one saw isolated angiomatous areas. The denser areas, which made up the greater part of the tumor, conformed to the immature type of tumor described in the text, that is, collapsed capillaries and interstices lined with endothelial cells supported in a network of connective tissue and stromal cells of a more embryonal character. Occasionally a cell was observed in mitotic division.

CASE 2 E S, (No 22433, P-510), white, nullipara, age 30. The patient's last menstrual period occurred on August 15, 1932, expected date of confinement was May 22, 1933. There was a normal antenatal course with no history of premature rupture of the membranes. Spontaneous delivery of a normal, female, living infant weighing 2,850 grams, June 2, 1933. Duration of labor, 7 hours 9 minutes, blood loss, 300 cubic centimeters, puerperium, normal.

Placenta The placenta weighed 720 grams, the dimensions were 4 by 8 by 10 centimeters. A small, firm, rounded tumor measuring 3 centimeters in diameter was found just beneath the amnion on the fetal surface halfway between the centrally inserted umbilical cord and the margin of the placenta. Microscopic study showed that it was a well preserved chorio-angioma of the vascular type. Uniformly it consisted of dilated capillaries filled with red blood cells. The stroma was composed of ovoid cells which were found scattered in small numbers in the connective tissue spaces between the capillaries. Inasmuch as compact cellular areas or degenerated ones were entirely absent in this tumor, it can be considered an example of the mature variety of chorio-angioma.

CASE 3 M T, (No 44808, P-738), white, quintipara, age 30. The patient had her last menstrual period on February 1, 1933, expected date of confinement was November 8, 1933. The antenatal course was complicated by hypertension and chronic nephritis. On November 8, 1933, spontaneous delivery occurred of a normal, female, living infant weighing 3,300 grams. Duration of labor was 1 hour and 50 minutes, blood loss was 200 cubic centimeters. The patient was discharged in good condition.

Placenta The weight of the placenta was 420 grams, the dimensions, 2 by 15.5 by 17 centimeters. Buried in the substance of the placenta, at the time that it was examined and sectioned, a small firm nodule 1.5 by 2.5 centimeters was found. The small tumor was readily enucleated from the surrounding placental tissue and its consistency was noted to be just a little firmer than the placenta itself. Microscopic examination disclosed that it was a chorio-angioma of the degenerated type. In general one finds vacuolated areas resembling areolar or myxomatous tissue. The capillaries have lost their endothelial lining, wholly or in part, and for the most part the red blood cells have disappeared from the lumina of the vessels. Here and there one does find areas in a better state of preservation making its recognition as a chorio-angioma unmistakable.

CASE 4 E R, (No 107080, P-1695), white, nullipara, age 24. The last menstrual period occurred on December 28, 1934, expected date of confinement was October 5, 1935. Antenatal course was normal. On September 26, 1935, there was a low forceps delivery, because of a prolonged second stage, of a normal, male, living infant weighing 3,220 grams. Duration of labor was 9 hours and 6 minutes, blood loss 400 cubic centimeters, puerperium was normal.

Placenta The weight of the placenta was 850 grams, the dimensions 2 by 19 by 19 centimeters. A tumor 5 by 6 by 6 centimeters was found on the margin of the fetal surface. Microscopic study showed that it was a chorio-angioma of the vascular variety. This one is not found as entirely typical as the tumor described in Case 2. There are a few regions showing transition from the cellular structure to the angiomatous one. However, considered as a whole the pattern conformed to the more mature or vascular chorio-angioma.

(Harper, Hodgen, Loeb) It is quite conceivable that a submucous myoma can be overlapped by a placenta and form vascular connections with it. At the completion of delivery the myoma may detach itself with the placenta or it may be removed manually because of postpartum hemorrhage, an experience which we have already encountered in this clinic. Gheorghiu's and Hoynacki's cases also, were probable instances of submucous myomas and not placental fibromas.

The full grown angiomatous tumor should in our opinion be regarded as the vascular or mature chorio angioma. This is the type that has been least mistaken even though it has had its share of diverse designations. At this point, it would be well to discuss and direct attention to a condition which may be commonly seen in placental villi. This is not a tumor formation but has been incorrectly diagnosed chorio angioma. Occasionally in the intraplacental substance one finds circumscribed or diffuse areas of agglutinated villi. These fused villi show some edema of the stroma, partial or total loss of their surface epithelium and above all dilatation of the individual blood vessels (Fig 14). G. Mueller classifies it as a pseudo angiomatous structure and in our opinion correctly designates it as angiectasis of the chorionic villi. Meyenburg prefers to speak of it as *hemangiomatosis diffusa placenta* or simply *angiomatosis of the placenta*. Schickel terms it an intraplacental angioma resulting from blood vessel proliferation in an already formed villus. The cases reported by Moller and Lohse, Gueniot and Brugger are examples of angiectasis.

Finally, there is the type showing various degrees of degenerative changes. This form with its vacuolated, areola like edematous areas has been frequently interpreted as myxomatous. Oskar Frankl objects to the affixation *myxomatousum*, and states that this term is incorrect inasmuch as mucus cells do not come into the consideration.

It is obvious that these characteristic types develop in the same or in different chorio angiomas, but we wish to emphasize and are quite confident that they represent various phases of development in the same tumor process.

CLINICAL ASPECTS

From the purely clinical point of view it is apparent that chorio angioma has been given more significance in relation to the welfare of the mother and fetus than it merits.

It is important to point out that it is always a benign tumor. Authors in particular Bochi who have emphasized the sarcomatous histological characteristics of the cellular type have in turn indicated the benign nature of the tumor as borne out by the course and follow up of their patients. No relationship has been definitely established between any disease complicating pregnancy and chorio angioma.

The frequent association of hydramnios with this tumor is being recognized as more accidental than actual. Formerly more emphasis was placed upon chorio angioma and hydramnios with its consequent morbid relationship to the fetus, prematurity, stillbirth, malformations, etc. Theveney intimates that this correlation is purely coincidental. Schickel, discussing Thomas' case in 1905 could not definitely link the 2 conditions. More recently Kuehnell in his critical, statistical study, although leaving the question open, tended to present evidence in favor of it being coincidental. However Szarthy reports a hydramnios incidence of 31 per cent in his review of the literature, a figure which is impressively high and would seem to connote an interrelationship between the tumors and excessive amniotic fluid.

One complication, though rare, which may arise is the possibility of a large chorio angioma being so situated that it may cause an obstruction to the normal birth of the fetus. Emge and Margeson have each reported a case in which cesarean section was performed for dystocia, later finding that the circumstance mentioned above was the provocative cause.

Chorio angiomas have been considered to have a deleterious effect upon the fetus. From the studies of Siddall, Kuehnell and others, closer evaluation of their statistics seem to indicate that the high incidences of prematurity, stillbirths, and premature rupture of the membrane are attributable to other more significant causes and complications. In our small series of 8 cases the welfare of the mother

CASE 5 J C, (Berwind No 40891 P 2956) white septipara age 37 The patient's last menstrual period took place on March 6 1937 expected date of confinement was December 13 1937 The antenatal course was normal Spontaneous delivery of a normal female living infant weighing 3500 grams occurred on December 10 1937 There was no history of a premature rupture of the membranes Duration of labor was 3 hours and 42 minutes blood loss 175 cubic centimeters and the puerperium was normal

Placenta The weight of the placenta was 700 grams the dimensions 3 by 23 by 29 centimeters Protruding from the margin of the maternal surface was a tumor measuring 3 by 3 by 4 centimeters Microscopic examination revealed that the tumor was a chorio angioma of the cellular variety The histological picture was similar to the one described in Case 1 except that there were fewer angiomatous changes in Case 5

CASE 6 A S (No 194682 P 3125) white, primipara age 37 The last menstrual period occurred on July 11 1937 expected date of confinement was April 18 1938 The antenatal course was complicated by a toxemia chronic nephritis The membranes ruptured at the onset of labor and there was a low forceps delivery of a normal premature female living infant weighing 2230 grams and whose length measured 40 centimeters Delivery occurred on March 29 1938 Duration of labor was 5 hours and 47 minutes blood loss 80 cubic centimeters The patient was discharged in good condition as was also the baby

Placenta The placenta weighed 600 grams and measured 3 by 16 by 18 centimeters About 4 centimeters away from the insertion of the cord on the fetal surface just beneath the amnion a small tumor 1 by 1 centimeters was enucleated Microscopic study demonstrated a chorio angioma of the degenerated type This tumor was not unlike the one described in Case 3

CASE 7 E H (No 82873 I 3093) white primipara age 34 The last menstrual period was on January 4 1930 expected date of confinement was October 11 1930 The antenatal course was complicated by an unclassified toxemia On October 9 1930 a mid forceps delivery of a normal female living infant weighing 2400 grams and 40 centimeters long was performed Duration of labor was 65 hours and 30 minutes without a history of premature rupture of the membranes blood loss 400 cubic centimeters puerperium was normal

Placenta The weight of the placenta was 540 grams the dimensions 17 by 17 by 19 centimeters Close to the insertion of the cord on the fetal surface a tumor was found measuring 2 by 3 by 3 centimeters Microscopic examination showed that it was a chorio-angioma of the immature type It conformed in structure and pattern to the cellular variety described in the text

CASE 8 (P 3004) The clinical history of this patient could not be found However the specimen

was preserved in our museum and a photograph of it is reproduced in the text (Fig 1) In its fixed condition the placenta weighed 700 grams and measured 4.5 by 8 by 10 centimeters Microscopic study disclosed that it was a chorio angioma of the vascular type

SUMMARY

1 Benign tumors of the placenta designated as chorio angiomas are relatively rare

2 On the basis of their histological structure and pattern these tumors are differentiated into several types The cellular or immature, the vascular or more mature type, and that type accompanied by varying degrees of degenerative changes are presented These forms may intermingle in all gradations in the same tumor

3 The histogenesis of these tumors is fairly well established The tissue originates from the chorionic mesenchyme the proliferating endothelium and blood vessels playing the leading rôle, the stroma a subordinate or accessory rôle

4 Whether the neoplasm is a true tumor according to Ribbert's idea or a malformation as explained by R Meyer is still an open question

5 The older discarded theories of the origin of the tumors and that which has been accepted are discussed

6 Clinically it is believed that chorio angiomas are of little significance

7 Two hundred and nine cases are collected from the literature, to which are added 8 of our own bringing the total number to 217

Fig 2 The relation of the blood iodine level to the basal metabolic rate before and after subtotal thyroidectomy in cases of Group II

the pre-operative and at each postoperative period. The average of the basal metabolic tests on these patients has been included. The findings are shown in Table I. From Table I it will be seen that the blood iodine level paralleled the basal metabolic rate in that the pre-operative elevation in both instances fell to normal values following subtotal thyroidectomy, as shown graphically in Figure 1.

The clinical records of the cases of Group I were noteworthy. Of the 170 cases followed, 154 patients (90.6 per cent) were completely relieved, 15 patients (8.8 per cent) showed transitory postoperative myxedema, 1 patient (0.6 per cent) had recurrent hyperthyroidism.

Group II Of 61 cases with a normal pre-operative and a postoperative increase in blood iodine, 28 were followed for 1 year. In the majority of instances, the maximal elevation

in the level of iodine in the blood occurred at the sixth month following operation. The average blood iodine values together with the average basal metabolic rates are shown in Table II. From Table II, it will be seen that no apparent relationship existed between the blood iodine level and the basal metabolic rate. The results are shown graphically in Figure 2.

Analysis of the clinical histories of the cases of Group II revealed that of the 61 patients followed, 45 (73.7 per cent) were clinically cured, 2 (3.3 per cent) had transitory postoperative myxedema, 12 (19.7 per cent) had persistence or recurrence, and 2 (3.3 per cent) had malignant exophthalmos without symptoms of hyperthyroidism.

The high incidence of recurrent hyperthyroidism in patients with a normal or low pre-operative level of iodine in the blood con-

BLOOD IODINE LEVELS RELATED TO THE RECURRENCE OF HYPERTHYROIDISM

H J PERKIN M A and RICHARD B CATTELL MD FACS
Boston Massachusetts

A BETTER understanding of the metabolism of iodine in patients with goiter has been realized by the quantitative analysis of iodine in the blood. Many investigators (1, 2, 3, 4, 11) have repeatedly demonstrated the presence of abnormal blood iodine levels in cases of hyperthyroidism. In previous reports, we have shown that the estimation of the pre-operative level of blood iodine has been an aid not only in establishing the clinical diagnosis (5) but also in evaluating the severity of the disease (6). Two reports (1, 9), dealing with the blood iodine level at intervals after operation, have appeared in the literature. In this connection our previous work (9) indicated that, following subtotal thyroidectomy, estimations of the level of iodine in the blood taken at stated intervals have given us a means whereby cases can be predicted which are predisposed to recurrence or persistence of clinical hyperthyroidism. The present report consists of further observations on the level of iodine in the blood before and after subtotal thyroidectomy for hyperthyroidism. Furthermore we wish to present additional evidence from the present results, which permits a selection of patients in whom recurrence is likely to follow subtotal thyroidectomy. It is our belief that more radical operations in these cases will result in a lower incidence of recurrent hyperthyroidism.

The study is based on 256 cases of exophthalmic goiter with 833 blood iodine values of these patients. This comprises an additional group to those previously reported (9). In so far as could be determined none of the patients had received any treatment for their hyperthyroidism prior to coming under observation at The Lahey Clinic. The blood iodine level was determined in each case before beginning the administration of Lugol's

solution (7, 8). All the patients were examined at intervals following operation at which time the amount of iodine in the blood was again estimated. Of the 256 patients 100 returned at intervals during 1 year for these check up examinations. During the course of this study, while observing these 256 patients approximately 750 additional cases were studied by the same methods and criteria. This larger group was excluded from the present report because of positive or presumptive evidence from either the patient or referring physician that iodine medication had been received prior to coming under our observation. It is probable that a few of these cases not included in this report should not have been excluded.

In a previous report (9), the findings showed that patients with hyperthyroidism with a pre-operative elevation in blood iodine have normal levels following subtotal thyroidectomy (designated as Group I below). On the other hand we found that individuals with signs and symptoms of hyperthyroidism in the presence of a normal blood iodine, had a relative increase in the blood iodine level after operation (Group II). The additional findings to be presented in this paper confirmed the above observations. In addition a group of cases has been encountered in which the pre-operative blood iodine value was found to be normal with no change in this level following subtotal thyroidectomy (designated as Group III). Since all of our cases with hyperthyroidism studied fall into one of the above groups, we have divided them into the 3 groups mentioned Groups I, II and III.

Group I. Of 170 patients with hyperthyroidism with an elevated pre-operative blood iodine level who were examined after operation at regular intervals 59 were followed for 1 year. Since the results of the group as a whole were relatively consistent it is considered fair to average the blood iodine values at

increase in the duration of symptoms, reaching a maximum at the 4 to 5 year duration period

Our present conception of the clinical aspects of exophthalmic goiter permits certain correlations with the results of study of the pre-operative and postoperative blood iodine levels. Clinical experience attests to the view that certain features of thyrotoxicosis differentiate those individuals with acute recent onset and those who have been suffering from the disease for a considerable period of time. In this connection, the present results suggest that there may be an actual hypersecretion of iodine from the thyroid gland during the earlier stages of the disease. Such an interpretation, however, is only reasonable if the blood iodine level is influenced by excessive thyroid secretion. Should this hypothesis be adopted, it follows that subtotal thyroidectomy would remove the source of the excessive secretion with symptomatic relief. The elevated pre-operative and normal postoperative blood iodine levels of the cases of Group I lend credence to such a view.

The above hypothesis, however, does not appear to hold for the majority of individuals who have had untreated hyperthyroidism for 1 year. In these cases the pre-operative blood iodine level was generally found to be normal (10). That hypersecretion of iodine products from the thyroid gland could account for the symptoms of thyrotoxicosis seems doubtful. This becomes still more confusing when it is noted that, following surgical treatment, the blood iodine level usually increased to approximately twice the normal level (cases of Group II). Although 19.7 per cent of patients showing such a phenomenon had recurrence or persistence of hyperthyroidism, 73.7 per cent of the patients having similar blood iodine levels were considered to be clinically cured. At least in this group of cases (Group II) it is difficult to conceive that excessive thyroid secretion was a primary factor.

Furthermore, it would appear that, if the symptoms of clinical hyperthyroidism were allowed to persist untreated from 4 to 5 years, the blood iodine level is not only normal, but in most cases uninfluenced by subtotal thyroidectomy. The interpretation for these cases

(Group III) would appear to be that the iodine metabolism, as reflected by the blood iodine level, is a secondary factor in very long standing cases of untreated hyperthyroidism.

The pre-operative level of iodine in the blood of patients with untreated hyperthyroidism can be used as an index of the amount of thyroid gland to be excised. We have correlated the postoperative results with the pre-operative blood iodine levels. Following operation, patients obtain complete relief or have recurrence or myxedema. In cases of Group I with an elevation of the pre-operative iodine in the blood, the unsatisfactory results are primarily due to myxedema, whereas the recurrence rate is very low. A less radical operation is indicated in this group of cases. The unsatisfactory results in Group II, with a normal pre-operative blood iodine level, are chiefly from recurrence, myxedema is rare in this group. The results in cases of Group III in which the pre-operative blood iodine is again normal, are very satisfactory. Since the pre-operative blood iodine is normal in both Group II and Group III, in order to decrease the recurrence rate of cases of Group II it becomes necessary to do a more radical subtotal thyroidectomy in all of the cases in both groups. This seems justified since there is a very low incidence of postoperative myxedema in both Groups II and III. These cases represent only 33.6 per cent of the total but all of the recurrences are found in these 2 groups. In view of the fact that it does no apparent harm and offers a definite opportunity for decreasing the number of recurrences, we strongly urge a radical subtotal thyroidectomy in all cases of hyperthyroidism in which the blood iodine level is normal pre-operatively.

SUMMARY

- 1 The pre-operative and postoperative blood iodine levels are reported for 256 cases of exophthalmic goiter, 100 of these patients were followed for 1 year.

- 2 Patients with hyperthyroidism having an elevated pre-operative blood iodine level showed a normal blood iodine level following subtotal thyroidectomy. The incidence of such cases decreased with an increase in the duration of symptoms before treatment.

Fig 3 The relation of the blood iodine level to the basal metabolic rate before and after subtotal thyroidectomy in cases of Group III

firmed our former observations (9). Further more, there was a consistent increase in the blood iodine after operation in these patients with recurrence of symptoms (Table II). In this group of cases (Group II) myxedema following subtotal thyroidectomy was rare (3.3 per cent). These findings in our opinion justify a more radical thyroidectomy in patients with a normal or low pre-operative blood iodine, in other words relatively smaller thyroid remnants should be left than when the pre-operative blood iodine level is elevated.

Group III. There were 25 patients in the group with hyperthyroidism who had a normal blood iodine level before operation and no change in level following subtotal thyroidectomy. Thirteen of these individuals were followed for 1 year. The results of this group are shown in Table III. Table III shows that as in the cases of Group II, there was no obvious

relationship between the basal metabolic rate and the level of iodine in the blood. The results are illustrated graphically in Figure 3. Clinical data of the cases of Group III revealed that of the 25 cases followed 24 patients (96 per cent) were clinically cured and 1 patient (4 per cent) had transitory postoperative myxedema. The hyperthyroid cases of Group III appeared to have the most favorable clinical course following subtotal thyroidectomy of the 3 groups.

Recent studies (10) concerning the relationship between the blood iodine level and the duration of symptoms in individuals with exophthalmic goiter have shown that the blood iodine is usually elevated when the hyperthyroid symptoms have been present for less than 9 months. On the other hand, patients exhibiting untreated symptoms of hyperthyroidism for 1 year or longer usually have blood iodine values within the range of normal. This observation may be correlated with the results of the present study. With the duration of symptoms heretofore established (10) the number of cases in Groups I, II, and III was charted against the duration of symptoms prior to treatment for each case respectively (Table IV).

As will be seen from Table IV: (a) The incidence of hyperthyroid cases with an elevated pre-operative and a postoperative fall in blood iodine (cases of Group I) decreased as the duration of symptoms for the cases increased. (b) The incidence of hyperthyroid cases with a normal pre-operative and a postoperative increase in blood iodine (cases of Group II) increased with a corresponding increase in the duration of symptoms, the greater percentage of such cases occurring at the duration period of 10 to 12 months. (c) The incidence of hyperthyroid cases with a normal pre-operative blood iodine and no change in blood iodine following subtotal thyroidectomy increased (cases of Group III) from 10 to 12 months, with an

THE INFLUENCE OF PAPAVERINE ON MUSCULAR TONE OF THE INTESTINAL TRACT

J ARNOLD BARGEN, M D , and RAYMOND J. JACKMAN, M D , Rochester, Minnesota

IT has frequently been demonstrated that morphine sulphate causes an increase in the muscular tone of both the large and small intestine of man and that its administration results in an increase in the frequency and amplitude of the peristaltic waves as well as in the amplitude of the rhythmic contractions. These changes are not prevented by the usual doses of such antispasmodics as atropine.

We previously have suggested the similarity in the state of muscular tone existing in the bowel in cases of the severe toxemia of peritonitis and in cases in which the intestine was affected by morphine sulphate. Regions of contracted bowel, obstructive in nature, alternating with stretches of distended bowel, will be noted. In spite of this, morphine is probably the most commonly used drug for the relief of pain and postoperative discomfort, following gastro-intestinal operations. Likewise, it has long been used as the drug of choice to "splint" or put the bowel at rest in cases of peritonitis. Because of the intestinal hypermotility and obstructive type of contractions that morphine produces we decided to investigate the other alkaloids of opium as well as opium products that are intended to replace morphine or have advantages over the latter drug.

METHOD OF STUDY

Several patients, who previously had undergone a colostomy because of an intestinal lesion, kindly consented to submit to certain harmless and painless tests in order that they might assist us in this study.

The method of studying these drugs has been described elsewhere (2). It is a well recognized fact that such alkaloids as morphine, codeine, papaverine, narcotine, and thebaine all play parts in the action of opium. Differ-

ent specimens of opium may contain variable amounts of each alkaloid but the average amounts of the various alkaloids found in opium are as follows: morphine, 10 per cent; narcotine, 6 per cent, papaverine, 1 per cent; codeine, 0.5 per cent, thebaine, 0.3 per cent, and narceine, 0.2 per cent. The other alkaloids occur in such small quantities in the crude drug that their action may be considered negligible.

RESULTS

Pantopon Although the other alkaloids may modify the effect of opium, any action of this drug is the result of the comparatively large amount of morphine it contains. The view that opium is a more effective narcotic than morphine has been brought forth from time to time, and one comparatively recent preparation of the alkaloids as they exist in Smyrna opium has been introduced under the trade name of "pantopon." It has not been shown that the narcotic effect of this drug is greater than that of the morphine it contains. It has been said that pantopon has a greater sedative effect on the gastro-intestinal tract than has morphine. If this is true, the effect may be attributable to the papaverine it contains. Our observations suggest that morphine and pantopon act very much alike in increasing muscular tone, peristalsis, and the amplitude of contractions of the intestinal muscle.

Codeine The action of codeine on the bowel was less striking than that of morphine, but when codeine was administered in large enough doses the action was essentially the same as that of morphine.

Papaverine Allen and MacLean have described the antispasmodic effect of the intravenous administration of papaverine hydrochloride in cases of sudden arterial occlusion. They reported a case in which, after intravenous administration of papaverine, the circulation was re-established. In this case

From the Division of Medicine and the Section on Proctology, The Mayo Clinic

3 The majority of patients with hyperthyroidism with symptoms for 1 year had a normal blood iodine level and following subtotal thyroidectomy had an increase in the level of iodine in the blood. The incidence of recurrence in these patients was 19.7 per cent.

4 After symptoms of hyperthyroidism have been present from 4 to 5 years, the blood iodine level was generally normal and usually uninfluenced by subtotal thyroidectomy.

5 Evidence is presented to show that the pre-operative blood iodine level can be used as an index of the amount of thyroid gland to be removed in patients with hyperthyroidism.

6 A radical subtotal thyroidectomy is recommended in all cases of hyperthyroidism with a normal or low pre-operative blood iodine level.

A STUDY OF THE FLUID AND SODIUM CHLORIDE BALANCE IN PATIENTS TREATED WITH CONTINUOUS SUCTION APPLIED TO INDWELLING DUODENAL TUBES

JOHN R. PAINE, M.D., and WALLACE D. ARMSTRONG, M.D.,
Minneapolis, Minnesota

ALTHOUGH suction applied to an indwelling duodenal tube has, in general, come to be accepted as the method of choice in the management of postoperative distention, occasional disconcerting reports, such as that of Taylor, appear in the literature in which it is alleged that the aspiration of the gastric and duodenal juices has produced serious dechlorination and dehydration. That the possibility of such an occurrence exists unless the fluid and sodium chloride balance is adequately maintained can not be denied. In our experience, however, at the University of Minnesota Hospitals, during the past 6 years no such occurrence has been recognized.

The changed blood chemistry which attends the loss of the upper gastro-intestinal secretions in high mechanical obstruction was first indicated by Hayden and Orr in 1923. In 1926, Walters and Bollman showed that similar changes occurred in dogs with experimental gastric fistulas. Four years later Ellman and Hartman showed that in dogs with complete loss of pancreatic secretion death occurred with characteristic changes in the level of the blood electrolytes. These experimental results have been confirmed by clinical study of patients. The deleterious effects of the loss of fluid *per se* have been studied in considerable detail. The fundamental studies of Gamble on the causes and effects of dehydration have been supplemented recently by the practical investigations of Maddock and Collier. These latter investigators have been concerned with the fluid requirements of surgical patients. Their results have indicated that such patients require more fluid than most clinicians have thought necessary heretofore.

In the light of the above considerations it would seem desirable to determine the extent to which the acid-base and fluid balances of the body are disturbed by the use of suction applied to indwelling duodenal tubes for the removal of gas and fluid from the upper portion of the gastro-intestinal tract. The use of this method of treatment combined with the adequate administration of para-oral fluids gives eminently satisfactory results as far as decompression of the upper gastro-intestinal tract is concerned, but the amount of glucose and saline solutions which should be administered to each individual patient is a question which up to the present time has not been adequately investigated.

METHOD OF STUDY

This paper is based on the study of the sodium chloride and fluid balances of 19 patients on the surgical service of the University of Minnesota Hospitals.

Choice of patients for study. Patients were entirely unselected. All but one were subjected to a major surgical procedure and treated with suction applied to an indwelling duodenal tube during the period of the study. In some cases the studies were begun before operation and carried through the postoperative period for several days. In other cases the studies were begun immediately after operation. Two patients were studied in the relatively remote postoperative period.

Administration of fluid. Sixteen patients were allowed to drink as much water as they desired. No other fluid was offered by mouth. In 3 patients no oral fluid was allowed. Para-oral fluid of 3 kinds, normal saline solution, 5 per cent glucose in triple distilled water, and 5 per cent glucose in normal saline solution, was given in variable amounts and combi-

From the Departments of Surgery and Physiology, University of Minnesota Medical School.

Fig. 1 Effect of 1 cubic centimeter of intravenous administration of papaverine compound (spasmalgin) on the muscular tone of the terminal portion of the ileum: the temporary increase in the tone and motility is the result

of the alkaloid morphine in the spasmalgin: the subsequent decrease in the tone and motility continued for a period of 60 minutes before the normal tonus was gradually resumed.

morphine sulphate as well as intermittent suction and pressure (pavex treatment) had little value in relieving the pain or in re-establishing the circulation. Other writers have reported similar results with papaverine. In our study the intravenous administration of papaverine hydrochloride in doses of 1 to 1½ grain (0.065 to 0.097 gram), caused a decrease in tone of the intestinal muscle. This was not constant but an increase of tone was not observed when using papaverine in any of our cases studied.

Papaverine compound. This drug was introduced commercially under the trade name of spasmalgin; it contains papaverine hydrochloride 0.021 gram, "pantopon" 0.012 gram and "atrinol" 0.001 gram in 1 cubic centimeter of the drug. The addition of the opiate and slower acting antispasmodic atropine has been found to be advantageous in increasing the antispasmodic properties and controlling the pain which usually accompanies visceral spasm. As shown in Figure 1 the comparatively small amount of morphine that spasmalgin contains, although it manifests itself by the temporary increase in tone, is overcome by the papaverine and atropine so that the subsequent and desirable decrease in tone and immobility of the bowel is striking.

Lolling reported the use of spasmalgin in various types of angina and visceral colics, such as those associated with stones in the biliary ducts and ureters. In these conditions pantopon or morphine alone did not produce relief as effectively as did spasmalgin.

SUMMARY AND CONCLUSION

It is hardly necessary to call attention to the fact that morphine is one of the most valuable drugs in any physician's practice and we do not presume to supplant it or find a substitute. We would like to call attention, however, to the fact that morphine causes an increase in motility and tone of the large and small intestine of man. It may be that the constipating effect of morphine is attributable to the regions of spasm which it initiates.

The value of papaverine hydrochloride, as such, or in combination with pantopon and atropine should be given serious thought. Clinically, this combination of drugs has been found to have great value in relieving the distressing abdominal cramps and frequent purulent, bloody discharges associated with the acute phase of chronic ulcerative colitis and other acute dysenteries. Experimental evidence has substantiated the antispasmodic effect of this papaverine compound.

Papaverine compound has certain advantages over morphine sulphate in cases in which it is desired to immobilize or put the bowel at rest.

patient, the diagnosis, the type of operation performed, and the position of the end of the duodenal tube are given. The volume of the urine and aspirated fluid together with the results of the analysis of each are presented. It will be noted that the complete analysis was not made in each case, but the determination of the sodium chloride content was made in practically every instance. With few exceptions the results of blood chemistry studies are given for each day. The two right hand columns of the table show the state of the measurable fluid balance and sodium chloride balance. No account has been taken of the water available from endogenous metabolism, the water lost in the feces, or that lost by vaporization from the skin. As Maddock and Collier have pointed out, these factors must be taken into account in any estimation of the patient's fluid requirements.

It will be noted at once that the amount of fluid aspirated through the duodenal tube varies roughly with the amount of fluid taken by mouth. This is to be expected since most of the fluid swallowed is immediately removed from the stomach by the tube. As the measured quantities of fluid show, however, this relationship is far from exact. Of more importance is the tendency of those patients with a relatively large fluid intake to lose greater amounts of chlorides in the aspirated fluid than do those patients with a more moderate oral fluid intake. Mr W C who was encouraged to drink large amounts of distilled water illustrates this point most clearly. The results in the other patients would indicate that variations in the oral intake of water below 2,000 cubic centimeters for each 24 hours affect the chloride excretion in no characteristic manner. The average patient treated with suction applied to an indwelling duodenal tube loses up to 70 grams of chloride expressed as sodium chloride per day in the aspirated fluid.

The quantitative chemical analysis of the urine revealed no unexpected results. Others have called attention to the failure of the kidneys to eliminate chloride when the blood chloride level is decreased appreciably below the normal level. Patients, Mr D S, Mr W C, Miss R. J, Mr F. S, Mr V S, were all given 1,500 to 3,000 cubic centimeters of 5

per cent glucose in triple distilled water each day for several days. Under these circumstances the daily excretion of chloride by the urine decreased steadily so that in some cases only traces could be detected. Simultaneously with this fall in urinary chloride the level of the plasma chlorides of the blood also fell. It would therefore appear that the chloride content of the urine represents the portion of this element that the body has no use for. Patients treated with suction, as well as other patients who excrete an appreciable amount of chloride in the urine, are receiving an adequate intake of this element and there exists little danger of achlorhydric alkalosis and uremia. As the study of the patients mentioned has shown, however, a good urinary output of over 1,000 cubic centimeters per day may be present despite an inadequate intake of sodium chloride if 5 per cent glucose solution is given para-orally in sufficient amounts.

The results of some of the qualitative tests on the urine specimens were surprising at first sight. Many of the urine specimens gave positive tests for acetone and diacetic acid, even though they contained large amounts of glucose. The formation of these ketone bodies is undoubtedly due to the fact that these patients, with a relative deficiency in carbohydrate, were forced to utilize their body fat to supply their caloric requirements. This phenomenon was noted in patients receiving as much as 3,000 cubic centimeters of 5 per cent glucose solution per day intravenously. None of the patients reported in this paper had diabetes mellitus as shown in the following table.

The importance of a moderately restricted oral and an adequate para-oral intake of fluid in the prevention of an abnormal alteration of blood non-protein nitrogen was indicated by the results obtained in the study of Mrs V S. This patient had had continuous suction applied to an indwelling duodenal tube 14 days preceding the study of his acid-base balance, but had received daily an average of 2,500 cubic centimeters of 5 per cent glucose in normal saline solution intravenously. The non-protein nitrogen of the blood was found to be 37 milligrams per cent on the fourteenth day.

nations to the different patients. In certain cases the fluid administration was so controlled as to provide the optimum conditions for dehydration and alkalosis.

Aspiration of gastric and duodenal secretions During the period of study all patients were treated with continuous suction applied to an indwelling duodenal tube. All of these tubes had perforations extending back from the tip some 8 or 9 inches so that even though the tip of the tube extended well into the duodenum, suction would be effectual in both the stomach and duodenum. The position of the tip of the duodenal tube was determined by an x-ray film of the abdomen in each case. Even though in many cases aspiration was confined wholly to the stomach, fluid was apparently removed from both the duodenum and stomach, as attested by its greenish yellow color.

Collection of urine and aspirated fluid The urinary output and duodenal tube aspirations were collected for each 24 hour period beginning at 8:30 a.m. All para-oral fluids which in most instances were administered intravenously, were given between 9:00 a.m. and 4:00 p.m. Blood samples for the study of blood chemistry were drawn in the morning before the administration of any para-oral fluid. The urine was preserved by refrigeration and the addition of a small quantity of toluol.

Analytical methods An aliquot of the aspirated fluid was filtered by suction through cotton. Free hydrochloric acid was determined by titration to the first transition interval of thymol blue. The total base was determined on 1 cubic centimeter aliquots by the method of Stadie and Ross. The accuracy of this determination was controlled by the analysis of standard potassium chloride solutions containing sucrose.

The specific gravity was determined and the quantitative tests performed on urine by standard procedures. The titratable acidity of urine was determined by the titration of 10 cubic centimeters of urine diluted to 250 cubic centimeters phenol red being used as indicator. The end point of the titration was 7.4 hydrogen ion concentration. A permanent phosphate buffer solution was used for reference. Alkaline urines were titrated to the

same end point with acid and the result reported as acid deficit. Chloride was determined on aspirated fluid, urine, and blood by the method of Cavett and Holdridge. Some difficulty was experienced in the preparation of protein free filtrates of the aspirated fluid by the method of Folin and Wu. In all such cases 5 per cent sulphosalicylic acid was found to remove effectively all protein from this fluid. The quantitative glucose determinations were made by Benedict's titration procedure. The results are reported in grams for total 24 hour samples. Standard procedures were used for the determination of the carbon dioxide combining power of plasma and for whole blood non protein nitrogen analyses.

It was realized that a very significant determination was that of the amount of chloride excretion in the urine, and it seemed desirable to develop a highly simplified and rapid procedure for this determination which could be employed in the routine observation and care of patients. An attempt was made to adapt Purdy's method (8), but in our hands the original method gave inconsistent results. A modification of this method was made where by 10 cubic centimeters of urine were treated in a conical graduated centrifuge tube with 5 cubic centimeters of 6 per cent silver nitrate in 0.03 normal nitric acid. The tube was centrifuged until the volume of precipitate was constant. By this technique 0.1 cubic centimeter volume of precipitate is equivalent to 3.36 milligrams of sodium chloride per 100 cubic centimeters of urine. The results agreed with the titration method within 5 to 10 per cent.

An alternative method and one equally adaptable to clinical use consists in the titration of 5 cubic centimeters of urine diluted to 100 cubic centimeters, with a standard mercuric nitrate solution. Three drops of a 5 per cent sodium nitroprusside solution is used as an indicator and the end point is reached when a permanent turbidity is produced. This method is slightly more accurate than the centrifuge method.

RESULTS

The results obtained are presented in the accompanying table. The identification of the

In 2 patients, Mr J W, and Mrs V S, the blood non protein nitrogen was definitely elevated. Mr J W was a 65 year old man with mild hypertensive heart disease and Mrs V S was a 24 year old woman with localized peritonitis from a ruptured appendix. Some doubt exists as to the effect of dechlorination incident to gastroduodenal aspiration in causing the slight increase in the non protein nitrogen in the case of Mr J W, but in the case of Mrs V S it is probable that an inadequate intake of sodium chloride was an important factor in the elevation of the blood non-protein nitrogen level. It will be noted that in this case the blood chlorides fell and the carbon dioxide combining power rose.

Most of the patients studied show a carbon dioxide combining power of over 55 volumes per cent. Such values may indicate a mild alkalosis but these can scarcely be attributed to dechlorination, as equally high values are found in those patients with positive chloride balances as in those with negative chloride balances.

A study of the calculated chloride balance, expressed in terms of sodium chloride, shows that no patient who received 2 000 cubic centimeters or more of normal saline solution daily had a negative chloride balance. Furthermore, the negative balances which consistently occurred in those patients given only 5 per cent glucose in distilled water would all have been adequately covered by 2 000 cubic centimeters of normal saline solution. It has been the practice at the University of Minnesota Hospitals for the past 6 years to give patients treated with continuous suction applied to indwelling duodenal tubes between 2 000 and 3 000 cubic centimeters of normal saline solution each day with or without 5 per cent glucose. That such a regimen will consistently prevent dechlorination and alkalosis has been proved both by experience in hundreds of cases and by the results of the studies here reported. It is not meant to convey the impression however that exceptional cases will not occur from time to time in which some variation from this rule will not be indicated. It is our impression that in the usual patient treated with suction to whom inadequate amounts of saline solution are administered several

days must elapse before any real harm is done by the dechlorinating effect of the gastroduodenal aspiration.

SUMMARY

The fluid and chloride balances of 19 patients on the surgical service of the University of Minnesota Hospitals treated by continuous suction applied to an indwelling duodenal tube have been studied. Most of these patients were subjected to major surgical procedures and the studies were made in the immediate postoperative period. The duodenal tube aspirations and the urine collected from these patients were subjected to certain quantitative analytical tests. The daily variations in the blood chlorides, carbon dioxide combining power, and non protein nitrogen were followed. The quantity and character of the fluid intake was varied in certain patients. A description of the analytical methods used is given. Two practical clinical methods for the quantitative estimation of chloride in the urine are described.

CONCLUSIONS

- 1 The administration of 2 000 cubic centimeters of normal saline solution daily to the usual patient treated with continuous suction applied to an indwelling duodenal tube will maintain a positive chloride balance and prevent any serious alkalosis.

- 2 Several days (4 to 5) must elapse before dechlorination incident to the aspiration of the gastroduodenal secretions through an indwelling duodenal tube can do harm to a patient inadequately supplied with sodium chloride.

- 3 Many patients treated with suction applied to indwelling duodenal tubes will have ketone bodies in the urine despite the daily intravenous administration of 3 000 cubic centimeters of 5 per cent glucose in distilled water or normal saline solution.

- 4 The patient who excretes daily 3 or more grams of chloride expressed as sodium chloride in the urine is in no danger of achlorhydric alkalosis.

- 5 The patient's sodium chloride requirements can be as satisfactorily determined by measuring the quantity of chloride present in

developed, the pneumonia was usually secondary to a fulminating pneumococcal peritonitis. There were 6 males and 2 females in this group with a mortality of 62.5 per cent. The third group consists of 16 patients who also had nephrosis as the predisposing cause. There were 11 males and 5 females in this group with a mortality of 68.7 per cent. This is the group in which pneumococcal peritonitis may recur several times, but the children eventually die in childhood due either to the nephrosis or a severe peritonitis. The high mortality from peritonitis in this group may surprise some observers, but the figure seems plausible as only those cases in which the peritonitis was proved by bacteriology or autopsy are included. Even in these cases, there was often a previous history suggesting an attack of pneumococcal peritonitis with recovery.

The age incidence in the cases of pneumococcus peritonitis is evenly distributed between the first and tenth year. This is in contrast to the streptococcus cases, the great majority of which occur between the ages of 6 months and 2 years. Contrary to many reports on pneumococcus peritonitis, which emphasizes the frequency in females, there does not appear to be any significant difference in the sex incidence. In fact in this series, there were more males who had the disease in both the streptococcus and pneumococcus groups, which suggests that the genital organs are not the chief portal of entry.

The clinical manifestations vary according to the severity of the disease. Abdominal pain is the cardinal symptom. It is usually diffuse, but unfortunately from the diagnostic standpoint it sometimes begins in the right lower quadrant. The mode of onset of the pain and its character are difficult to ascertain because of the age of the patient. Other important symptoms are loss of appetite with nausea, and persistent vomiting; fever and diarrhea are also common.

The duration of the symptoms before admission is usually from 1 to 4 days. This does not apply to the group with nephrosis, several of whom developed a respiratory infection while in the hospital and subsequently developed peritonitis. There is a small group of

patients who have been seen 2 to 6 weeks following an attack of abdominal pain with vomiting and fever, and who, on examination, appear emaciated and have a large peritoneal abscess. These large abscesses usually occur in the pelvic region, but sometimes occur in the epigastric region simulating a pancreatic cyst.

Perhaps the most common finding upon physical examination is abdominal distention with tenderness to deep palpation. The degree of muscular rigidity and spasm is unreliable and in several cases the abdomen had been reported as greatly distended but soft with little tenderness. The children usually look sick and dehydrated and in a fulmination case may be in shock. Often an upper respiratory infection is present, as demonstrated in one-fourth of this series, which may predominate the picture and focus all of the attention upon the lungs or ears. Any sudden rise in temperature with abdominal pain and vomiting in children with nephrosis is suggestive of pneumococcus peritonitis. The temperature usually ranges from 101 degrees to 104 degrees and the white blood count is generally higher than one sees in appendicitis, being between 20,000 and 40,000.

In the differential diagnosis appendicitis with peritonitis and a severe upper respiratory infection with abdominal symptoms must be ruled out. In these cases puncture of the abdominal wall with a spinal puncture needle and examination of the peritoneal fluid is of great value, provided a positive result is obtained. This procedure has been described by Neuhof and Cohen, Danzer, Pollock, and others. The present method of abdominal puncture, as described by Neuhof and Cohen in 1926 is a simple and safe procedure and is used whenever the necessity arises in the department of pediatrics. Danzer in a recent article stresses the importance of the interpretation of the positive and negative results, and emphasizes that only 1 or 2 drops of pus are necessary for diagnosis if a positive smear is obtained.

Treatment There is a marked difference in the mortality figures in the cases of pneumococcus peritonitis in which patients were submitted to surgical drainage as compared to

PRIMARY STREPTOCOCCUS AND PNEUMOCOCCUS PERITONITIS IN CHILDREN

A Study of 61 Cases with the Report of Two Interesting Recoveries

EDWARD T. NEWELL, Jr. M.D. Chattanooga Tennessee

THE idiopathic or so called "primary" cases of peritonitis, caused by the Beta streptococcus and the various types of the pneumococcus, while not common in children, occur with greater frequency than is generally recognized. There is considerable variation in the treatment of these cases as can be ascertained readily by reviewing the literature of recent years. Some observers believe in surgical intervention, either early or late, along with medical procedures such as serum, etc., while others believe only in supportive measures. The question of the portal of entry remains obscure although the point has been much discussed.

This report reviews the available cases of primary pneumococcus and streptococcus peritonitis from the departments of surgery and pediatrics of the Johns Hopkins Hospital. It includes 2 remarkable recoveries which have occurred this year by newer methods of treatment and which the author has had the opportunity of following carefully. The first was a fulminating case of streptococcus peritonitis in a premature infant which recovered with sulfanilamide therapy. The second was a severe case of pneumococcus peritonitis Type I in which pneumococcus rabbit serum Type I was used with recovery. Both are reported in detail later in this paper. These cases offer hope that the mortality figures which in the literature average from 80 to 100 per cent for streptococcus peritonitis and from 40 to 65 per cent for pneumococcus peritonitis, may be considerably reduced. The incidence of primary peritonitis in children has been variously quoted by European and American authors as between 2 and 10 per cent of the acute abdominal conditions in children. During recent years in the Harriet

Lane Dispensary, 2 to 4 cases of pneumococcus peritonitis and 2 to 3 cases of streptococcus peritonitis are seen each year. The incidence is sufficiently high to warrant special study of this condition.

ANALYSIS OF CASES

The cases have been derived from the records of the Harriet Lane Home for Children and from the department of surgery covering the past 25 years. There have been 25 cases of primary streptococcus peritonitis and 36 cases of primary pneumococcus peritonitis proved by bacteriological and pathological study. The mortality for the former group is 92 per cent, and for the latter group 61 per cent. Of the total 61 cases, 36 have come to autopsy and have had careful examination of all the organs, both in the gross and microscopically. For the sake of clarity, the 2 groups will be discussed separately and will be further subdivided.

PNEUMOCOCCUS PERITONITIS

Clinical. Most authors divide pneumococcus peritonitis into 2 groups: the severe fulminating cases, and the subacute cases. Some of the patients in the latter group are not seen until the acute symptoms are over and seek admission because of a peritoneal abscess. In the present study a somewhat different classification has been used. The cases of primary pneumococcus peritonitis have been subdivided into 3 groups. The first group is the so called idiopathic group consisting of 12 children. The mortality was 50 per cent in this group, there being 5 males and 7 females. The second group consists of 8 cases in which primary peritonitis was associated with an upper respiratory infection. The upper respiratory infection usually preceded the peritonitis but when pneumonia

From the Surgical Pathological Laboratory, Department of Surgery, Johns Hopkins Hospital and University.
William Stewart Habsted Fellow in Surgery 1937-1938

were negative. A diagnosis of appendicitis with peritonitis was made. After intravenous fluids, laparotomy was performed which revealed a generalized peritonitis which was thought to be of gonococcal origin although the fallopian tubes were not greatly inflamed. A normal appendix was removed and the wound closed without drainage. The report of the culture 2 days later from the peritoneal pus was pneumococcus Type I. This was also confirmed on the same day by blood culture. During the interval, the child had declined steadily with frequent vomiting, delirium, temperature 104.6 degrees, and the pulse rate averaging around 170 to 190 despite continuous intravenous therapy. As soon as the cultures were reported, she was transferred to Harriet Lane where, after negative conjunctival and intradermal test doses, a total dose of 295,000 units of anti-pneumococcus rabbit serum was given intravenously at 2 hour intervals over a period of 12 hours. There was rapid improvement, the temperature falling to 99.4 degrees at the end of 24 hours. She received 2 small transfusions of 150 cubic centimeters each on March 2 and March 8, 1938. The only serum reaction was a chill after the first injection and some incontinence 1 week later.

The ultimate recovery of this patient was long and protracted. Twenty-two days later the patient developed a consolidation of the lower lobe of the left lung, which was shown by x-ray. This cleared up but a mechanical intestinal obstruction developed which necessitated an exploratory laparotomy on April 19 and again on April 27 with release of adhesions and evacuation of a small pocket of pus. Culture of this pus was sterile. After this the patient steadily improved and was discharged May 16, 1938, more than 2½ months after admission.

Another interesting case of pneumococcus peritonitis has recently been admitted which is almost identical with the case just reported. The prompt improvement after receiving anti-pneumococcus rabbit serum warrants a preliminary report.

A colored girl, 8 years of age, was admitted on March 27, 1938, acutely ill with signs of generalized peritonitis. She had been sick for 2 days complaining of abdominal pain which began in the right lower quadrant. Vomiting and diarrhea followed 8 hours after the onset of her illness. She had been given castor oil on 2 occasions. At exploratory laparotomy, the appendix was normal but there was a generalized peritonitis from which a smear and culture were taken. Type I pneumococcus was typed from the smear and was later grown from the peritoneal and blood cultures. She received 300,000 units of anti-pneumococcus rabbit serum in the same manner as Case 1 with prompt improvement. Her convalescence was satisfactory until the patient developed a peritoneal abscess which was incised

and drained, pneumococci being cultured from the abscess. After this procedure, the patient improved more rapidly and was discharged on April 20, 1938, 24 days after admission to the hospital.

STREPTOCOCCUS PERITONITIS

Clinical. These cases have been divided into 2 groups: the idiopathic group and the group associated with erysipelas. In the idiopathic group, there were 17 cases with a mortality of 88.2 per cent. There were 11 males and 6 females. In the erysipelas group the mortality was 100 per cent, there being 8 cases, 4 males and 4 females. Race is apparently of no importance in either the streptococcus or pneumococcus group, the proportion of white to colored children being approximately the same as the general admissions to the hospital.

The age incidence for streptococcus peritonitis differs considerably from the cases of pneumococcus peritonitis, most of these cases occurring in the first 6 months of life (18 of the 25 cases). This is of importance in diagnosis, as appendicitis in children is extremely uncommon before the age of 2 years according to Lipshultz, Lowenburg, Marsch, and others. Marsch's figures for 9,000 cases of appendicitis reveal that only 1.1 per cent occurred between the ages of 1 and 5 years.

The most important symptoms in the cases of streptococcus peritonitis in the order of their frequency are: vomiting, diarrhea, and abdominal pain. Many of these children are too young to reveal pain except by fretfulness and crying, particularly when the abdomen is touched.

The more important signs are an acutely ill, often moribund, child with considerable abdominal distention. The abdomen is tender to palpation but not board-like. In several of the cases the umbilicus and surrounding area for about 2 centimeters were red and swollen. Unfortunately, this is a late sign, which usually is seen in moribund infants. The children may have evidence of a streptococcus infection elsewhere, such as a pharyngitis, a cellulitis of the skin, or an otitis media. Leopold and Kaufman quote Mordlund's series of primary streptococcus peritonitis in which 63 per cent of the cases have a preceding upper respiratory infection.

those who were not. The 15 cases which were drained had a mortality of 26.6 per cent as compared to a mortality of 82.6 per cent in the 23 cases in which surgery was not attempted. However, these statistics need qualification. First it is well accepted that surgical drainage is indicated in those cases in which localization has occurred but in the early acute stages there is considerable disagreement as to the value of drainage. In this series it is suggestive but not conclusive that early operation and drainage are of value. If the cases of nephrosis and all subacute or chronic cases are omitted, 14 similar cases of acute primary peritonitis remain. Of this number, 7 were drained early with a mortality of 42.8 per cent while the 7 which received only the same type of supportive measures had a mortality of 85.7 per cent. No serum was given in either group. The only factor which is not identical in the 2 groups is that of age. The patients treated surgically are slightly older, especially those who recovered. In reviewing the whole series, it is clear that in general, the older the child the better the prognosis. Whether age is the chief factor in the recovery of these children it is difficult to state because of insufficient controls. Most of the children over 2 years of age were treated surgically while most of the younger children were not treated surgically. It is interesting to note that 2 children who recovered, aged 20 months and 4 years, respectively, drained spontaneously from the umbilicus.

The use of serum has been advocated in pneumococcus peritonitis for some years. The reports in the literature have included excellent results as well as failures. Since the recent reports on anti pneumococcus rabbit serum in the treatment of lobar pneumonia at the Rockefeller Institute it seems likely that this type of serum may be of benefit in the treatment of primary peritonitis. According to Horsfall et al. horse serum anti bodies have never been demonstrated in the pleural effusions of pneumococcus empyema, while the smaller rabbit serum anti bodies readily diffuse into the pleural cavity. This same principle may apply to the peritoneum although the fact has not yet been definitely demonstrated.

Rabbit serum was given to only one patient with primary peritonitis and it apparently contributed to the recovery of this patient. It may develop that serum therapy will supplant the necessity of operation after a study of a large series of such cases.

In considering the differential diagnosis, it must be remembered that, unlike the streptococcus cases, the age incidence in pneumococcus peritonitis parallels the age incidence for appendicitis in children fairly closely, and sometimes appendicitis cannot be ruled out unless a positive peritoneal puncture has been obtained so that operation may be indicated. Case 1 reported below illustrates the difficulty which is encountered in making a proper diagnosis. While studying the present series the author examined a colored girl, age 6 years, who was thought to have a ruptured appendix with generalized peritonitis. The diagnosis seemed so definite that pneumococcus peritonitis was not even considered, and operation was recommended. At laparotomy this proved to be a case of pneumococcus peritonitis.

It is suggestive but not conclusive that the proper treatment of pneumococcus peritonitis in the majority of acute cases is early surgical exploration with bilateral drainage in both lower quadrants, preferably by a laparotomy incision on the right and a small stab wound on the left. This is the method which most of the surgical cases have received. Supportive measures in the form of intravenous fluids and small transfusions, should be given as indicated. Nothing should be given by mouth until all nausea and vomiting have ceased. As soon as the pneumococcus has been typed serum therapy should be given when possible.

CASE 1. A colored girl, age 6 years, was seen in the Harriet Lane Dispensary on February 25, 1938, complaining of abdominal pain and vomiting for 2 days. The pain was said to have started in the right lower quadrant which became worse after the mother had given the child castor oil. Physical examination revealed an acutely ill child with a temperature of 101.4 degrees, pulse 140, respiration 20, white blood count 25,000, urine negative and vaginal smear negative for gonococci. Distention was not marked but there was generalized lower abdominal tenderness and moderate muscle spasm. Rectal examination revealed tenderness on both sides but no masses. The throat, heart and lungs

were negative. A diagnosis of appendicitis with peritonitis was made. After intravenous fluids, laparotomy was performed which revealed a generalized peritonitis which was thought to be of gonococcal origin although the fallopian tubes were not greatly inflamed. A normal appendix was removed and the wound closed without drainage. The report of the culture 2 days later from the peritoneal pus was pneumococcus Type I. This was also confirmed on the same day by blood culture. During the interval, the child had declined steadily with frequent vomiting, delirium, temperature 104.6 degrees, and the pulse rate averaging around 170 to 190 despite continuous intravenous therapy. As soon as the cultures were reported, she was transferred to Harriet Lane where, after negative conjunctival and intradermal test doses, a total dose of 295,000 units of anti-pneumococcus rabbit serum was given intravenously at 2 hour intervals over a period of 12 hours. There was rapid improvement, the temperature falling to 99.4 degrees at the end of 24 hours. She received 2 small transfusions of 150 cubic centimeters each on March 2 and March 8, 1938. The only serum reaction was a chill after the first injection and some incontinence 1 week later.

The ultimate recovery of this patient was long and protracted. Twenty-two days later the patient developed a consolidation of the lower lobe of the left lung, which was shown by x-ray. This cleared up but a mechanical intestinal obstruction developed which necessitated an exploratory laparotomy on April 19 and again on April 27 with release of adhesions and evacuation of a small pocket of pus. Culture of this pus was sterile. After this the patient steadily improved and was discharged May 16, 1938, more than 2½ months after admission.

Another interesting case of pneumococcus peritonitis has recently been admitted which is almost identical with the case just reported. The prompt improvement after receiving anti-pneumococcus rabbit serum warrants a preliminary report:

A colored girl, 8 years of age, was admitted on March 27, 1938, acutely ill with signs of generalized peritonitis. She had been sick for 2 days complaining of abdominal pain which began in the right lower quadrant. Vomiting and diarrhea followed 8 hours after the onset of her illness. She had been given castor oil on 2 occasions. At exploratory laparotomy, the appendix was normal but there was a generalized peritonitis from which a smear and culture were taken. Type I pneumococcus was typed from the smear and was later grown from the peritoneal and blood cultures. She received 300,000 units of anti-pneumococcus rabbit serum in the same manner as Case 1 with prompt improvement. Her convalescence was satisfactory until the patient developed a peritoneal abscess which was incised

and drained, pneumococci being cultured from the abscess. After this procedure, the patient improved more rapidly and was discharged on April 20, 1938, 24 days after admission to the hospital.

STREPTOCOCCUS PERITONITIS

Clinical These cases have been divided into 2 groups the idiopathic group and the group associated with erysipelas. In the idiopathic group, there were 17 cases with a mortality of 88.2 per cent. There were 11 males and 6 females. In the erysipelas group the mortality was 100 per cent, there being 8 cases, 4 males and 4 females. Race is apparently of no importance in either the streptococcus or pneumococcus group, the proportion of white to colored children being approximately the same as the general admissions to the hospital.

The age incidence for streptococcus peritonitis differs considerably from the cases of pneumococcus peritonitis, most of these cases occurring in the first 6 months of life (18 of the 25 cases). This is of importance in diagnosis, as appendicitis in children is extremely uncommon before the age of 2 years according to Lipshultz, Lowenburg, Marsch, and others. Marsch's figures for 9,000 cases of appendicitis reveal that only 1.1 per cent occurred between the ages of 1 and 5 years.

The most important symptoms in the cases of streptococcus peritonitis in the order of their frequency are vomiting, diarrhea, and abdominal pain. Many of these children are too young to reveal pain except by fretfulness and crying, particularly when the abdomen is touched.

The more important signs are an acutely ill, often moribund, child with considerable abdominal distention. The abdomen is tender to palpation but not board-like. In several of the cases the umbilicus and surrounding area for about 2 centimeters were red and swollen. Unfortunately, this is a late sign, which usually is seen in moribund infants. The children may have evidence of a streptococcus infection elsewhere, such as a pharyngitis, a cellulitis of the skin, or an otitis media. Leopold and Kaufman quote Mordlund's series of primary streptococcus peritonitis in which 63 per cent of the cases have a preceding upper respiratory infection.

The cases of primary streptococcus peritonitis all appear to have a fulminating type of the disease there being no subacute or chronic types. The temperature is high from 103 degrees to 106 degrees the white blood count ranges between 2700 and 45000. The low white blood count occurs not infrequently, along with a subnormal temperature in children who are moribund and in shock.

In the cases associated with erysipelas peritonitis usually develops as soon as the infection spreads to the region of the umbilicus. This would suggest that the infection of the peritoneum occurs by direct extension although a septicemia is usually present by this time. Study of the cases at autopsy suggest this mode of extension in 1 and perhaps 2 cases, but this cannot be shown in all cases.

Differential diagnosis consists in ruling out an acute dysentery, appendicitis, meningitis, and a severe respiratory infection. The peritoneal puncture is perhaps more valuable in these cases than in the pneumococcus group. Since the introduction of sulphanilamide, differentiation between streptococcus and pneumococcus is extremely important therapeutically.

Treatment. The conservative treatment of streptococcus peritonitis appears to offer the most at the present time, since the use of sulfanilamide has been shown to be of such value in Beta streptococcus infections. In reviewing the present series of cases the mortality rate was 100 per cent in the 9 patients operated upon and 87.5 per cent in the 16 patients treated without operation. So far sulfanilamide therapy has been given to 3 patients with primary streptococcus peritonitis 2 of whom died and the third a premature infant of 2 months recovered. This case is reported below. The first patient who received sulfanilamide was a boy, aged 4 months who had a laparotomy with drainage in December 1936. Beta streptococcus was cultured and sulfanilamide given subcutaneously. The child survived longer than usual but died on the twelfth day. The other patient to receive sulfanilamide was admitted moribund and died within 6 hours.

In summarizing it should be emphasized that in the treatment of streptococcus peri-

tonitis early diagnosis is of the greatest importance. This can usually be confirmed by peritoneal puncture eliminating the necessity for laparotomy. Sulfanilamide should be given as early as possible. The patient who recovered was given sulfanilamide both subcutaneously and intraperitoneally. Normal saline and sodium lactate were also given intravenously to prevent acidosis, which occurs so readily when administering sulfanilamide to infants, supportive measures were given as indicated.

CASE 2. A premature colored boy was admitted to the Harnet Lane Home at the age of 1 day because of prematurity. His course was uneventful until the age of 2 months when he developed a severe respiratory infection accompanied by vomiting, diarrhea and severe distention. Physical examination at that time revealed an acutely ill child with a temperature of 104 degrees, pulse rate thready, respiration laborious and a white blood count of 12700. The urine was negative on examination. The abdomen was distended and there was definite generalized tenderness. A peritoneal puncture was performed and 5 cubic centimeters of purulent material obtained. A smear revealed streptococci in chains and the culture report was Beta streptococci. By 6 o'clock in the evening on November 29, 1937 the child was in shock and one half cubic centimeter of coramine was administered. The first dose of sulfanilamide (30 cubic centimeters of a 1 per cent solution) was given intraperitoneally at 11 o'clock that night. The child received a second dose of 30 cubic centimeters intraperitoneally the next morning along with subcutaneous infusions of a 1 per cent solution twice a day for 5 consecutive days. The average subcutaneous dose was 40 cubic centimeters or 0.4 gram of sulfanilamide. A one sixth molar solution of sodium lactate was given along with the sulfanilamide to combat acidosis. Frequent small blood transfusions of 30 to 40 cubic centimeters were also given. Under this regimen the infant improved steadily. Two weeks later a scrotal abscess developed. This was incised and drained. Beta streptococci being obtained from the culture. Sulfanilamide was again given along with 3 additional blood transfusions. The infant recovered and was discharged on January 1, 1938, 2 months after the peritonitis developed. This is apparently the youngest case which has recovered from a primary streptococcus peritonitis that has been reported in the American literature.

BACTERIOLOGY AND PATHOLOGY

The question of the etiology and the mode of entrance of the organisms into the peritoneal cavity is discussed in most papers on primary peritonitis. The 3 modes of entrance

generally considered are: (1) the blood stream, (2) the intestinal tract, and (3) the genital organs of the female. Perhaps the viewpoint of Cole who thinks that there is probably more than one avenue of entrance is most logical. The blood stream seems to be the most common pathway, but why the peritoneum is selected by the organisms is open to speculation. A careful study of the 36 autopsies in this series does not aid in clarifying this point. Studies from a physiological viewpoint might prove helpful.

A study of the cultures of the organisms obtained in these 2 groups is of interest. The typing of the pneumococcus is important in selecting the cases in which horse or rabbit anti-pneumococcus serum may be readily used. Thus in the 36 cases the type of pneumococcus was as follows: Type I, 5 cases, Type II, 4 cases, Type III, 2 cases, Group IV, 14 cases, not typed, 11 cases, total number of cases 36.

A positive blood culture was obtained either before or after death in 17 of the 25 cases in which it was attempted, the vast majority being premortem cultures. In the 29 cultures of the peritoneal material all were positive for pneumococcus. Eleven throat cultures were taken, 8 of which were positive with the same type pneumococcus as was obtained from the blood or peritoneal culture. Sporadic cultures were also taken from the vagina, spinal fluid, colon, and lungs. There were 6 positive lung cultures and no positive vaginal cultures with the same type organism as in the blood or peritoneum.

In considering the bacteriology of the 25 streptococcus cases, the Beta streptococcus was cultured from either the blood or peritoneal fluid in 24 cases, an unusual Gamma streptococcus being cultured from both the blood and the peritoneal fluid in the other case. There were 21 positive blood cultures and 4 negative cultures. There were also 21 positive peritoneal cultures and 1 negative culture. Sporadic cultures were also taken from the vagina, urine, stools, spinal fluid, throat, lungs, and skin. There were 5 positive and 2 negative throat cultures and unlike the pneumococcus group, there was 1 positive and 1 negative vaginal culture. There was

also 1 positive culture from a scrotal abscess, and 4 positive cultures from the skin of erysipelas patients.

SUMMARY AND CONCLUSIONS

Twenty-five cases of primary streptococcus peritonitis and 36 cases of primary pneumococcus peritonitis have been studied. One case of primary streptococcus peritonitis which recovered with sulfanilamide therapy, has been reported in detail. One case of primary pneumococcus peritonitis, Type I, which reacted favorably to anti-pneumococcus rabbit serum Type I, has also been reported in detail. The clinical findings, bacteriology, pathology, and treatment have been analyzed. No definite avenue of entrance could be found to explain the spread of the organisms into the peritoneal cavity, but it seems likely that there are several pathways of entrance, the blood stream being the most common way through which the organisms reach the peritoneum.

The mortality figures are quite high for both the streptococcus and pneumococcus cases of primary peritonitis. Two newer methods of treatment, i.e., sulfanilamide, and anti-pneumococcus rabbit serum, are reported, and it is hoped that after a longer period of trial the mortality figures will be reduced considerably by these methods. In considering the surgical results of these 61 cases, it is suggestive that early laparotomy with drainage is of definite value in selected cases of pneumococcus peritonitis, and of no value in the cases of streptococcus peritonitis.

A summary has been made of the 36 cases of streptococcus and pneumococcus peritonitis which came to autopsy in the department of pathology.

No mention has been made of primary peritonitis in adults although it does occur less commonly than in children. Two fulminating cases of adult Beta streptococcus peritonitis have come to autopsy this year in which the infection was thought to have arisen in association with chronic gonococcal salpingitis.

The author wishes to express his appreciation for the permission given him by Dr. Edwards A. Park to include the cases from the department of pediatrics of the Johns Hopkins Hospital in this report, and to Dr. Charles Geschickter and Dr. Arnold Rich for their constructive suggestions.

ARRHENOBLASTOMA

MALCOLM B DOCKERTY, M D, and WILLIAM CARPENTER MacCARTY, M D.,

Rochester, Minnesota

IN 1905, Pick, of Germany, first described a peculiar ovarian tumor composed, in the main, of epithelial elements in tubular arrangement different from any structure found in a normal ovary but bearing a strong resemblance to adenomatous tissue found and described in connection with the gonads of male pseudohermaphrodites. He considered this tumor as being of the nature of an enlarged ovotestis and called it a testicular tubular adenoma. Schickele, in 1907, and Bell of England, in 1915, reported similar examples, the latter giving a detailed report of a girl, aged 18 years, who presented a symptom complex consisting of amenorrhea, hirsutism with a male distribution of hair, atrophy of the breasts, changes in the voice, and the presence of a left ovarian tumor. The syndrome, which had developed within a period of 18 months, retrogressed completely to a condition of normalcy following removal of the affected ovary. Pathological study of the surgical specimen revealed what Bell considered an example of a tumor in an ovotestis. He described, along with the tubular and adenomatous structures noted by Pick, certain interstitial cellular elements which, when stained with sudan III, were seen to contain lipid within their cytoplasm.

Meyer, over the period from 1915 to 1918, in an extensive study, found 17 instances of ovarian tumor of a similar nature. He noted the frequent occurrence of the peculiarly associated symptom complex and gave the tumor the name it now bears, "arrhenoblastoma." His work on the histogenesis of this tumor brought him to the conclusion that it arose from undifferentiated testicular remnants caught up in the ovarian hilus during early embryological development. From his rather large bulk of material he found that there were 3 pathological types of arrhenoblastoma: (1) that having a tubular pattern,

(2) that having a diffuse or sarcomatoid structure, and (3) that representing an intermediate form in which the cellular elements of the tumor had a cylindroid arrangement. He recognized that the masculinizing syndrome was associated principally with the latter 2 types. He regarded the tumor as being of a low grade of malignancy, only one of his patients dying of metastasis, although several of his patients went through normal pregnancies following removal of the tumor.

Moots, in 1921, described the first case reported from this continent. In spite of a typical clinical and pathological picture of arrhenoblastoma and the fact that his patient had a complete return to normal following operation, he described the condition in the older terminology of "lateral partial glandular hermaphroditism."

Popoff, Spielman, Novak and Long, Mathias, Meyer, and more recently McLester, have reported cases of arrhenoblastoma. In 1933, there were some 26 cases reported in the literature, since then this number has been increased to more than 30.

HISTOGENESIS

As with the origin of other tumors of the ovary, there is no universal agreement regarding the parent tissue from which these tumors develop. Meyer, Goodall, Novak, and others champion the theory that these tumors arise from embryonic rests in the ovarian hilus and that these rests differentiate along male lines. Meyer has found embryonic remnants of seminiferous tubules in the hilus of otherwise normal ovaries, and Popoff discovered a small nodule arising from similar structures resembling in miniature the picture of arrhenoblastoma. The tumor studied in the case reported by Bell was only the size of a plum and appeared to arise from hilar structures because it possessed, at the periphery, an

investment of ovarian cortical tissue. Others, prominent among whom is McLester, believe that the tumor represents a one-sided development of a teratoma. In the tumor reported by McLester, there were cysts lined with large mucus-producing cells bearing no resemblance to normal ovarian structures or to the cellular elements in other parts of the tumor. He pointed out the fact that, in some instances, it may be difficult to find anything except thyroid tissue in an ovarian teratoma and postulated that the same is probably true as far as testicular elements are concerned. The question is still unsettled.

PATHOLOGY OF ARRHENOBLASTOMA

The gross appearance of these tumors is more or less characteristic. Meyer, Neumann, and McLester noted the smooth, grayish surface without adhesions and without invasion by tumor cells. As in Bell's and Neumann's cases, this is supposed to represent the stretched-out remains of ovarian cortex. The tumor arising from medullary remnants. Microscopically, Meyer found 2 cellular types: the large polygonal cell with clear cytoplasm and a dark-staining, clearly outlined nucleus with a prominent nucleolus. The other was a spindle cell which he considered

to be a modified epithelial cell. The epithelial elements were arranged in 3 definite patterns: (1) an alveolar or tubular pattern with central lumens either empty or containing a homogeneous secretion, the lining cells being large polygonal and in orderly arrangement; (2) a disposition in solid cords or anastomosing strands, the so-called intermediate group; and (3) a diffuse or sarcomatoid arrangement. Mitotic figures have been found but are not frequent, and the degree of differentiation together with this and other features indicate a low grade of malignancy.

Spielman, Bell, and, more recently, McLester, have demonstrated the presence of lipid globules within the cytoplasm of both the large polygonal cells and the fusiform cells. These droplets are supposed to have a peculiar disposition in a crescentic fashion around vacuoles in the cytoplasm. The picture closely resembles that of the interstitial cells of the testis studied by Crew, and these peculiar cells are purported to play the role of producing the secondary sex characteristics observed through the elaboration of the male sex hormone. In the first 3 cases reported below, lipid droplets were a prominent feature in the cytoplasm of the large polygonal cells. In the second case, a gradual transition is seen between these epithelial elements and

CASE REPORTS

The following 4 examples of arrhenoblastoma were found in an examination of the material collected from the museum of The Mayo Clinic in the period from 1910 to 1936 inclusive. The tissue was old and fixed in formalin and the histories were not taken with special reference to a diagnosis of this type of neoplasm, but the cases contain so much of interest from clinical and patho-

Fig 5 Case 3 Showing smooth, rounded contours of the tumor

logical standpoints that they deserve more than passing consideration. Multiple blocks were taken from these tumors and were studied from frozen and paraffin sections. They were stained with hematoxylin and eosin, sudan III, and by the Galantha method for mucin.

CASE 1 A married, white primipara, aged 25 years, registered at the clinic October 15, 1934. Her past medical history was negative except for having had an appendectomy performed in 1926, at which time pelvic exploration had revealed no abnormality. In 1930 she had experienced a normal pregnancy.

Her present illness had dated back 2½ years when, following 4 months of menorrhagia, her menses had suddenly ceased. Coincidentally with

investment of ovarian cortical tissue. Others, prominent among whom is McLester, believed that the tumor represents a one sided development of a teratoma. In the tumor reported by McLester, there were cysts lined with large mucus producing cells bearing no resemblance to normal ovarian structures or to the cellular elements in other parts of the tumor. He pointed out the fact that in some instances, it may be difficult to find anything except thyroid tissue in an ovarian teratoma and postulated that the same is probably true as far as testicular elements are concerned. The question is still unsettled.

PATHOLOGY OF ARRHENOBLASTOMA

The gross appearance of these tumors is more or less characteristic. Meyer, Neumann and McLester noted the smooth grayish surface without adhesions and without invasion by tumor cells. As in Bell's and Neumann's cases this is supposed to represent the stretched out remains of ovarian cortex the tumor arising from medullary remnants. Microscopically Meyer found 2 cellular types: the large polygonal cell with clear cytoplasm and a dark staining, clearly outlined nucleus with a prominent nucleolus. The other was a spindle cell which he considered

to be a modified epithelial cell. The epithelial elements were arranged in 3 definite patterns: (1) an alveolar or tubular pattern with central lumens either empty or containing a homogeneous secretion, the lining cells being large polygonal and in orderly arrangement; (2) a disposition in solid cords or anastomosing strands, the so called intermediate group; and (3) a diffuse or sarcomatoid arrangement. Mitotic figures have been found but are not frequent and the degree of differentiation together with this and other features indicate a low grade or malignancy.

Spielman, Bell and, more recently, McLester have demonstrated the presence of lipid globules within the cytoplasm of both the large polygonal cells and the fusiform cells. These droplets are supposed to have a peculiar disposition in a crescentic fashion around vacuoles in the cytoplasm. The picture closely resembles that of the interstitial cells of the testis studied by Crew and these peculiar cells are purported to play the role of producing the secondary sex characteristics observed through the elaboration of the male sex hormone. In the first 3 cases reported below, lipid droplets were a prominent feature in the cytoplasm of the large polygonal cells. In the second case a gradual transition is seen between these epithelial elements and

extending half way to the umbilicus, and (4) blood pressure of 165 millimeters of mercury systolic, and 90 diastolic

At operation on March 26, 1931, a hysterectomy and bilateral salpingo-oophorectomy were performed for a solid neoplasm of the left ovary. Fifty cubic centimeters of straw colored fluid were present in the pelvis but evidence of local extension or of distant metastasis was not found.

This patient was given a course of colloidal lead phosphate intravenously. Six months later at a subsequent examination, there was no evidence of recurrence. Hypertrichosis was still present although not to such a severe degree as formerly.

On pathological examination, the uterus, right tube, and right ovary presented no remarkable features. The left ovary was replaced by a solid mass measuring 20 by 15 by 14 centimeters of smooth surface and without adhesions. On section, as in Case 1, the neoplasm contained multicentric grayish brown nodules of tumor tissue separated from one another by trabeculae of connective tissue and containing in their center tiny cystic spaces filled with coagulated fluid (Fig. 3). Surrounding the tumor proper was a rim of edematous ovarian stroma 3 millimeters in thickness (Fig. 4).

Microscopically the picture differed little from that of Case 1 except for a relative absence of *interstitial* cells and the presence of small cysts. All these cysts were lined with a type of epithelium similar to that forming the tubular structures of which the tumor was mainly composed. Stains for lipid demonstrated but minimal amounts of this substance, the tumor being an almost pure testicular tubular adenoma (so called).

CASE 3. A single, white nullipara, aged 15 years, registered at the clinic on March 1, 1937, complaining of amenorrhea and an abnormal growth of hair over the body. Her family history and personal history had been essentially negative except for an appendectomy for acute appendicitis at the age of 13 years. Menses had begun at the age of 12 years and, for 12 months, had been regular. Following her appendectomy she did not menstruate for 2 months and then had one period of scanty flow. She had not menstruated since then. Nine months prior to admission she had noted that her voice was becoming husky and, several months later, had observed atrophy of the breasts. For 3 months there had been a definite growth of facial, axillary, and pubic hair. A persistent acne had developed.

Positive physical findings were limited to the coarse voice, hypertrichosis with a male pattern of distribution, atrophy of the breasts, and hypertrophy of the clitoris. There was an acneiform type of cutaneous eruption. Pelvic examination disclosed a right ovarian tumor. Her blood pressure was 118 millimeters of mercury systolic, and 80 diastolic. Her basal metabolic rate was minus 7.

At operation on March 4, 1937, a right salpingo-oophorectomy was done for a solid tumor of the right ovary. The uterus appeared small. The left adnexa

were grossly normal. The patient was discharged on the fifteenth postoperative day. At a subsequent visit 3 months later she was menstruating regularly and there was great diminution of her previous symptoms of masculinization. Urinary estimations for prolactin gave negative results.

On pathological examination, the right ovary was the site of a solid tumor measuring 7 by 6 by 5 centimeters. This tumor had the same general gross characteristics as those described in Cases 1 and 2 (Fig. 5). Microscopically the tumor had all the features which mark the maturation of an arrhenoblastoma. The majority of sections had a diffuse arrangement of closely packed oval dark staining cells. In other regions, the picture was that of cuboidal dark staining cells arranged in solid cords (Figs. 6 and 7). Careful search revealed a tubular arrangement with transition to the other patterns in many areas. Scattered diffusely, or aggregated in small groups, were large pale cells with vacuolated cytoplasm. Stains for fat demonstrated the presence of lipid droplets within the cytoplasm of these cells. Sections through the capsule of the tumor revealed many small graafian follicles containing degenerated ova. Corpora lutea were not seen. This tumor represents the type of arrhenoblastoma which, as Meyer has pointed out, is almost invariably productive of the masculinizing syndrome (Fig. 8). This illustration presents a diffuse pattern with a large number of pale, interstitial cells, associated with extreme signs of masculinization.

CASE 4. A white multipara, aged 51 years, registered at the clinic on May 2, 1930, because of postmenopausal bleeding. Her family history and personal history were negative. Her menses, prior to the climacterium at the age of 48 years, had for years been irregular, scanty and, at times, were spaced 3 to 4 months apart. During the 2 years prior to registration she had experienced 2 prolonged episodes of daily vaginal spotting. The last episode had begun 4 months prior to admission and had continued until the time of admission. Examination revealed multiple uterine fibromyomas and a firm mass in the right side of the pelvis. Laboratory data were negative.

At operation on May 9, 1930, a total abdominal hysterectomy was done with removal of both adnexa for uterine fibromyomas and a right ovarian tumor. The patient had an uneventful convalescence and was given a course of deep roentgen therapy before she went home. She was living when last heard from in 1937.

On pathological examination, the uterus was the site of multiple fibromyomas measuring as much as 4 centimeters in diameter (Fig. 4). There was an endometrial polyp at the fundus. Both tubes and the left ovary were essentially normal. The right ovary was the site of a solid tumor of a description similar to that of the other cases. Microscopically, as in Case 3, the tumor contained all 3 cellular patterns of Meyer's classification. There was, however, an almost complete lack of interstitial cells.

Fig 6

Fig 8

Fig 8 Case 3 Diffuse pattern with a large number of pale interstitial cells, associated with extreme signs of masculinization $\times 175$

the onset of amenorrhea she had noted an overgrowth of facial hair which had gradually increased in amount until shaving had become a frequent necessity. She had gained 20 pounds since the beginning of her illness and had complained of recurrent attacks of mild pain in the left lower abdominal quadrant.

Physical examination revealed an obese white woman with a somewhat boyish figure and a distinctly masculine distribution of hair. There was extreme hypertrophy of the clitoris and moderate atrophy of the breasts. Erythematous patches were present in the skin over both legs. Pelvic examination disclosed a tender mass in the left adnexal region. Her blood pressure was 98 millimeters of mercury systolic and 60 diastolic. The only positive laboratory finding was the Allen Doisy reaction for an excess of urinary prolactin (66 units). Roentgenological examinations of the sella gave negative results. The basal metabolic rate was minus 9.

At operation on October 23, 1934, a solid tumor of the left ovary was removed and a biopsy was performed on the right ovary. Convalescence was uneventful and the patient returned home on the thirteenth postoperative day. Twenty-eight days following her operation she had a normal menstrual period. One year later she gave birth to a baby boy.

At a subsequent examination, 2 years after her first visit, the right ovary was palpably enlarged. There was still present moderate hirsutism and the clitoris still was somewhat enlarged. Tests of the urine for prolactin, however, gave negative results.

On pathological examination the solid tumor was 5 centimeters in diameter and its surface was smooth and glistening (Fig 1). On section the mass was grayish-tan in color and solid throughout, but with

multicentric nodules of greater density. Microscopically, in the capsular zone of the tumor there were graafian follicles and corpora albicantes, the stretched out remnant of normal ovarian tissue. Underneath this the tumor contained trabeculated strands of large polyhedral cells in tubular or alveolar arrangement but with intervening solid cords of pale staining interstitial cells (Fig 2). The cytoplasm of the polyhedral cells was clear or finely reticulated; the nuclei were small and dark staining with nucleoli relatively pin point in size. Mitotic figures were scarce. Stains for lipid showed the presence of fatty droplets in the cytoplasm of both cellular types but without any special intracellular distribution. The typical sarcomatoid pattern was not observed. The entire picture resembled that characteristic for the group classified by Meyer as not usually giving rise to symptoms of masculinization. Evidence pointing to a teratomatous origin of this tumor could not be found. Sections of the specimen removed from the right ovary for biopsy were normal.

CASE 2 A single white nullipara aged 31 years registered at the clinic March 20, 1931. She complained of an abdominal swelling and hypertrichosis of 2 years' duration. Her family history and personal history were irrelevant. Her menses had been regular until 3 months prior to registration when her period stopped abruptly. This was followed by 2 episodes of bleeding regularly paced but small in amount. There had been considerable gain in weight over the period of her present illness.

Examination revealed the following positive features: (1) pituitary type of adiposity; (2) heavy growth of hair over the body with a masculine type of distribution; (3) hard pelvic abdominal tumor

DISCUSSION

In the presence of a palpable pelvic tumor, associated with the masculinizing syndrome, a diagnosis of arrhenoblastoma seems justified. However, basophilic pituitary adenomas, pinealomas and adrenal cortical tumors may be associated with a similar clinical picture. Certain features help in distinguishing between them. Hypertension, a cardinal symptom of adrenal and pituitary neoplasms, is unusual in cases of arrhenoblastoma. A definite increase in weight with a "buffalo" distribution of fat is associated frequently with an adrenal or pituitary neoplasm but may occur in association with ovarian tumor. Acne seems to occur frequently with all these conditions and was observed in 2 of the cases studied. Pituitary changes of a hyaline nature have been encountered in cases in which death has occurred owing to arrhenoblastoma. This leads to the question of whether or not this master gland may not be the basis of secondary sex changes. Positive prolan tests would point to such a conclusion.

Granulosa cell tumors offer the only difficulty in making a differential diagnosis histologically. The pathological characteristics of both tumors have a certain similarity but interstitial cells are absent in granulosa cell neoplasms and tubular structures are almost never observed. From a hormonal standpoint they are entirely different, granulosa cell tumors containing large amounts of estrin without prolan and the reverse being true in cases of arrhenoblastoma.

Most authors are now agreed that more than 80 per cent of these tumors are clinically benign. Malignancy in an arrhenoblastoma is shown by the usual criteria of multiple mitotic figures, irregularity in the size and staining properties of the nuclei and local invasion. It can be recognized in fresh sections of tumor tissue and, when present, warrants radical operation. Treatment, especially among younger individuals, should otherwise be conservative.

There are cases on record like Case 2 in the present series, in which pregnancy has ensued following local resection. Recurrences in the preserved ovary are infrequent. Little is known of the effect of radiation on these tumors because of the small number of re-

ported examples. Some authors hold that arrhenoblastomas are highly radiosensitive.

SUMMARY AND CONCLUSIONS

- 1 Four cases of arrhenoblastoma are presented.
- 2 The clinical syndrome of sterility with amenorrhea, hirsutism, atrophy of the breasts, hypertrophy of the clitoris, and changes in the voice were all noted in 2 cases. In one case absence of follicular hormone with an increase of anterior pituitary hormone was found on examination of the urine.
- 3 Production of hormone by these tumor cells is probably linked up with lipid metabolism.
- 4 These tumors are of but a low grade of malignancy, in most instances responding well to local surgical removal.
- 5 These tumors probably arise from embryonic structures within the ovarian hilus, growing and differentiating along male lines.

series exhibited this deformity. Posterior displacements of a vertebral body are frequently observed developmentally and as a result of trauma

Five patients in this series presented an increase in the anterior displacement of the affected vertebral body while under observation, varying from one sixteenth to five-eighths inch. It is noteworthy that 2 of these patients developed spondylolisthesis following previous definite roentgenographic evidence of spondylolysis. These patients were all under treatment during the period of observation, and in no case was additional trauma recorded while the patient was being followed. The paucity of cases and the slight degree of increased slipping of the affected vertebra would tend to indicate that there is not a marked tendency for the deformity to increase

It is of unusual interest to report that 2 patients in the total number of cases, both of whom presented symptoms and roentgenographic evidence of typical spondylolisthesis of the fifth lumbar vertebra, have subsequently become married to each other. Two children have been born, and recent roentgenographic studies have been made of the lumbosacral spines of these children, both males. In the first child, now 17 years of age, an incomplete sacralization of the fifth lumbar vertebra is present. In the second child, now 12 years of age, there is evidence of spondylolysis of the fifth lumbar vertebra.

Since no disease process is known which is likely to produce a narrow transverse defect of one or both laminae of a lumbar vertebra, and since pathologists have reported no surrounding soft tissue involvement, inflammation may be ruled out as the etiological factor in spondylolisthesis. Belief that the lesion is congenital in nature is favored by lack of evidence at the time of operative procedures or postmortem examinations of callus formation at the site of the defect. No one has presented a case of spondylolisthesis attributed to trauma in which previous roentgenograms were found to show a normal lumbosacral spine. The fact that unilateral cases exist (in 25 per cent of cases, according to Willis), and the striking uniformity of defects in each

lamina are points against fracture as the etiological agent. The laminae affected are themselves often defectively developed. The frequency of associated congenital defects in many patients in this series would further substantiate a developmental anomaly as the etiological basis.

INCIDENCE

Interarticular neural arch defects have been variously reported by different authors as follows: (1) Neugebauer reports arch defects in 5 per cent of spinal columns, (2) Willis, in 4.3 per cent of 748 American spines, in 5.2 per cent of 1,520 human skeletons, and in 6 per cent of cadavers, (3) Shore, in 9.1 per cent of 56 Bantu South African native skeletons; (4) Stewart, in 39 per cent of 187 spinal columns from Eskimos living north of the Yukon, and in 14.7 per cent of 225 spinal columns from Eskimos living in or south of the Yukon, (5) Mitchell, in 3 per cent of European skeletons; and (6) Congdon, in 5 per cent of 200 skeletons of American aborigines.

Bohart, in 1929, examined roentgenographically the spines of 931 employees of the Belt Railway Company in Chicago, in almost 50 per cent of whom spinal variations and anomalies obtained. Three of these individuals had spondylolisthesis. Herndon found 2 cases of spondylolisthesis in treating 941 consecutive cases of back injuries in industrial employees.

During the 4 year period from 1934 to 1937, 2,683 patients were examined at the New York Orthopaedic Dispensary and Hospital who presented evidence of congenital deformity or mechanical instability of the lumbar spine. A further group of 503 patients presented evidence of other conditions involving the lumbar spine. During this 4 year period, 108 patients with spondylolisthesis and 7 patients with spondylolysis were examined, a total of 115 patients. This represents an incidence of 3.5 per cent in the group of 3,301 patients examined because of signs and symptoms referable to the lumbar spine. In comparison with other reported figures this incidence would suggest that interarticular neural arch defects occur in many individuals without producing symptoms.

SPONDYLOLISTHESIS

EVERETT MOORE GEORGE, A B M D, C M New York New York

IN THE 27 year period from 1911 to March 1, 1938, more than 210 000 patients have been examined at the New York Orthopaedic Dispensary and Hospital. The diagnostic classification of the case histories of these patients revealed 313 individuals presenting evidence of spondylolisthesis or spondylolysis, all confirmed by roentgenographic studies. This paper is a comparative study of the conservative and operative treatment of this group as a whole.

DEFINITION AND ETIOLOGY

The term, spondylolisthesis implies a failure of union of the laminae to the pedicles together with an associated slipping forward of the body of a vertebra usually in the lumbar region of the spine. Spondylolysis previously termed *prespondylolisthesis*, implies a congenital non union of the lamina without forward displacement of the vertebral body.

The author believes the etiology of the lesion is essentially a congenital developmental defect in the interarticular portion of the involved vertebra. Willis has demonstrated that a lumbar vertebra is formed from 5 centers of ossification, 1 for the body and 2 for each half of the posterior arch. Of the latter 1 anterior center forms the pedicle, including the superior articular facet and 1 posterior center forms the lamina with the inferior articular facet. Ramnaud and Renault, in 1864 referred to the formation of the neural arch by union of lateral anterior and posterior centers of ossification. If these lateral centers of ossification fail to unite, a defect results on each side between the superior and inferior articular facets and a separation of the body from the posterior arch.

In spondylolisthesis the lumbar vertebral body becomes narrower and the sacrum broader in the anteroposterior plane due to developmental response to strains. This indicates that the defect has been present for

some considerable time, certainly longer than the period incident to the usual history of any associated trauma with the onset of symptoms. Capener noted that bone often proliferates from the anterior surface of the sacrum beneath the displaced portion of the fifth lumbar vertebra, forming a buttress which tends to prevent further slipping. A study was made of the roentgenograms of 108 consecutive lumbosacral spines, which happened to include 9 cases of spondylolisthesis. In 80 of these patients the body of the fifth lumbar vertebra was broader than the sacrum, or in 74 per cent of the spines studied. A comparable study of roentgenograms of 125 patients with spondylolisthesis revealed the sacrum to be broader than the fifth lumbar vertebral body in 91 cases, or in 73 per cent of the spines studied. The average broadening of the sacrum for the latter 125 cases was 0.08 inch.

A fracture dislocation of the spine resulting from trauma may simulate spondylolisthesis in late clinical symptoms and in roentgenograms. It is well known that severe trauma to the lumbosacral region can occur without spondylolisthesis resulting. In 5 patients in this series each of whom gave a history of severe trauma at the onset of symptoms, roentgenographic evidence points to the trauma as the exciting factor in the origin of the deformity. Three of this group exhibit a fracture dislocation of the spine at the fourth lumbar vertebra and the 2 other patients show fracture dislocation at the fifth lumbar vertebra. One hundred and nine other patients in this study gave a history of definite trauma which was usually associated with the time of the onset of symptoms and varied markedly in degree. No posterior displacement has been observed associated with the lesion of spondylolisthesis. Junghans has described a *reverse spondylolisthesis* in which there is posterior displacement of the vertebral body associated with arthritis deformans at the articular facets but no patient in this

series exhibited this deformity. Posterior displacements of a vertebral body are frequently observed developmentally and as a result of trauma

Five patients in this series presented an increase in the anterior displacement of the affected vertebral body while under observation, varying from one sixteenth to five-eighths inch. It is noteworthy that 2 of these patients developed spondylolisthesis following previous definite roentgenographic evidence of spondylolysis. These patients were all under treatment during the period of observation, and in no case was additional trauma recorded while the patient was being followed. The paucity of cases and the slight degree of increased slipping of the affected vertebra would tend to indicate that there is not a marked tendency for the deformity to increase.

It is of unusual interest to report that 2 patients in the total number of cases, both of whom presented symptoms and roentgenographic evidence of typical spondylolisthesis of the fifth lumbar vertebra, have subsequently become married to each other. Two children have been born, and recent roentgenographic studies have been made of the lumbosacral spines of these children, both males. In the first child, now 17 years of age, an incomplete sacralization of the fifth lumbar vertebra is present. In the second child, now 12 years of age, there is evidence of spondylolysis of the fifth lumbar vertebra.

Since no disease process is known which is likely to produce a narrow transverse defect of one or both laminae of a lumbar vertebra, and since pathologists have reported no surrounding soft tissue involvement, inflammation may be ruled out as the etiological factor in spondylolisthesis. Belief that the lesion is congenital in nature is favored by lack of evidence at the time of operative procedures or postmortem examinations of callus formation at the site of the defect. No one has presented a case of spondylolisthesis attributed to trauma in which previous roentgenograms were found to show a normal lumbosacral spine. The fact that unilateral cases exist (in 25 per cent of cases, according to Willis), and the striking uniformity of defects in each

lamina are points against fracture as the etiological agent. The laminae affected are themselves often defectively developed. The frequency of associated congenital defects in many patients in this series would further substantiate a developmental anomaly as the etiological basis.

INCIDENCE

Interarticular neural arch defects have been variously reported by different authors as follows: (1) Neugebauer reports arch defects in 5 per cent of spinal columns; (2) Willis, in 4.3 per cent of 748 American spines, in 5.2 per cent of 1,520 human skeletons, and in 6 per cent of cadavers; (3) Shore, in 9.1 per cent of 56 Bantu South African native skeletons; (4) Stewart, in 39 per cent of 187 spinal columns from Eskimos living north of the Yukon, and in 14.7 per cent of 225 spinal columns from Eskimos living in or south of the Yukon; (5) Mitchell, in 3 per cent of European skeletons, and (6) Congdon, in 5 per cent of 200 skeletons of American aborigines.

Bohart, in 1929, examined roentgenographically the spines of 931 employees of the Belt Railway Company in Chicago, in almost 50 per cent of whom spinal variations and anomalies obtained. Three of these individuals had spondylolisthesis. Herndon found 2 cases of spondylolisthesis in treating 941 consecutive cases of back injuries in industrial employees.

During the 4 year period from 1934 to 1937, 2,683 patients were examined at the New York Orthopaedic Dispensary and Hospital who presented evidence of congenital deformity or mechanical instability of the lumbar spine. A further group of 503 patients presented evidence of other conditions involving the lumbar spine. During this 4 year period, 108 patients with spondylolisthesis and 7 patients with spondylolysis were examined, a total of 115 patients. This represents an incidence of 3.5 per cent in the group of 3,301 patients examined because of signs and symptoms referable to the lumbar spine. In comparison with other reported figures this incidence would suggest that interarticular neural arch defects occur in many individuals without producing symptoms.

PATHOLOGY

In spondylolisthesis the break in the osseous ring is always found between the articular facets, the inferior facets remaining attached to the laminae. Thus the body of the affected vertebra with its supernumbent weight-bearing bone connection with the spinous and inferior articular processes that anchor the trunk to the pelvis. The defect may be unilateral but is usually bilateral (Fig 1). In the slipping forward of the fifth lumbar vertebra only the anterior portion of the vertebra is affected, there being no real unlocking of the interarticular joints (Fig 2). The soft tissues elongate and undergo pathological changes not unlike the response to strain in unreduced congenital dislocation of the hip where the capsule and muscles are stretched and thickened with weight bearing.

SYMPTOMS

Pain in the low back was practically the universal chief complaint that was encountered in this series of patients, with considerable variation in the intensity of the pain. However, 13 individuals were entirely free from pain and in 10 instances the deformity was an incidental finding upon examination of the patient for other conditions. Weakness, fatigue or stiffness in the low back as opposed to definite severe pain caused several patients to seek treatment. Low back pain ranging from an occasional ache to constant, severe pain occurred in 255 patients. Thirty-six individuals localized their pain at the hip, 17 in the buttock, and 9 in the coccyx. Radiation of pain down the leg was present in 129 individuals and confined to the distribution of the sciatic nerve in 27 of these patients. Ten individuals suffered pain in the foot down to the toes. Patients suffering from paraplegia associated with spondylolisthesis have been reported in the literature but were not found in this series. Duration of symptoms varied from 12 hours to 30 years. The average duration of symptoms was 50 months.

The clinical picture of the patient suffering from severe spondylolisthesis has been classically described by Turner and Tchirkin with particular attention directed to the lumbar

lordotic hollow, shortened trunk, prominent spinous process of the fifth lumbar vertebra, and fatty skin folds above the iliac crests.

Although several patients in the series presented complete anterior displacement, with the fifth lumbar vertebra rotated on a transverse axis so that its inferior surface rested upon the proximal portion of the anterior surface of the sacrum, the usual clinical picture was less clearly defined. Diminution in the anteroposterior diameter of the pelvic inlet has been especially noted by obstetricians.

In this series, 103 patients presented lumbar muscle spasm. One hundred and thirty-four were tender on pressure over the spinous process of the fifth lumbar vertebra. Increased lumbar lordosis was found in 92 instances although in 30 others there was decreased lumbar lordosis, all confirmed by roentgenograms. In 42 patients the spinous process of the fifth lumbar vertebra and in 5 patients the spinous process of the fourth lumbar vertebra was prominent. In 2 cases there was a kyphosis of the lumbar spine. Spine flexion was limited by pain in 56 individuals. Forty-three were tender on pressure over the sacroiliac region, 8 over the sacrum, and 7 over the coccyx. Thirty-five patients presented a list of the trunk, and 20 others had an associated scoliosis.

There were 175 males and 138 female patients in the series. The youngest patient was 2 years of age, and the oldest 76 years. The average age at first examination was 34 years. The average age at onset of symptoms was 30 years.

ROENTGENOGRAPHY

Interpretation of the roentgenographic examination of each patient in this series was made by Dr. Albert B. Ferguson, roentgenologist at the New York Orthopedic Dispensary and Hospital. In all cases it was a routine procedure to take a lateral picture of the lumbosacral region, one anteroposterior view and another anteroposterior view at an angle of 45 degrees, the latter film showing the sacrum and sacroiliac joints better and the relationship of the transverse processes of the last lumbar vertebra to the lateral masses of the sacrum.

Spondylolysis or spondylolisthesis was found in the second lumbar vertebra in 3 individuals, in the third lumbar vertebra in 6 patients, in the fourth lumbar vertebra in 35 instances, in the fifth lumbar vertebra in 267 individuals, and in the sixth lumbar vertebra in 2 cases. Complete failure of fusion of the laminae to the pedicles was present in 257 patients. In 37 individuals asymmetry of the articular facets was also present, and increased obliquity of the articular facets was noted in 61 others. Arthritic lipping was found in 40 patients. In 40 instances there was proximity of the spinous processes of the affected vertebrae. Thinning of the intervertebral disc was present in 32 cases. In 156 patients the lumbosacral angle exceeded 40 degrees. Posterior sacral defects were noted in 45 patients.

In 6 patients the lesions of both spondylolisthesis and spondylolysis were found in different vertebrae. There were 6 cases of unilateral spondylolysis in which the neural arch defect was confined to one side, the opposite laminar development being normal.

DIFFERENTIAL DIAGNOSIS

Careful physical examination with proper roentgenographic study of the patient are the essential factors in establishing the diagnosis. In spondylolysis and in no other condition is there a characteristic defect in the lamina which is always localized to the interarticular portion of the posterior arch between the superior and inferior facets. In spondylolisthesis there is added a slipping forward of the vertebral body. Frequently there is an associated underdevelopment of the posterior vertebral arch. There is anteroposterior broadening of the sacrum in relation to the vertebral body of the fifth lumbar vertebra, when the lesion is located at the lumbosacral joint.

Fracture-dislocation at the lumbosacral joint is accompanied by either a dislocation of the facets, or fracture of the facets. The laminae remain intact, the facets going forward with the body. There is usually evidence of callus formation at the site of the lesion. There is no evidence of developmental changes in anteroposterior diameter of the sacrum and fifth lumbar vertebral body. There is a separation of the spinous processes.

In Pott's disease an effusion, even though mild, is present. There is bone destruction, cavitating the vertebral body; there is usually a kyphos in the alinement of the spinous processes; there is no separation of the vertebral body forward from the arch unless there is great destruction, in which case there will be evidence of sequestration.

In Kuemmel's disease there is simple wedging of the vertebral body. No features of spondylolisthesis are present.

In osteomalacia there is wedging of the vertebral body. Often there is expansion of the intervertebral disc. The lesion is almost always multiple and no features of spondylolisthesis are present.

Malignancies do not tend to induce displacement or deformity of the vertebral body. The destruction cavitates the vertebral body and does not represent a pressure loss of substance.

Congenital dislocation of the hips and coxa vara may be ruled out by the condition of the hips in the absence of signs of spondylolisthesis in roentgenograms of the lumbar spine.

Interarticular neural arch defects or luxation of the vertebral body are usually not found in roentgenograms of the lumbosacral spine in those patients whose symptoms follow rupture of the nucleus pulposus of the intervertebral disc or hypertrophy of the ligamentum flavum.

OPERATION

By means of the spine fusion operation bony continuity is restored between the lumbar spine and the sacrum. Solid bony fusion precludes further anterior displacement of the affected vertebral body. The operation essentially extends the sacrum in a proximal direction. Fusion of the fifth lumbar vertebra alone to the sacrum, when the spondylolisthesis affects the fifth lumbar vertebra, is insufficient to restore bony continuity. Fusion from the fourth lumbar vertebra to the sacrum has been found practical in cases with spondylolisthesis of the fifth lumbar vertebra, and it is not essential to include the third lumbar vertebra in the fusion area as was done in several instances in this series. The third lumbar vertebra must be included in the

fusion area, however, when the spondylolisthesis is present at the fourth lumbar vertebra

The indication for operation procedures is usually determined by the degree and duration of pain. In other words, when the pain becomes so severe that the sufferer demands relief not obtained by conservative methods of treatment, the operation is definitely indicated. Once the diagnosis has been established and there are no contra indications to operation because of age or physical condition, the patient is advised to undergo the operative treatment. The giving of such advice has caused many patients in this series to seek other forms of treatment elsewhere before conservative methods of treatment, including physiotherapy and local support, could be instituted.

The first spine fusion in this series for spondylolisthesis was done on October 13, 1914, and the first fusion operation for spondylolysis was performed on March 28, 1928. One hundred and ten patients have been treated by the spine fusion operation, performed in each instance according to the technique first described by Dr. Russell A. Hibbs. One hundred and two of these patients had spondylolisthesis and eight had spondylolysis. Occasionally the spinous process of the third lumbar vertebra or bone from the adjacent posterior superior iliac spine has been utilized as a source of additional bone chips for reinforcement. No bone graft or osteoperiosteal graft was used because multiple bone chips are considered preferable for the purposes of fusion. In one individual an osteoperiosteal graft inserted at another hospital had to be removed before fusion could be obtained. The duration of each operation ranged as a rule between one and one and one-half hours. A typical fusion mass is shown 8 months following operation for spondylolisthesis (Fig. 3).

Anterior approach to the lumbosacral region of the spine has been utilized in fusion operations for spondylolisthesis by Burns and by Mercer. Necessity of invading the peritoneal cavity plus possible hemorrhage from the lumbar veins which lie anterior to the lumbosacral area to mention no further technical difficulties are sufficient reasons for hesitancy

in using the anterior approach method in the light of results as obtained by the spine fusion according to the technique of Hibbs performed through the posterior approach. No method has been found to assure reduction of the anterior luxation of the affected vertebra in this series. In several of the patients, plaster jackets were applied under traction in an effort to reduce the deformity but review of these cases fails to indicate any reduction of the anterior slip of the involved vertebral body.

The treatment following operation consisted of a period of recumbency in bed for 6 to 12 weeks during which time a light steel spinal brace extending from the shoulders to the sacrum is worn. The length of time the patient wears the brace while ambulatory varied between 3 months and 1 year depending upon the type of the individual patient and solidity of the fusion mass as judged from roentgenograms. The optimum period is now deemed to be 12 weeks of recumbency following operation as a minimum, with ambulatory wearing of the spinal brace for at least 6 months following the operation.

In this series there were no operative deaths. There were 3 infections, one of which was due to mixed *Staphylococcus* and *Streptococcus* infection, and 2 due to *Staphylococcus* alone. All 3 infections cleared up after incision and drainage of the operative wound and all 3 patients demonstrated a solid fusion mass in roentgenograms subsequent to operation. In a few instances the meninges were opened unintentionally during operation with no ill results to the patient.

Although 22 or 24 per cent of the 91 patients included in the follow up study of the operated cases developed a failure of fusion or pseudoarthrosis this apparently high incidence of pseudoarthrosis is not considered surprising in view of the very severe stresses and strains which beset the lumbar spine and more especially the lumbosacral juncture.

FOLLOW UP STUDY

Nineteen patients operated upon because of spondylolisthesis were followed after operation less than 1 year and therefore, are not included in the follow up study. The efficacy

Fig 1 Forty-five degree anteroposterior view showing bilateral interarticular defect in spondylolisthesis of the fifth lumbar vertebra in a male patient 15 years of age

Fig 2 Lateral roentgenogram of spondylolisthesis of the fifth lumbar vertebra present in a female patient 34 years of age

of the spine fusion operation must, therefore, be judged from the results obtained in 83 patients with spondylolisthesis and 8 patients with spondylolysis, a total of 91 patients. One hundred and twelve fusion operations were performed upon these 91 patients, as 14 patients required secondary operations for repair of pseudoarthrosis. The shortest follow-up period included was 1 year. There is 1 patient who has been followed for 19 years. The average follow-up period for the 91 cases is 5 years.

Seventy-four patients, or 81.3 per cent of the cases in this group, were entirely relieved from pain by the operative procedure. Several of these patients have returned to work as laborer, bricklayer, painter, or machinist, which illustrates that it is possible for these individuals to resume former occupations. Thirteen patients, or 14.3 per cent, have been improved by the spine fusion operation, but were not entirely relieved from all low back pain. Several of these individuals complain only of an undue sense of fatigue in the low back area after long hours of work. In 7 of

Fig 3 Lateral view of spine fusion mass extending from the fourth lumbar vertebra to the sacrum. Same patient as shown in Figure 2

the group roentgenographic examination indicates the presence of pseudoarthrosis in the spine fusion mass, but further operative measures have been denied by the patient. No patient in this class is suffering from pain as intense as that present before operation, and all have secured more than 50 per cent improvement in relief of their pre operative pain.

Four patients or 4.4 per cent of the 91 patients in the follow up study, have not been improved by the spine fusion operation. One of these patients showed no fusion present 5 years after the spine fusion operation. At that time a refusion operation was performed in another hospital, following which the patient died with urinary suppression due to a chronic nephritis. In the other 3 patients there was roentgenographic evidence of pseudoarthrosis in the spine fusion area. A refusion operation was therefore indicated, and was performed in another hospital in 1 instance. Permission for refusion has been withheld in the second patient, and is *contra indicated* in the third patient who suffers from a severe cardiac lesion.

The ability to secure solid bony fusion in the spine fusion mass varies individually due to factors which are obscure at the present time. Ten patients underwent refusion before securing solid bony union. Three other patients had 2 refusion operations performed before solid fusion was present. In 1 other patient it was necessary to perform 3 refusion operations. Co operation of the patient is considered to be of uppermost importance. The best of nursing care with gentleness in turning the patient while in bed, is a prerequisite. A well balanced diet, adequate in vitamins is also thought important. These patients are encouraged to increase their consumption of milk following the spine fusion operation.

CONSERVATIVE TREATMENT

Many patients in this series feared and refused operative measures to secure relief from their symptoms, or were considered poor candidates for the spine fusion operation because of advanced age or physical condition. Frequently physiotherapy in the form of local

heat and massage to the lumbosacral region postural exercises to reduce lumbar lordosis, a firm bed, and support to the lumbosacral spine with a belt or corset, will afford symptomatic relief to these patients. Fifty of these individuals have been followed from 1 to 18 years. Thirty one, or 62 per cent of these patients, have had no improvement in their condition from the conservative methods of therapy. Ten or 20 per cent of these individuals, have been relieved somewhat by conservative treatment, and only 9, or 18 per cent, have been entirely relieved from recurrence of their symptoms.

SUMMARY

1 Two hundred and seventy one patients with spondylolisthesis and 42 patients with spondylolysis, a total of 313 cases, are reported.

2 A follow up study of 91 patients who underwent spine fusion operations, after the technique of Hibbs, between October 13, 1914, and February 12, 1937, is reported.

3 There were 175 male and 138 female patients in the series.

4 The age at the time of examination varied between 2 and 76 years of age, the average being 34 years.

5 There was no operative death in the series.

6 There were 22 patients, or 24 per cent, who developed failure of fusion or pseudoarthrosis many of whom were relieved by repair of the pseudoarthrosis at a second operation.

7 Thirty-one patients or 62 per cent of 50 individuals studied failed to obtain relief from conservative methods of treatment.

8 Seventy four patients or 81 per cent of 91 individuals receiving the operative treatment were completely relieved of symptoms.

9 In spondylolisthesis or spondylolysis a spine fusion operation is considered to be the method of treatment best calculated to give permanent relief from symptoms and to be fully justified by the results obtained in this series of cases.

10 Evidence is presented which tends to confirm the theory that the lesion in spondylolisthesis and spondylolysis is essentially a

congenital developmental defect in the inter-articular portion of the laminae of the involved vertebra rather than the result of trauma

CLINICAL SURGERY

FROM THE KING'S COLLEGE HOSPITAL

TRACHEOTOMY

TERENCE CAWTHORNE F.R.C.S., London, England

TRACHEOTOMY consists in making an opening into the trachea below the larynx and to be successful the opening must be below the obstruction that makes the operation necessary and it must be maintained free from subsequent obstruction.

The operation is simple provided that it can be done without undue haste and in good surgical surroundings. Moreover, any possible dangers are easily avoided by obeying the few well defined rules that will be described later, and no complications are likely to follow a good operation that receives proper attention afterward. It should be the aim of every doctor who has to deal with a case of laryngeal obstruction requiring tracheotomy to plan the operation so that it may be carried out in a deliberate, orderly and unhurried manner. If however, laryngeal obstruction develops rapidly, or if medical advice is not sought until the obstruction is in an advanced stage a hurried operation in unfavorable surroundings may be essential if life is to be saved.

It is the purpose of this article to describe the deliberate operation step by step, not only because this is the method of choice but also because a thorough appreciation of the planned operation will aid the surgeon when circumstances demand the hurried operation as a life saving measure.

INDICATIONS

Tracheotomy is required when obstruction at or about the larynx so diminishes the respiratory exchange that it is insufficient for the needs of the body when at rest. Tracheotomy may also be required as a preliminary stage in certain operations on the air passages. Finally it has been recommended recently in certain cases of tracheo-bronchial suppuration.

Laryngeal obstruction may be produced by a variety of causes but as the most urgent consideration is to relieve the condition it will be better to consider in detail the prominent features of laryngeal obstruction rather than to enumerate a list of conditions that may cause it.

The picture produced by laryngeal obstruction depends largely upon the time which such an obstruction takes to develop. When the onset is sudden and the rate of increase fast, the symptoms, signs and the remedy required are only too obvious, even to the lay eye. When the obstruction increases slowly the significance of the panorama that gradually unfolds itself may not always be appreciated in the early stages or if it is surgical relief may be withheld in the vain hope of a spontaneous cure.

Respiratory system. Audible respiration is the most obvious sign of laryngeal obstruction and is present in every case. The pitch and amplitude of the sound may depend to a certain extent upon the age and sex of the patient and upon the degree of obstruction. The timbre of the sound however, is constant in all cases. It can be produced by anyone at will by making a forced inspiration with the glottis nearly closed. It is usually described as *crowing* and must be distinguished from obstruction in the lower part of the tracheo-bronchial tree in which the noise is a *whistle* usually more noticeable on expiration. This is rather an important point because the writer has been asked on more than one occasion to perform a tracheotomy on a patient with obstruction in the lower part of the trachea. Had the referring physician trained his ear to recognize the difference between a crow and a whistle he would have realized that the obstruction could not be relieved by tracheotomy.

At the onset of laryngeal obstruction audible respiration may not be noticed when the breathing is quiet and shallow. Anything that may increase the rate or extent of the respiratory exchange will tend to initiate or augment audible respiration. This accounts for the phenomenon not infrequently seen in children where a fit of struggling for breath and rapid and exaggerated respiratory efforts are succeeded by exhaustion in which the quiet and shallow respiratory movements cause the audible respiration to disappear. In brief every case of audible respiration should

be considered as a potential candidate for tracheotomy. For the large majority of these cases tracheotomy will not be necessary, but an attitude of preparedness will go far to avoid the tragedies resulting from the neglect of one of nature's greatest danger signals.

The bringing into action of the accessory muscles of respiration in conjunction with other signs indicate laryngeal obstruction. In this connection it is worth while mentioning the significance of the alternate periods of quiet sleeping and choking fits with waking that are so characteristic of increasing obstruction. While the patient is conscious the voluntary or accessory muscles of respiration are brought into use, but as the patient falls asleep the voluntary muscles stop working. This may not be noticed for some seconds or minutes, but gradually diminished air entry calls for deeper respiration and this causes choking and the patient awakes.

The soft tissues which clothe the thoracic cage may be indrawn on each inspiration. This can be seen at the suprasternal notch, in the supraclavicular region, and between the ribs. It should always be sought for, and the degree and extent of the indrawing is a rough index of the severity of the laryngeal obstruction. On inspiration the rush of air acts on the soft tissues surrounding the upper margins of the larynx and draws them in, thus further narrowing the already restricted airway. It is this mechanism which accounts for the increased distress that is noticed with forcible inspiration and is such a marked feature of the complaint in children. When the laryngeal obstruction is very gradual in its onset and extremely slow in its progress, such as in the case of a neoplasm, the patient learns to economize in respiratory movements and may reach a very high degree of tolerance to the obstruction, so that life is possible with an airway that would have been totally inadequate if the onset of the condition had been rapid.

In the terminal stages of laryngeal obstruction the respiratory mechanism is likely to show signs of exhaustion, and the respiratory movements become more gentle until at last they quietly cease forever.

Cardiovascular system. In advanced stages of respiratory obstruction diminished oxygenation of the blood will result in cyanosis, and the degree in which this is reflected in the skin depends upon several factors. In those cases in which there is a good peripheral circulation and a normally fresh color, cyanosis will be obvious. In the normally pale, or in those in whom the heart is already enfeebled by disease, cyanosis may be absent

and there may only be increasing pallor with a slightly leaden or mauve tinge to indicate the true state of affairs. This is especially noticeable in the most dangerous type of case under consideration, diphtheritic laryngeal obstruction in childhood in which the already enfeebled heart is handicapped by a tremendous increase in work. This results in pallor due to the poor peripheral circulation and such pallor may only give way to cyanosis in the ultimate stages of the complaint. In other words, cyanosis may be obvious only as a terminal event and should not be waited for before advising tracheotomy. What is not generally realized is the tremendous increase in work that the heart is called upon to do in cases of respiratory obstruction. In small children, in the presence of audible respiration, it is very strongly felt that one of the most urgent reasons for tracheotomy is an increasing pulse rate and signs of dilatation of the right side of the heart.

PRE-OPERATIVE PREPARATION

Tracheotomy does not call for any special pre-operative measures apart from ensuring that the necessary equipment is at hand and in good working order. This is a very necessary pre-operative precaution because tracheotomy is a relatively infrequent operation, and unless periodically overhauled the instruments have a way of getting mislaid. Whenever time will permit, steps should be taken to provide proper postoperative care, because the ultimate success of the operation depends so much upon this.

The method that will be described is employed in the clinic at King's College Hospital whenever the condition of the patient will permit. The operation need not take more than 10 minutes and is always employed when the patient has sufficient airway to enable him to be removed to a properly equipped operating theater. Sometimes the need for relief of laryngeal obstruction is so urgent that more rapid methods must be employed, possibly in unfavorable surroundings without all the equipment and assistance that may seem necessary. Then the method employed to relieve the obstruction will depend upon the resources available and no definite rule can be laid down as to exact procedure. If, however, the cardinal features of the more deliberate operation can be committed to memory, the undoubted difficulties of the life saving emergency tracheotomy will be minimized. The strain of a hurried, and of necessity unsurgical, operation is so great both on the patient and the surgeon that no effort should be spared to bring a patient to operation in time to avoid this.

Fig. 1. A folded towel which is placed under the shoulders extends the neck so that the trachea is brought nearer to the surface.

Fig. 2. The field of operation showing the principal landmarks: the thyroid cartilage above the suprasternal notch below and the sternomastoid muscles on either side.

Anesthetic. Any form of general anesthetic, however skilfully administered, is bound to aggravate laryngeal obstruction. The possible advantage of unconsciousness to the patient is far outweighed by the danger of increasing any pre-existing obstruction to the airway, and for this reason a general anesthetic cannot be recommended.

Subcutaneous infiltration of the operative areas with 1 per cent novocain not only renders the operation painless but also diminishes the tendency to bleeding. This form of anesthesia should always be employed when time will allow. Urgent dyspnea or infection in the tissues overlying the trachea may require operation without any form of anesthesia at all.

Position. The patient should be lying on his back with a sandbag or folded towel underneath

the shoulders so as to extend the neck and thus bring the trachea nearer to the surface. The head should be extended on the neck and it must be kept strictly in the midline so that the nose, chin and suprasternal notch are in one line. Any deviation from this midline position will alter the normal relationships of the trachea and add to the difficulties of the operation. This is so important that an assistant can be well employed in steadying the head and seeing that it is kept in the midline. It sometimes happens that the prone position with extended neck makes a partial laryngeal obstruction complete. Then in order to operate in an orderly unhurried manner it may be necessary to work with the patient sitting up. This is not easy and should be considered only in the non-urgent cases of obstruction where speed is not essential.

Infiltration. The skin and subcutaneous tissues in the midline of the neck are infiltrated with 1 per cent novocain from the thyroid cartilage to the suprasternal notch. A band of infiltration one inch wide is required and can usually be obtained with 20 or 30 cubic centimeters of fluid; as much as 100 cubic centimeters may be used without any danger.

OPERATION

Incision. The surgeon stands on the right side of the patient and the principal assistant on the left. The mobile larynx and skin are fixed by the thumb and middle finger of the left hand. This is of special importance in children in whom the larynx is very mobile and is one of the essential steps of the emergency operation. The incision should extend vertically downward from the cricoid cartilage for at least 3 inches and must be

Fig. 3. The incision has exposed the pretracheal muscles and the line of separation between the muscles. The two lobes can be seen in the center.

Fig 4 The trachea has been exposed, and the isthmus of the thyroid gland is shown covering the third and fourth tracheal rings

Fig 5 The unimportant thyroid isthmus has been divided between ligatures so as to give better exposure of the trachea

strictly in the midline. The only exception to this rule is when the tracheotomy is required as a preliminary to a pharyngeal or laryngeal operation. In such a case an oblique or transverse incision 1 or 2 fingers' breadth below the cricoid cartilage may be used.

The incision should extend through the skin and down to the deep cervical fascia in its whole length. Any bleeding points are secured by artery forceps that may conveniently be curved so that they lie flat on the neck and act or be used as retractors. In the hurried operation the incision must go deeper than this, preferably down to the trachea, and bleeding is to be ignored.

Exposure of the trachea The deep fascia is incised, again strictly in the midline, when the division between the 2 sets of pretracheal muscles may be seen. Careful separation is important here, especially in children, because it is very easy to deviate from the midline, especially to the left. Loose cellular tissue will be found here, particularly in the lower part of the wound, and then another sheet of fascia comes into view. At this stage the position of the trachea may be confirmed by palpation with the left index finger. In the emergency operation directly after the deep incision the left index finger will be employed in feeling for the tracheal rings and continuing any essential blunt dissection. It must be remembered, however, that in very young children the cartilaginous rings of the trachea may be deceptively soft. Under this second sheet of fascia lies the trachea in the uppermost part of the wound. A little farther down is the isthmus of the thyroid gland. The isthmus usually lies over the third and fourth tracheal rings and may easily be retracted downward. If unusually high or diffi-

cult to retract, the isthmus should be divided between forceps without hesitation, as it is only of anatomical importance. If special angular clamps are used on the isthmus they may, after it has been divided, be rotated outward, thus bringing the trachea more to the surface. Incision of the investing tracheal fascia reveals the tracheal rings.

Intratracheal injection At this stage, if time permits, it will be advantageous to insert the needle of a hypodermic syringe charged with 10 per cent cocaine between 2 tracheal rings and to inject a few millimeters of the cocaine solution into the tracheal lumen. This serves to lessen the spasm of coughing that would otherwise occur when the trachea is opened, and makes for what its originator, Sir St Clair Thomson, describes as tranquil tracheotomy.

Fig 6 A disk has been cut out of the anterior tracheal wall just sufficiently large to admit the tracheotomy cannula

Hemostasis At this stage all bleeding points should be ligatured and artery forceps removed. It is important not to trust to the temporary pressure of the artery forceps to arrest hemorrhage, because it not infrequently happens that unligatured vessels may start to bleed after the vasoconstrictor effect of the local anesthetic has worn off. In the hurried operation both this and the preceding stages will be omitted and bleeding can be dealt with after the trachea is opened.

Opening the trachea The site of election is through the third and fourth tracheal rings. In no circumstances should the cricoid cartilage or first ring of the trachea be cut across for fear of subsequent laryngeal stenosis. Insufficient attention is paid to this essential point in many of the descriptions appearing in textbooks and possibly only those who have the unenviable task of trying to cure laryngeal stenosis realize how important it is to maintain the integrity of the cricoid cartilage and uppermost tracheal ring.

In small children in whom the trachea is very mobile it may be advisable to steady the trachea by inserting a sharp hook into or just below the cricoid cartilage and having this held by an assistant. At this stage the end piece of a suction apparatus should be held near the trachea so the tracheal opening may be kept free from secretion and blood prevented from entering the trachea.

With a fine bladed scalpel a short transverse incision is made to one side of the center of the front wall of the trachea between the third and fourth tracheal rings. Into this incision is inserted one blade of a pair of fine toothed forceps. The tracheal wall is grasped by the forceps and one blade of a pair of fine fully curved scissors is inserted and a small disc of the anterior tracheal wall cut away. This disc should be the same size as the diameter of the tracheotomy tube so that when the tube is in position it will fit tightly and prevent any escape of tracheal secretion or air into the wound. During this maneuver care must be taken so that the posterior tracheal wall is not injured because the violent expiratory effects that may accompany the opening of the trachea especially if cocaine has not been previously injected will bring the posterior wall forward so that it may almost bulge into the tracheal opening. Even worse than this would be perforation of the posterior tracheal wall and injury of the esophagus. This might happen if the scalpel were indiscriminately plunged into the trachea. The possibility of this occurring can be prevented by so holding the scalpel that only a quarter of an inch projects beyond the end of the index finger.

An alternative method is to incise vertically the third and fourth tracheal rings in the midline and then to insert a pair of dilating forceps. This will be the procedure in hurried cases but if speed is not essential the careful removal of a small disk of tracheal wall is preferred. It makes introduction and removal of the cannula easier and in the event of the outer cannula being accidentally displaced retraction of the edges of the wound will enable the patient to breathe until skilled help is as available to replace the tube.

Insertion of the tracheotomy tube The tracheotomy tube is now inserted with its pilot which is withdrawn when the tube is in position and the inner tube is inserted. Prior to this one fourth inch linen tape has been threaded on to the wings of the tube. The inner 2 inches of each tape is guarded by a piece of rubber tubing which prevents the tape from cutting into the sides of the wound. In emergency cases artificial respiration and stimulants may be required at this stage. The bleeding also that had been ignored previously, will not have to be stopped although the opening of the trachea will have done much to lessen it.

Dressing While the tube is held in position by an assistant the wound is lightly packed with 2 inch ribbon gauze impregnated with iodoform. Under no circumstances should the part of the wound below the cannula be sutured for fear of surgical emphysema or spreading sepsis. Two squares of gauze are placed over the dressing one above and one below the tube and the tapes are tied around the neck over this.

The skin below the wound may be smeared with soft paraffin to prevent irritation from secretion. Over all this is placed a veil of oiled silk with a hole in the center through which the tube projects. This helps to keep the dressing from being unduly soiled by tracheal secretion.

Asapnia Before the patient leaves the theater a final inspection should be made to ensure that there are no bleeding points and a note should be made of the respiration. Numerous fatalities have been recorded from time to time that occurred shortly after the trachea was opened. These have often been in cases of long standing laryngeal obstruction and it has been shown by X-rays that they are due to asapnia. During the period of laryngeal obstruction there has been a steady increase in the carbon dioxide content of the alveolar air and also in the carbon dioxide content of the blood. Sudden removal of the obstruction results in this excess of carbon dioxide suddenly being reduced. The respiratory center has been accustomed to an increased carbon

dioxide stimulus, and when this is suddenly removed it refuses to respond. Unless carbon dioxide is available the patient may die from apapnia. Therefore, provision should be made in the operating theater and at the patient's bedside for a carbon dioxide-oxygen mixture to be available if required.

POSTOPERATIVE CARE

The relief of laryngeal obstruction by the provision of an alternative airway does not mean that medical supervision can be relaxed. On the contrary, it initiates an entirely fresh set of therapeutic problems that require careful and constant attention if a successful outcome is to be attained. The problems that are the immediate concern of those responsible for the after-care are (1) the maintenance of a free airway, (2) the accommodation of the patient to the altered conditions of his respiratory mechanism, and (3) the neutralizing of the ill effects produced by prolonged obstruction on the lower respiratory tract. In order that these problems may receive the attention they require, constant nursing supervision is necessary and certain special equipment must be available at the bedside. It will be convenient here to give separate descriptions of the more important factors concerned.

Bedside equipment. It has already been mentioned that a cylinder of carbon dioxide and oxygen should be at hand. A trolley should contain sterile duplicate cannulae, retractors, a tracheal dilator, inner tubes, lotion, cleaning material for removal of secretion from inner tubes before boiling, a suction apparatus with two or more fine rubber catheters ready to be attached, and sterile dressings. These are the essentials that should be at the bedside of every tracheotomy patient.

Free airway. Constant attention is necessary for this. Secretion must be removed from the tracheal tube either by mopping or by suction. Any audible respiration means that some part of the respiratory tract is obstructed, and it may be helpful to pass a catheter down into the trachea and connect it to the suction apparatus. This may save the patient much laborious coughing. It will probably be necessary to remove the inner tube frequently for cleaning, and this should be instantly replaced by a spare inner tube, the soiled one being cleaned before boiling. It cannot be too firmly impressed upon the nurse in charge of the case that her main duty is to see that instant attention be given to any signs of obstruction, i.e., audible respiration or rapidly increased respiratory movements. Should the outer cannula become dislodged, she should

remove all dressings, retract the wound edges, and wait for skilled help if she cannot easily replace the outer cannula herself. Central heating may reduce the humidity of the air, so that steps should be taken to remedy this. Care must be taken, however, not to overdo this, as it is felt that overuse of the steam kettle may do as much harm as it does good.

Accommodation to altered mechanism. It is always advisable to protect the patient from rapid changes of the temperature of the inspired air by means of a tent or screen around the head of the bed. One of the most important reasons for constant supervision during the first few hours after the operation is that the patient is deprived of his voice and is unable to call for assistance. Some slight difficulty in swallowing may sometimes be experienced, but encouragement with sips of water will usually overcome this. Excessive coughing may cause some distress, as the alteration of the normal coughing mechanism may make the bringing up of tenacious secretion a laborious matter. This can to a certain extent be overcome by using a suction apparatus to aspirate tenacious secretion from the trachea.

Lower respiratory tract. The removal of retained secretion can be assisted by the suction pump, in the way just described. At this stage it is wiser not to give any sedative that might in any way obtund the cough reflex. In order to assist expansion of the lungs the patient should be sat upright and encouraged to move from side to side so as to prevent stagnation at the bases of the lungs. An additional help in this direction will be the administration of the carbon dioxide-oxygen mixture for a few minutes every hour. When the secretion is very thick and tenacious the administration of alkalis may help to loosen it. Cases of laryngotracheobronchitis in which there may be a tendency to form crusts within the trachea and bronchi must be watched carefully. Increased respiration rate, distress, and on examination of the chest little or no expansion and air entry indicate blocking of a main bronchus with a plug. This calls for bronchoscopy which in severe cases may have to be repeated frequently.

Dressing. This will require frequent changing during the first day or two. The gauze squares should be changed whenever they are soiled, while the iodoform gauze packing in the wound should be changed at least once, if not twice, every 24 hours. It is rarely necessary to change the gauze more often than this and if the surrounding skin is kept protected by sterile soft paraffin no irrita-

tion from being constantly bathed in secretion should occur

At every change of dressing the opportunity should be taken to examine the wound for any suggestion of spreading sepsis or surgical emphysema. All assistants should be warned not to use gauze with loose threads and never to use wool, because these can easily be inspired into the tracheobronchial tree. The same thing applies to blankets which should not be allowed near the tracheotomy tube for fear that fluff from them may be inspired.

General Treatment will naturally be directed toward the cure of the laryngeal obstruction but is beyond the scope of this article. Adequate nourishment is essential and a large fluid intake must be encouraged.

When the cardiovascular system has been subjected to strain, small but regular doses of brandy should be given or more severe cases may require some form of digitalis or one of the more powerful cardiac stimulants such as coramine.

As soon as the general condition of the patient will permit, he should be encouraged to move from his bed. This will help to exercise the lungs.

Decannulation This must be a gradual process. As soon as the patient can breathe comfortably with a finger over the tracheotomy tube it should be half corked. When the patient can sleep comfortably with this, the half cork can be replaced by a complete cork. Comfortable sleep with the tube completely corked is the indication for decannulation.

The return to laryngeal breathing may, at first, cause slight dyspnea especially in children. If decannulation is too rapid the dyspnea may result in panic, exaggerated respiratory efforts and an increase in the dyspnea possibly sufficient to call for recannulation. Once this has happened the child will lose confidence, and further decannulation may be quite difficult.

Recannulation This small maneuver has been the cause of so much trouble that it deserves a paragraph to itself. During the first few days after a tracheotomy it is not as a rule necessary to change the outer tube. Should it become necessary it must be done by the surgeon or a skilled assistant.

It is in the cases that have been decannulated too soon that the chief difficulties arise. It may be some hours after decannulation before the necessity for reinserting a tube is apparent. Unless a disk had been cut from the trachea at the time of operation this may be difficult. In any case it should not be attempted without a

good light, dilating forceps and, if available, a suction pump. It will simplify matters if the wound is packed for a few moments with gauze wrung out of 2½ per cent cocaine. This procedure is given special mention because the writer has found that the re introduction of a tracheotomy tube some time after it had been removed has often caused considerable trouble especially to those who approach the problem overconfident and not prepared.

SUMMARY

1 Tracheotomy is required to relieve increasing laryngeal obstruction and should not be postponed until the urgency of the symptoms demand a hurried operation.

2 General anesthesia increases the danger of the operation. Local infiltration renders the operation painless and reduces bleeding.

3 The midline position, a midline incision, and midline dissection will expose the trachea and avoid other important structures. Deviation from this midline rule is the commonest cause of operative difficulties.

4 The trachea must never be incised above the second ring but preferably through the third and fourth. This will avoid the possibility of subsequent laryngeal stenosis, a permanent tube, and loss of voice for life.

5 The intratracheal injection of a few millimeters of cocaine and the excision of a disk of tracheal wall instead of the usual vertical slit are modifications of the traditional technique that make the operation more tranquil and the after treatment more simple.

6 Carbon dioxide should be at hand both in the operating theater and at the bedside in case apnoea should develop. This applies especially to cases of long standing laryngeal obstruction.

7 After care demands constant nursing attention and is directed toward keeping the airway clear, adjusting the respiratory mechanism to altered conditions and combating the effects of laryngeal obstruction on the lower respiratory tract.

8 Decannulation should be gradual and should not be attempted until the patient can sleep comfortably with the tube completely corked.

A NEW ASEPTIC DOUBLE-VALVED TUBOGASTROSTOMY

JACOB A GLASSMAN, M D, Chicago, Illinois

THE writer introduces a new, simple, and improved method of gastrostomy which is accomplished by a technique that is aseptic throughout.¹ This technique was developed to replace the long and complicated procedures employed today, in which excessive clamping, ligating, cutting, and sewing as well as exposure of the peritoneal cavity to contaminating substances from the gastric content, are objectionable features

STAGES IN THE EVOLUTION OF GASTROSTOMY

Here a few remarks may be devoted to those stages in the evolution of gastrostomy which lead to the writer's new step. In 1893, Ssabanejew devised a method of gastrostomy in which a cone of stomach was formed by traction upward with an Allis forceps and brought out to the exterior. A second smaller incision was then made nearby through the skin and subcutaneous layer, and the cone carried to it by tunneling through the subcutaneous tissue between the 2 incisions. The apex of the cone after being brought through the second skin incision and attached to its edges, is then opened.

In 1896, Senn described a circular valve method. Purse-string sutures were placed at the base of a cone of stomach wall to fix it in place. An incision was then made into the apex of the conical structure, its free edges inverted, and the resulting fold fixed by sewing its rim, thereby creating a circular valve projecting inward toward the lumen of the stomach.

In 1896, Fontan described a valvular gastrostomy which he produced by elevating a conical diverticulum from the stomach by traction with a forceps, fixing its crown to the abdominal incision, invaginating the apex, and puncturing it. It is seen that it resembles the method devised independently by Senn in the same year.

In 1913, Janeway and Depage, working independently of each other, developed a flap from the anterior wall of the stomach, consisting of all

layers, which was converted into a tube, lined with gastric mucosa, one end of this tube representing the opening into the stomach, and the other end the mouth to the exterior. Depage acknowledged Janeway's work, but it is established that priority really belongs to Depage. This method of gastrostomy proved to be inefficient because of the absence of a valvular structure.

In 1929, Spivack greatly advanced the surgery of gastrostomy by combining the tube formation of Depage and Janeway and his own method of forming a valve by invaginating all layers of the stomach wall, thereby evolving a very useful and efficient tubovalvular gastrostomy. Later McNealy and Thorek contributed to Spivack's operation by attempting to seal off possible points of leakage with omentum and falciform ligament.

DOUBLE-VALVED TUBOGASTROSTOMY

The great mortality rate following present day methods of gastrostomy is readily explained. Patients who require gastrostomy are those afflicted with esophageal obstruction of a benign or malignant nature. Pathological conditions of this sort weaken the patient to such an extent that by the time an operation is advised and accepted, marked emaciation has already set in, primarily because of the prolonged period of starvation. Obviously, such persons, who in most instances are past middle age, cannot tolerate any abdominal operation of long duration. The contamination of the peritoneum and the severe shock of surgical manipulation weaken the subject, so that death is a common sequel. It is estimated from the writer's gastrostomies on a series of dogs and on human patients that the duration of his method is diminished from approximately 1 to 1½ hours, which is the time required for the present day improved, but more intricate, gastrostomy, to about 20 to 30 minutes, thereby greatly reducing the mortality rate.

The method here described furnishes a double valve of excellent function and in the cases in which it was tried has remained competent throughout the period of observation that has extended over months. Through a left upper paramedian incision the stomach is exposed, and as illustrated in Figure 1, A, the anterior wall of the stomach is grasped with an Allis forceps at

Read before the chapter of Sigma Xi, University of Illinois, College of Medicine, March 30, 1938.

¹ The technique herein described was developed and perfected in the Department of Anatomy of the University of Illinois, College of Medicine, with the aid of Dr. Otto F. Kampmeier, professor of anatomy and head of the department. To him as well as to Dr. Ingve Joranson, Dr. W. H. Cole, Dr. M. Davison, and Dr. L. Aries the writer is greatly indebted for their invaluable help.

Fig. 1 A Formation of a cone shaped diverticulum from the anterior wall of stomach by traction B Fixation of the formed diverticulum by 2 basal purse string sutures C Insertion of the third purse string suture approximately midway between the basal sutures and the apex of the diverticulum

the most mobile point, which is usually midway between the fundus and the pyloric antrum and equidistant from the greater and lesser curvatures. With the application of traction at this point a portion of the anterior wall is converted into a cone shaped diverticulum. A purse string suture of braided silk is then introduced into the

Fig. 2 D Anchoring of the anterior stomach wall to the peritoneum and posterior rectus sheath by means of the desired over-and-over seromuscular stitch E The diverticulum protruding through the opening allowed during the closure of the peritoneum and posterior rectus sheath. More interrupted silk sutures are shown anchoring the lateral sides of the base of the diverticulum to the peritoneum.

seromuscular layer at the base of the diverticulum (Fig. 1, B), and with each stitch the tissue at the base is puckered until upon completion of this purse string suture, the lumen at the base as been almost but not completely constricted. A second purse string suture is then applied in the same fashion as the first about $\frac{1}{4}$ inch proximal to the first suture. The ends of these 2 sutures are employed for traction when the Allis forceps at the apex is removed. A third purse string suture is then introduced around the diverticulum midway between the apex and base to create a second valve more peripherally placed. Both valves are then reinforced by applying interrupted Lembert stitches of braided silk in the seromuscular layer at right angles to the purse string suture (Figs. 1, C, D, E). At this point the diverticulum, which has been constricted at two levels, usually presents a cyanotic hue but in spite of the disturbance of circulation thus produced no sloughing was noted in a series of 20 experimental animals. Traction on the diverticulum is still kept upward by the assistant. Interrupted seromuscular sutures are inserted in the anterior wall of the stomach at points superior, inferior, and lateral to the base of the tubal projection in order to fix the stomach wall to the peritoneum and to the posterior rectus sheath. It is very important that the sutures be embedded repeatedly in the seromuscular layer of the stomach wall before they are tied, since a single stitch may tear through the seromuscular layer. The

Fig. 3 F Two untied sutures shown: the lower one representing the suture that attaches the tube to the anterior rectus sheath and the upper one the suture employed further to anchor the tube to the subcutaneous tissue. The circles represent suture ties employed throughout the operative procedure.

tube itself is attached to the anterior rectus sheath and subcutaneous tissue as the various layers are reconstructed

An opening into the apex of the tube by means of cautery may be made at any time from the first to the seventh day after the completion of the operation. It was found more desirable to delay the opening until near the seventh day, depending upon the patient's ability to swallow liquids, since a greater time is allotted for adhesions to form without any disturbance from external sources. This step is the culmination of an operative procedure which was achieved with entire asepsis, that is, without opening the stomach in the presence of peritoneal exposure, and without clamping, ligating, or cutting.

In G of Figure 3 a diagrammatic cross-section illustrates the arrangement of the initial or basal valve to the more peripheral valve. The circles therein represent suture ties, at points previously referred to, in anchoring the stomach and tube to the various abdominal layers.

By employing a technique similar to that described, an aseptic tubovalvular cystostomy is made possible.

The writer, in working out the details of the operation, recognized some modifications in technique which may or may not be advisable in particular cases. For example, in certain cases in which ample mobilization and additional stomach wall is required to establish the tubovalvular formation, partial detachment of the hepatogastric, or of the gastrocolic ligaments is undertaken.

THE SURGICAL TREATMENT OF SPASTIC PARALYSIS

CLARENCE H HEYMAN, M.D. F.A.C.S. Cleveland, Ohio

THIS study is based on the results of 280 operations upon 176 patients with cerebral spastic paralysis. All of the operations performed upon the upper extremity were in cases of hemiplegia. Spastic contracture or rigidity at the upper extremity is rarely present in diplegia where the disturbance in function is rather the result of loss of muscle control, athetosis, mass reaction, and inco-ordination.

Only a relatively small number of patients with spastic paralysis are amenable to surgical treatment. While no accurate figures are available, it is estimated that the 176 patients operated upon were selected from approximately 1,500 cases. Treatment in the majority of patients, should consist only of education, muscle training, occupational therapy, prevention of deformity, and correction of mild contractures by muscle stretching and educational methods. However there are frequent instances where correction of contractures or impairment of function can be accomplished only by surgical means.

It should be our aim to consider surgical treatment as only an important and sometimes necessary adjunct to a broad therapeutic regimen. While this is the ideal conception in the treatment of the patient with spastic paralysis it is not always possible. Unfortunately, it is the exception rather than the rule that skilled mental and physical training is available. To be efficient this requires individual instruction over a prolonged period of time on the part of trained personnel. The majority of the patients included in this report have not had available facilities for prolonged pre-operative and postoperative treatment. Hence any improvement resulting after operation must be ascribed to the operation and not to other accessory treatments. An attempt was made to have postoperative training available in all cases of the upper extremity, but in only a few instances was this possible. A reasonable degree of intelligence was considered desirable but not essential before operation was performed upon the lower extremity. On the other hand the use of the upper extremity is intricate and requires at least a fair degree of intelligence to overcome handicaps through postoperative instruction, muscle education, and co-operation on the part of the patient. Fortunately in this

respect contracture at the upper extremity occurs only in cases of hemiplegia which is likely traumatic in origin, and in which low grades of mentality are not common.

In our early experience operation upon the lower extremity was sometimes done before the patient could stand alone, that is, before a definite sense of balance had developed. Occasionally, improvement was rapid and the child was able to walk shortly after operation. Further experience taught us that as a rule it is better to wait until the patient is able to stand alone or walk, or until it is apparent that he could stand or walk provided the contractures were relieved.

In the selection of patients for treatment, training or surgical the question of the patient's mentality commonly arises. For approximately half a century after Little's publications there were practically no attempts made along the line of muscle training. It was supposed that almost all of these patients were feeble minded, and treatment was either not worth while or would be of no avail because of a lack of co-operation. Numerous surgeons observed an apparent improvement in mentality following relief of spasm and contracture, particularly during muscle training. This led many to believe that the mentality in these children is not so low as was formerly assumed and that a good mind may be masked behind the distortions of the facial muscles, the grimaces of athetosis, or the spasms and deformities of the extremities. It is now known that there is frequently a lack of correlation between motor handicaps and the mental condition. Some patients with a marked degree of speech impairment or loss of muscle control reveal a high degree of intelligence while others with practically no motor impairment are idiots. The difficulties involved in the interpretation of mental tests and measurements have been studied by Doll (2) in connection with his research at Vineland. At Spalding School in Chicago one third of a group of 150 children classed as spastics were said to have been mentally normal. Doll (3) said: "It is thus evident that the mental condition of birth injured children must be evaluated with more caution since motor handicap is not to be relied on as an index of the mental condition. Yet to most observers the physical difficulties which these cases present are so

extreme that one is likely to underestimate the child's capacity."

At the close of the first decade of the present century surgical treatment in spastic paralysis had been confined chiefly to stretching of muscles, tenotomies, and tenectomies. Surgeons agreed fairly well upon the usefulness of these methods. There was no agreement, however, on the value of tendon transplantation, and favorable results were attributed to a far greater degree to the removal of the deforming force rather than to the extending action of the flexor muscle. Early work directing the attack upon the central nervous system was in progress. Indeed, we may note the trend of treatment from multiple tenotomies during the first decade to posterior nerve root and motor nerve resection during the second decade, and then through ramisection during the third decade.

Attempts at nerve anastomosis, one peripheral nerve with another, were made by Spiller whose results at first seemed very promising. Steindler showed that while direct neurotization of paralyzed muscle was possible, muscle already supplied by healthy nerve does not take on an additional nerve supply. The clinical application of this is the impossibility of taking some of the nerve supply of the flexors and adding it to that of the extensors.

The suggestion of resection of posterior nerve roots to deal with spasticity and athetosis came from Spiller in 1905, but credit is usually awarded to Foerster who in 1908 and 1909 presented an exhaustive treatise on the theoretical and practical aspects of radicotomy. The Foerster operation was received with great enthusiasm, but has fallen into disfavor chiefly because of the high mortality, the difficult technique, and the inability to localize the effect of root resection to particular groups of muscles.

In 1908, Nutt proposed intraperineural neurotomy with division of the peripheral nerve and immediate suture. Allison and Schwab, impressed with the lack of permanent results following tenotomy, advocated alcohol injection of nerves leading to selected muscle groups. Stoffel proposed selective nerve resection for the purpose of diminishing motor nerve impulses permanently. This method rapidly received recognition and was popularized in this country by Gill.

Sympathetic ramisection, first proposed by Royle and Hunter in 1924 and followed by several subsequent reports, received world wide interest. It is now the opinion of most contributors to the subject that the clinical employment of ramisection in spastic paralysis has

failed to give amelioration of symptoms which the first cases seemed to promise.

This brief review is interesting, for of the various methods of surgical treatment which have stood the test of time there remain only motor nerve resection (Stoffel) and the usual orthopedic principles of tenotomy, tendon transplantation, and arthrodesis. The operations forming the basis of this report are tenotomy or tendon lengthening, motor nerve resection, arthrodesis, tendon transplantation, or a combination of these methods adapted to the individual case. End-results will be classified according to the type of operation and the location.

The interpretation of results of treatment is difficult. While results cannot be obtained comparable with the almost complete restoration of function possible in other deformities, a sufficient degree of improvement can be obtained to encourage continuation of efforts to lessen disability as much as possible. From a previously hopeless situation the parents of these children are appreciative of any gain in function. The relief of an unsightly and disabling contracture and physical and moral encouragement unquestionably stimulate the intelligent patient to a better social adjustment. On the other hand our effort is a failure when the correction of deformity does not result in the improvement in function of the part.

MOTOR NERVE RESECTION

Internal popliteal nerve In several cases a previous lengthening of the tendo achillis had resulted in a recurrence of the deformity. Final decision to lengthen the tendo achillis in addition to motor nerve resection was reserved until the patient was completely relaxed under anesthesia. If, during that time, the foot could not be dorsiflexed to a right angle it was assumed that a structural shortening of the muscle existed, and a plastic lengthening of the tendon was done. In all cases a plaster cast was applied immediately after operation, with care to hold the foot corrected only slightly beyond a right angle. This is most important in order to prevent a subsequent calcaneus deformity.

Results of internal popliteal nerve resection in cases of hemiplegia have been excellent in each of the 43 cases. There has been no calcaneus and no recurrence. Some of the patients now have a slight equinus which is not progressing. This is attributed to conservatism of nerve resection, and particularly to conservatism in fixation of the foot in dorsiflexion only slightly beyond a right angle. In none of these cases, however, was this slight equinus objectionable.

The next group of cases consisted of 20 operations upon 10 patients with a bilateral equinus deformity with no particular spasm of the hamstrings or adductor muscles. This group also gave excellent results. There is no calcaneus in any, but in one case there was a recurrence of equinus deformity. In this particular patient lengthening of the tendo achillis was done in addition to the Stoffel technique. I do not believe that the failure was due to the choice of method but rather to error in judgment in not excising enough nerve.

A third group of cases consisted of 44 operations upon 22 paraplegic patients who also had severe contractures of the hip adductors, and in some contracture of the hamstrings as well. The results in this group of cases showed a recurrence of equinus in 2 cases and a calcaneovalgus deformity in 2 cases. While the results were good they were not as uniformly satisfactory as in the less severe types. Even though contractures are relieved it does not follow that a good result will be obtained. Three patients, while relieved of the contractures for which they were operated upon are unable to walk. Mentality is low and there appears to be a complete absence of a sense of balance. Here again, I do not blame the method of the operation itself but attribute failure to poor judgment in the selection of cases for operation.

Obturator nerve. Operative treatment directed toward a relief of spastic adduction contracture was not found necessary in any case of hemiplegia. All operations were done in cases of paraplegia. Fifty-four resections of the obturator nerve were done upon 27 patients. Deformity of the feet, which was usually present, was treated by resection of the internal popliteal nerve or by a stabilizing operation. The results of resection of the obturator nerve have been most satisfactory. A sufficient degree of relaxation of the adductor muscles to correct interference at the knees was obtained in all cases. But here again, as in the last group of cases studied, relief from the adductor spasm does not necessarily indicate a good functional result for without a sufficient degree of a sense of balance and co-ordination the patient may still be unable to walk. Three patients were not appreciably improved. Therefore in order to make the operation worthwhile cases must be selected with care. Resection of the obturator nerve will relieve spastic adduction provided there is not a severe structural shortening of the muscles as determined by marked limitation to abduction while the patient is relaxed under anesthesia. When this is present

adductor tenotomy is also done. There have been no instances of overcorrection of the deformity or a complete paralysis of the adductor group. Immediately after the completion of this operation a double spica cast is applied holding the legs abducted to a moderate degree. The cast is removed at the end of 4 weeks when walking is encouraged.

Sciatic and external popliteal nerves. Only 4 operations were done on the sciatic nerve with failure to relieve flexion contracture of the knee in both cases of paraplegia. This operation was therefore discontinued and other methods were used to overcome flexion deformity at the knee. Transplantation of the hamstring tendons and Chandler's transplantation of the patellar tendon downward have given much more satisfactory results, particularly the latter which will be discussed under tendon transplantation.

There were 2 operations performed upon the external popliteal nerve to relieve spasm of the peroneal muscles in conjunction with a triple arthrodesis of the tarsal joints. There was no recurrence of the deformity in either case but in later cases it was thought to be more rational to transplant the peroneal muscles to the inner border of the foot in conjunction with the triple arthrodesis. This not only removes a deforming force but possibly assists actively in maintaining correction.

Median nerve. The indications for which the Stoffel operation was proposed on the median nerve are spastic contracture of the fingers and thumb, and a spastic contracture of the forearm in pronation. Accordingly with this object in mind 18 operations were performed upon 18 patients with hemiplegia. The technique as described by Stoffel and Gill was used. In some cases a preliminary splint to hold the forearm in supination and the wrist and fingers in extension was applied. Immediately after the operation a plaster cast was applied with the forearm supinated and the fingers and wrist fully extended. The cast was worn as a rule about 4 weeks. After the removal of the cast exercises and muscle training were applied for a variable period of time depending on the co-operation of the patient and physical facilities. There were no cases in which tenotomy or lengthening of the flexor tendons of the wrist or digits was done in addition to the nerve resection. In 3 cases a tenotomy of the pronator radii teres was done in addition to division of its nerve supply. The indication for tenotomy was inability to supinate the forearm completely while the patient was under anesthesia. In 5 cases the bundle lead ing

Fig 1

Fig 1 Recurrence of equinus deformity after 2 operations to lengthen the tendo achillis. There has been no recurrence following a third operation when this was combined with resection of the nerve supply to the gastrocnemius.

Fig 2 Illustration shows result following bilateral

nerve resection at the obturators and internal popliteals. Fig 3 Stoffel's operation of median nerve in spastic hemiplegia. The bundle to the pronator radii teres, flexor carpi radialis, and palmaris longus, was resected together with the bundle to the flexor sublimis digitorum muscle.

to the pronator radii teres, the flexor carpi radialis, and the palmaris longus muscles were resected together with the nerve supply to the flexor sublimis digitorum. This was for relief of pronation contracture of the forearm and flexion contracture of the fingers. In 10 cases the operation was directed toward relief of pronation contracture alone as there was no particular contracture of the fingers present.

The end-results were excellent for the relief of pronation contracture of the forearm. In all cases there has been practically a complete loss of resistance to passive supination, and in most of them there is good active power in supination. I continue to believe, therefore, that this aspect of the Stoffel operation to the median nerve has a distinct value. The results are permanent, and this operation is better than tenotomy alone or

Fig 3

transplantation of the insertion of the pronator radii teres according to the method of Tubby.

The results of the latter operation will be discussed later.

The results for improvement in function of the fingers, however, are disappointing. Three of the 8 cases are complete failures, 2 have only a fair result, and 3 have good results. A good result means that the patient has good active power in flexion of the fingers with little difficulty in extending them so as to be able to open the hand sufficiently to grasp.

The tight flexor spasm of the fingers was relieved in all cases, but in spite of splinting and exercise 5 patients of the 8 could not extend the fingers at will. In these no particular improvement in function resulted. In 2 patients there remains severe palmar flexion of the thumb which is held curled up in the palm.

Failures are indicated by a marked weakness of the extensors of the fingers or an inability to contract these muscles at will. The fine synergic control of the muscles of the hand cannot be restored simply by weakening the flexor groups. In 4 cases an ulnar deviation of the hand at the wrist occurred resulting likely from the paralysis of the flexor carpi radialis.

The end results, therefore, of the Stoffel operation on the median nerve are as a whole unsatisfactory. Pronation contracture of the forearm can be relieved but, as a rule, there will be but little improvement in the use of the fingers. One can not ignore, however, the 3 good results. This means that good results may be obtained in properly selected cases, but the difficulty arises in the selection of them. I would limit the Stoffel operation as applied to the fingers to those cases in which a distinct improvement in the use of the hand is made by preliminary splinting of the wrist and fingers in the cock up position. If this improvement fails to be maintained and deformity recurs after the splint has been discontinued, an operation to lessen the pull of the flexors may be of benefit. One must have assurance in other words, that the patient has at least some voluntary power in extension of the fingers while the wrist is in a position of extension.

One may briefly summarize the results of 187 Stoffel operations on 103 patients by saying that motor nerve resection is of great value in the lower extremity but of limited value in the upper extremity. The operation prevents recurrence of deformity which has been corrected by tenotomy and in some cases corrects deformity caused by muscle spasm. It is directed toward the relief of spasticity of definite local groups of muscles and is not indicated in any generalized diffuse spasm of an entire extremity.

TENDON TRANSPLANTATION AND ARTHRODESIS

Transplantation of the pronator radii teres (Tubby) This operation was done upon 4 patients for the relief of pronation contracture of the forearm. The broad insertion of the pronator radii teres was exposed and entirely severed. The tendon was passed between the radius and ulna and secured by means of silk sutures passed through a drill hole well around the posterior lateral aspect of the radius. The results were all failures. There was not only a failure to gain voluntary supination, but there remained the same resistance to passive supination. All these operations were done before the Stoffel operation was tried and the results present a marked contrast to the good results obtained by resection of

the nerve supply to the pronator radii teres muscle as discussed in the first section of this paper.

Tendon transplantation of the wrist and fingers Since results obtained by the Stoffel operation on the median nerve were generally unsatisfactory because of inability to extend the fingers and wrist, an attempt was made to combine the good features of the Stoffel as regards the relief of pronation contracture with tendon transplantation of the wrist flexors into the extensor tendons of the thumb and fingers. Of course the usual Stoffel method, which resects the nerve bundle leading to the flexor carpi radialis as well as to the pronator radii teres had to be modified if we wished to transplant the former. At one operation the median nerve was exposed and with great care the bundle leading only to the pronator radii teres muscle was resected leaving the nerve supply to the flexor carpi radialis intact. This was done with the assistance of direct electrical stimulation to the nerve. A plaster cast was then applied holding the forearm in supination. Later when examination proved that the flexors of the wrist were functioning a second operation was done namely transplantation of the flexor carpi radialis around the radius and attaching it to the extensor tendons of the thumb and index finger, and transplantation of the flexor carpi ulnaris around the ulna and attaching it to the extensor tendons of the middle, ring and little fingers. It was hoped that the pull of these tendons on the extensors of the fingers would enable the patient to hold the wrist in extension as well as to enable him to open the fingers to a degree sufficient to grasp. Of course good voluntary power of flexion of the fingers with no real spastic shortening was considered essential before operation. These operations were done at first, with an enthusiasm which gradually waned as time passed to determine the results. While flexion deformity of the wrist was corrected there followed an ulnar deviation at the wrist which sometimes resulted in a hand which looked worse than before operation. Function of the fingers was also not particularly improved. The proximal phalanges were held extended at the metacarpophalangeal joints but there was no improvement in the flexion deformity of the interphalangeal joints. The function of the fingers was therefore only slightly improved. Upon second thought this is what one would expect. A pull on the extensor tendons does not extend the interphalangeal joints but only the metacarpophalangeal joints. In paralysis of the musculospiral nerve a similar tendon transplantation is satisfactory because the patient has not

lost the ability to extend the distal 2 phalanges

Before realizing this an attempt was made to prevent ulnar deviation at the wrist, caused by the spastic flexor carpi ulnaris passed around the ulna, by performing an arthrodesis of the wrist. It was supposed that a bony ankylosis would prevent ulnar deformity at the wrist. Accordingly arthrodesis of the wrist was done on 10 patients. In 5 of these the arthrodesis was combined with transplantation of the wrist flexors as described above. Again ulnar deviation occurred in some cases in spite of arthrodesis. The deforming force of the flexor carpi ulnaris, which appears to be much stronger than that of the radialis, pulled the wrist ulnarwards in spite of arthrodesis.

Arthrodesis of the wrist either alone or combined with tendon transplantation gave better results than tendon transplantation alone. However, 5 failures to prevent severe adduction deformity out of 11 cases indicated that this method of treatment was not satisfactory in a high percentage of cases.

Crossed tendon transplantation Since it was believed that adduction deformity at the wrist was caused by the excessive spastic pull of the flexor carpi ulnaris, a method of transplantation was next devised crossing the tendons of the flexor carpi radialis and ulnaris attaching the ulnaris tendon to the radial side of the hand and the radialis tendon to the ulnar side. Instead of the usual technique of passing these tendons around the lateral aspects of the ulna and radius, they were passed between these bones just above the wrist. This technique was followed in 16 cases. In 4 of these the flexor carpi ulnaris was sutured to the extensor tendons of the thumb and index finger, and the flexor carpi radialis to the extensor tendons of the middle, ring, and little fingers. In 4 cases the same method of tendon transplantation was done combined with arthrodesis of the wrist. In still another group of 8 cases arthrodesis of the wrist was done combined with crossed tendon transplantation to the bones on the dorsal aspect of the wrist, the flexor carpi ulnaris to the radial border and the flexor carpi radialis to the ulnar border. In none of these 16 cases did adduction deformity at the wrist occur. Therefore, the object of this method of crossed tendon transplantation was realized. Inability to extend the fingers accounts for failure to improve the function of the hand in 4 cases. Crossed tendon transplantation then, is regarded as important in preventing adduction deformity at the wrist in spastic paralysis, for in my experience the usual tendon transplantation of the flexor carpi radialis to the extensor tendons on the

radial side of the hand and of the flexor carpi ulnaris to the extensor tendons on the ulnar side of the hand is followed in many cases by a more or less severe adduction deformity. It is not expected that tendon transplantation of a spastic muscle will activate antagonistic action. It is helpful chiefly in removing a deforming force and acting as a passive support.

SUMMARY OF RESULTS OF TENDON TRANSPLANTATION AND ARTHRODESIS OF WRIST, SEPARATELY OR COMBINED

Conclusions as to the value of tendon transplantation and arthrodesis, separately or combined, are based on the results of 34 operations. Seven were cases of uncrossed tendon transplantation of the wrist flexors to the finger extensors, 6 were cases of arthrodesis of the wrist alone, and in another 5 arthrodesis was combined with uncrossed tendon transplantation to the bones of the wrist, 4 were cases of crossed tendon transplantation to the extensors of the fingers, 4 were cases of crossed tendon transplantation to the extensors of the fingers together with arthrodesis of the wrist, and finally 8 were cases of crossed tendon transplantation to the bones of the wrist combined with arthrodesis. It is evident from these confusing figures that attempts at several combinations of tendon transplantation and arthrodesis of the wrist have not resulted in a single satisfactory method of improving the function of the spastic hand. The most satisfactory results, however, have followed arthrodesis of the wrist combined with crossed tendon transplantation to the wrist or extensor tendons of the fingers. A decision is not easily arrived at as to whether one should transplant the wrist flexors to the bones of the wrist or to the extensors of the fingers.

Objection may be raised as to the efficacy of transplantation of a spastic muscle, particularly to a contrary position. In practice these objections are partially confirmed. However, in a goodly proportion of cases improvement in power of extension of the fingers can be obtained by this means not possible by any other method.

Selection of cases for operation is not easy. If, when the flexed wrist is held passively in extension and the patient is still able to open the fingers sufficiently to grasp, assuming, of course, that there is good voluntary flexion of the fingers, crossed tendon transplantation will likely hold the wrist in extension without adduction deformity. If there is difficulty in extension of the fingers while the wrist is held passively extended, tendons are transplanted to the extensors of the thumb

Failures are indicated by a marked weakness of the extensors of the fingers or an inability to contract these muscles at will. The fine synergic control of the muscles of the hand cannot be restored simply by weakening the flexor groups. In 4 cases an ulnar deviation of the hand at the wrist occurred resulting likely from the paralysis of the flexor carpi radialis.

The end results, therefore, of the Stöffel operation on the median nerve are as a whole unsatisfactory. Pronation contracture of the forearm can be relieved but as a rule, there will be but little improvement in the use of the fingers. One can not ignore, however, the 3 good results. This means that good results may be obtained in properly selected cases, but the difficulty arises in the selection of them. I would limit the Stöffel operation as applied to the fingers to those cases in which a distinct improvement in the use of the hand is made by preliminary splinting of the wrist and fingers in the cock up position. If this improvement fails to be maintained and deformity recurs after the splint has been discontinued, an operation to lessen the pull of the flexors may be of benefit. One must have assurance, in other words, that the patient has at least some voluntary power in extension of the fingers while the wrist is in a position of extension.

One may briefly summarize the results of 187 Stöffel operations on 103 patients by saying that motor nerve resection is of great value in the lower extremity but of limited value in the upper extremity. The operation prevents recurrence of deformity which has been corrected by tenotomy, and in some cases corrects deformity caused by muscle spasm. It is directed toward the relief of spasticity of definite local groups of muscles and is not indicated in any generalized diffuse spasm of an entire extremity.

TENDON TRANSPLANTATION AND ARTHRODESIS

Transplantation of the pronator radii teres (Tubby). This operation was done upon 4 patients for the relief of pronation contracture of the forearm. The broad insertion of the pronator radii teres was exposed and entirely severed. The tendon was passed between the radius and ulna and secured by means of silk sutures passed through a drill hole well around the posterior lateral aspect of the radius. The results were all failures. There was not only a failure to gain voluntary supination but there remained the same resistance to passive supination. All these operations were done before the Stöffel operation was tried and the results present a marked contrast to the good results obtained by resection of

the nerve supply to the pronator radii teres muscle as discussed in the first section of this paper.

Tendon transplantation at the wrist and fingers. Since results obtained by the Stöffel operation on the median nerve were generally unsatisfactory because of inability to extend the fingers and wrist, an attempt was made to combine the good features of the Stöffel as regards the relief of pronation contracture with tendon transplantation of the wrist flexors into the extensor tendons of the thumb and fingers. Of course the usual Stöffel method which resects the nerve bundle leading to the flexor carpi radialis as well as to the pronator radii teres had to be modified if we wished to transplant the former. At one operation the median nerve was exposed and with great care the bundle leading only to the pronator radii teres muscle was resected leaving the nerve supply to the flexor carpi radialis intact. This was done with the assistance of direct electrical stimulation to the nerve. A plaster cast was then applied holding the forearm in supination. Later when examination proved that the flexors of the wrist were functioning, a second operation was done, namely, transplantation of the flexor carpi radialis around the radius and attaching it to the extensor tendons of the thumb and index finger, and transplantation of the flexor carpi ulnaris around the ulna and attaching it to the extensor tendons of the middle ring and little fingers. It was hoped that the pull of these tendons on the extensors of the fingers would enable the patient to hold the wrist in extension as well as to enable him to open the fingers to a degree sufficient to grasp. Of course, good voluntary power of flexion of the fingers with no real spastic shortening was considered essential before operation. These operations were done at first with an enthusiasm which gradually waned as time passed to determine the results. While flexion deformity of the wrist was corrected there followed an ulnar deviation at the wrist which sometimes resulted in a hand which looked worse than before operation. Function of the fingers was also not particularly improved. The proximal phalanges were held extended at the metacarpophalangeal joints but there was no improvement in the flexion deformity of the interphalangeal joints. The function of the fingers was therefore only slightly improved. Upon second thought this is what one would expect. A pull on the extensor tendons does not extend the interphalangeal joints but only the metacarpophalangeal joints. In paralysis of the musculospiral nerve a similar tendon transplantation is satisfactory because the patient has not

Fig 6

Fig 6 Crossed tendon transplantation to the wrist together with arthrodesis. There is no adduction deformity. The tendon of the flexor carpi ulnaris was passed between the radius and ulna and attached to the radial border of the wrist. There has been a moderate improvement in the function of the hand.

Fig 7

Fig 7 Arthrodesis of the wrist has resulted in inability to extend the fingers. The patient was formerly able to extend the fingers by flexing the wrist. One must be cautious when advising arthrodesis of the wrist without tendon transplantation to the extensor tendons of the thumb and fingers.

transferring the action toward the extension of the knee.

Transplantation of the patellar tendon (Chandler's operation) In 1933 Chandler, at a meeting of the Clinical Orthopedic Society in Chicago, demonstrated patients upon whom he had transplanted the patellar tendon downward at the knee (2). Since that time the writer has done 10 of these operations on 6 patients, all with spastic paraplegia. Results have been very satisfactory, and each patient now has active power in completely extending the knees when sitting and walking. This operation was proven to be so satisfactory that, in my hands, it has completely displaced transplantation of the hamstrings. Of course, as in transplantation of tendons elsewhere, complete passive extension of the knee must be possible beforehand, obtained either by stretching, tenotomies, or capsuloplasty, for tendon transplantation alone will not overcome contracture.

Arthrodesis and tendon transplantation at the foot Deformity of the foot other than a pure equinus has been observed with relative infrequency. This accounts for the few operations to correct a lateral deformity of the foot in spastic paralysis. Twenty operations were done on 12 patients for varus or valgus deformity. Subastragalar arthrodesis together with transplanta-

tion of the peroneus longus or tibialis anticus was done upon 14 patients, and in one case arthrodesis alone was done. Tendon transplantation in conjunction with arthrodesis removes the constant deforming force of a spastic muscle and lessens the likelihood of recurrence of deformity. The results of all these operations were satisfactory. It is believed necessary to dress these feet in a little more overcorrection than is done following arthrodesis of the foot to correct a paralytic deformity, as there seems to be a greater tendency toward recurrence. Subastragalar arthrodesis together with tendon transplantation solves the problem to correct valgus or varus deformity of the foot in spastic paralysis. Arthrodesis alone is apt to result in a recurrence of the deformity.

Posterior nerve root resection (Foerster) and sympathetic ramisection While it is not intended in this report to discuss the merits of nerve root resection and sympathectomy, brief comments will be made to record unfavorable impressions following my observation of patients operated upon by others. Two patients were under observation several years after posterior nerve root resection. Both had large trophic ulcers and a flaccid paralysis of the lower extremities with calcaneovalgus deformity and flexion contractures at the knees. One patient was incontinent and

Fig 4

Fig 4 Arthrodesis of the wrist together with uncrossed tendon transplantation. Note the severe adduction deformity. The tendons of the flexor carpi radialis and the flexor carpi ulnaris were passed around the radius and ulna respectively and attached to the carpus. This

Fig 5

deformity is common with this method of transplantation.

Fig 5 Nerve resection to the pronator teres muscle only. At a second operation the flexor carpi radialis and flexor carpi ulnaris were transplanted to the distal end of the wrist according to the crossed technique.

and fingers otherwise the patient would be unable to open the fingers sufficiently to grasp. With arthrodesis of the wrist it is advisable to transplant the wrist flexors. These muscles would have no function anyway after arthrodesis and when transplanted according to the crossed technique they will prevent adduction deformity. A large number of patients, however, have fair function in spite of a flexed position of the wrist for by flexing the wrist they are able to extend the fingers. It is best not to interfere with this type of hand. Possibly transference of the origin of the extensors further upward on the humerus would improve the ability to hold the wrist and fingers extended.

On the whole the results of tendon transplantation and arthrodesis in the upper extremity are encouraging. In a selected group of cases, however, a great improvement in function of the hand can be obtained by these measures. Spastic flexion of the thumb across the palm seriously interferes with the ability to grasp. Arthrodesis of the carpometacarpal joint together with tenodesis of the abductor pollicis longus to the lower end of the radius has been partially successful in holding the thumb out of the palm.

Transplantation of the biceps femoris. This operation was done to prevent sagging of the

knees in flexion. This was always bilateral and has not been observed in any case of hemiplegia. Fifteen operations were done on 9 patients. The usual technique was employed, namely, a small piece of the bony attachment at the head of the fibula was removed together with the biceps tendon and this was secured into a groove in the patella. Complete passive extension of the knee was a prerequisite before operation. One can not expect a transplanted tendon to overcome contracture. In 2 cases flexion contracture was severe, and required posterior capsuloplasty according to the method of Philip Wilson in order to obtain complete passive extension before tendon transplantation. In 5 cases the result was satisfactory. These patients are able to walk with the knees almost completely extended. In 2 the result was considered only as fair in the remaining 2 cases no benefit whatever was derived. Possibly a higher percentage of good results may have been obtained by transplanting both the external and internal hamstrings. The same objections hold true here as with transplantation of spastic muscle at the wrist. Possibly the same percentage of good results could have been obtained by tenotomy or tenectomy of the hamstrings. Tendon transplantation was done in order to utilize this force if possible by

A TECHNIQUE OF THYROIDECTOMY PERMITTING THE USE OF SILK

DONALD GUTHRIE, M D , F A C S , Sayre, Pennsylvania,
MERLE J BROWN, M D , Davenport, Iowa

THE general principles of thyroidectomy have become standardized but important variations and refinements of technique have been described in recent years which have improved results and decreased operative complications. The technique developed in this clinic has increased rapidity of recovery, decreased hospital morbidity, eliminated drainage, decreased incidence of infected wounds, and diminished incidence of postoperative complications.

In 1920, Pemberton suggested the primary superior polar attack for substernal thyroids and from the principles outlined our present method has been evolved. This method of attack is now applied to all types of goiters with equal effectiveness. Guthrie (1936) stated that the advantages of the method are obvious when the primary superior polar method used in substernal goiter is compared with the technique of rapid elevation, which is attended so often by an increase in respiratory difficulties instead of in their improve-

ment, which may necessitate the rapid and vain search for a hidden and deformed trachea in a neck already filled with thyroid before elevation of more thyroid, which carries with it the danger of further stretching an already overstretched recurrent laryngeal nerve, and which may be associated with deep alarming hemorrhage due to the pulling off of the inferior thyroid artery and vein, or both, and thus cause injury to the recurrent laryngeal nerve, the internal jugular vein, or the parathyroids, as a result of hectic efforts to control the severe and alarming hemorrhage.

Since the employment of this operative method, there has been a marked reduction in the postoperative respiratory and voice complications and there has been no need for tracheotomy for the relief of such complications. Lahey has recently advised that the recurrent laryngeal nerve be visualized and dissected out in order to prevent its injury and subsequent voice changes. Guthrie, however, believes that severing the inferior

Fig 1 In those patients with large thyroids the incision is placed high to prevent its prolapse upon the chest wall

Fig 2 Sharp dissection of the upper flap of the incision is carried out

died 10 years after operation because of sepsis. Ten patients were studied following sympathetic ramisection, and I have not been impressed with any improvement over their previous condition. In 2 cases of paraplegia where the operation was done on only one side there was no appreciable difference between the operated and the unoperated sides. These observations in general agree with other reports. One can not ignore, however, the careful studies of Steele Stewart who has had great experience with sympathectomy.

CONCLUSIONS

In this study of end results of the surgical treatment of spastic paralysis the striking contrast of poor results attending operation at the upper extremity as compared to good results at the lower extremity is apparent. Motor nerve resection combined with tenotomy when necessary has proved to be satisfactory in correcting equinus deformity and adduction contracture at the hips which are the deformities most commonly encountered. The likelihood of overcorrection of the deformity is more theoretical than real, for with care in judgment in the execution of nerve resection this should not occur. Valgus or varus instability or deformity at the foot may be corrected by subastragalar arthrodesis combined with tendon transplantation. Motor nerve resection of the sciatic nerve to control flexion deformity at the knee has been discarded as being of little value, and transplantation of the biceps femoris has been attendant with only indifferent success. Transplantation of the patellar tendon downward—advancement of its insertion—has shown such superiority over other methods to correct flexion deformity at the knee as to displace them entirely. I have had no experience with Durham's procedure of dividing the insertion of the internal rotator muscles at the hips to correct internal rotation contractures. His results are convincing and his method will be used when the opportunity arises.

To improve the function of the upper extremity is a much more difficult problem and is still not possible in many cases. It is best not to interfere with many of these for an injudicious operation

may result in an impairment of what little function exists. Motor nerve resection at the upper extremity has a narrow field of adaptability except for relieving pronation contracture of the forearm. Arthrodesis and crossed tendon transplantation offer better chances of success in carefully selected cases resulting occasionally in striking improvement. However, even with various combinations and methods the results of tendon transplantation and arthrodesis have been as a whole disappointing. While the nature of the lesion precludes curative treatment, the application of surgical methods unsatisfactory as they are, is often an indispensable and in further educational treatment.

silk in tissue than to catgut. They showed that silk knots and sutures become encapsulated early by a fibroblastic capsule. We have had a chance to verify this fact in secondary lobectomies which are performed 7 to 10 days after the primary operation. We have been amazed to find in this short period of time all silk ligatures encapsulated. Whipple, in 1933, emphasized the principles laid down by Halsted, and the spreading popularity of silk is largely due to his efforts. He emphasized the necessity of sharp dissection, complete hemostasis with fine pointed forceps, avoidance of mass ligatures and undue tension, interrupted sutures, avoiding the combination of silk and catgut in wounds, and the use of only the finest grades of silk in clean wounds. These principles are rigidly observed in our thyroidectomy technique. Guthrie and Sharer (1936) stated that in thyroid surgery the desire to close the wound if possible without drainage necessitated the use of

large amounts of catgut for complete hemostasis. The exudative response to this material caused serum collections which often required drainage and thereby invited infections. The swelling and softening of catgut about larger vessels may result in hemorrhage which may be concealed. Silk has been advocated for the solution of these difficulties. Guthrie and Sharer, in 1935, reported its use in ligation of all vessels while the hemostasis of the thyroid remnant was secured by a running lock suture of No 0 iodized catgut. Before this change of technique, drainage was employed routinely. This method permitted 60 per cent of the wounds to be closed without drainage. The wounds drained were particularly those with large unobliterated cavities. By this method there was a definite reduction in the incidence of wound infections and serum collections. Goiter patients in this clinic have been routinely tested for sensitivity to silk and it has been found that,

Fig. 3. Freeing the lower flap in the midline only over the suprasternal notch.

thyroid vessels high up on the gland and then ligating the vessels in the long axis of the neck safeguards the recurrent laryngeal nerve against injury at this point.

The technique which we now employ permits the safe use of silk. Halsted was the first surgeon

Fig. 4. Division of the fascia and the muscles in the midline.

in this country to use silk in wound repair and the principles he proposed have not been improved upon. He believed that even in the presence of slight infections, fine silk sutures would not be extruded. Howes and Harvey have shown that there is much less exudate and cellular response to

draining after 2 weeks. By improving the technique of regional anesthesia in 1935 drainage was reduced to 52 per cent. Collier reported, in 1937, that he uses drainage routinely in his cases.

TECHNIQUE OF SUBTOTAL THYROIDECTOMY

It is most important to obtain the best exposure of the thyroid bed at the beginning of the operation. The low collar incision (Fig 1) extends from the external jugular vein of one side to its fellow of the opposite side, and the skin and platysma of the upper flap are reflected upward to the level of the thyroid cartilage notch (Fig 2). It has been found best not to dissect the lower skin flap except slightly at the suprasternal notch (Fig 3), because separation of this flap is not necessary for exposure and its dissection encourages the formation of serum pockets. All vessels are caught by fine pointed Kelly hemostats and ligation is performed with fine silk. In dissecting the flap, care is taken to avoid cutting the anterior jugular veins. If these veins are injured the heart side of this vein is immediately clamped to prevent air embolism, as previously described by the senior author. At the point of injury the vein is completely severed before ligation because it is believed that there is less likelihood of the sutures slipping off as the operation proceeds and retraction is used. At this point all

forceps which have been used to secure vessels on the flaps and muscles are removed after ligation of the vessels. The fascia and muscles are

Fig 11 Dissection of the lobe from the trachea showing remnant of the gland left along the trachea

FIG. 9. Upper pole is mobilized by gentle downward traction.

even in those who react strongly positive the tendency to serum collection is definitely less than for catgut. The silk used in all cases has been fine Dicksel or a fine German made white silk.

In 1935 when silk was used for ligatures and remnants were sutured by a lock stitch of iodized No. 0 catgut 63 per cent of the wounds were healed at the time of discharge. A summary of the cases up to June 22 1937 showed that 6 per cent were closed without drainage and 61 per cent of these healed without serum collections while 3 per cent of the drained cases healed *per primam*. A total of 52 per cent of these patients were healed at time of discharge. Before the rubber sponge pressure dressing was routinely used in silk and catgut cases 40 per cent of the wounds were draining after 13 days but since the adoption of this dressing for all goiter cases only 1 per cent were draining after 11 days. Further in cases in which silk and catgut were both used serum collections were noted in 32 per cent.

In a review of the last 150 cases which have been completely done with silk there has been only one case requiring drainage. The drains were removed in 24 hours and primary healing resulted. There have been only 5 cases which developed serum collections and the 6 became dry after a single drainage of the serum. Of the 410 cases there has been only one infected wound which was slight and subsequently healed with out extrusion of silk knot.

When these figures are compared to reviews of case for years past there has been a remarkable improvement since the present technique has been used. Another very important point is that sub-ternal goiters which were previously drained now are now closed without drainage and without fear of mediastinitis. It was our custom formerly to drain these pockets freely at least 3 or 4 days. At the Mayo Clinic Zellhoefer in 1913 found that when local anesthesia was used in 80 per cent of the cases the wound were

Fig 13 Thyrohyoid muscles are sutured at the midline and to the lower portion of the remnant

interarytenoid muscles. The dissection then extends to the lateral thyroid veins, which are clamped and ligated. With this amount of mobilization the upper pole is elevated and drawn gently downward from without inward or in a reverse manner, the manipulations of the surgeon being guided by the respiration of the patient and the helpful co-operation of an experienced anesthetist.

In the dissection at this stage it is best to leave small amounts of thyroid tissue on the trachea and at the side for protection of the trachea itself and for anchoring the remnant. It was formerly thought that the lower pole was most frequently the site of nerve injury, but it is now well known that injuries take place most frequently in the groove between the esophagus and the trachea or near the upper pole. Lahey believes that many of these nerve injuries come from attempts to control troublesome hemorrhage from a branch of the inferior thyroid artery supplying the remnant left along the side of the trachea, and he advises that the inferior thyroid artery be ligated to control such hemorrhage.

The ascending branches of the inferior thyroid artery are next encountered and after these are severed a wide degree of mobility of the gland is found possible. In fact, very often a large substernal mass may be elevated into the wound by the most gentle traction without inserting the finger into the mediastinum (Fig 9). This is

Fig 14 Method used in the closing of the divided sternohyoid muscles

necessary for ligation of the lower pole and removal of the gland.

The remnant of the lobe is outlined by Kelly hemostats placed along the periphery of the lobe (Fig 10), as the lobe is divided the blood vessels in the thyroid substance are clamped

Fig 15 Closure of muscles and fascia in the midline when the sternohyoid muscles are not divided

Fig. 12 Method of controlling hemorrhage from the remnant by two rows of interrupted fine silk sutures placed at different levels in the long axis of the neck. In interrupted sutures are placed through the edges of the remnant and the fascia and thyroid tissue of the trachea inverting the outer surface of the remnant to conceal its incised surface.

separated in the midline (Fig. 4) and at the supra sternal notch care is taken to avoid injury to the venous jugular arch. The sternohyoid muscles may be clamped and divided on one or both sides and the sternomastoid may be separated from the sternohyoid muscle and retracted laterally if exposure is inadequate (Fig. 5). Free separation of the thyrohyoid muscle from the gland is important (Fig. 6).

The larger thyroid lobe is attacked first. The lobe is elevated by goiter tenacula and the suspensory fascia is severed. As the upper pole is elevated the branches of the superior thyroid artery are clamped by Kelly hemostats and divided (Fig. 7). There are usually three or five terminal branches. After severing the arterial branches the superior pole which tends to be flattened and wedge shaped rolls outward from

its bed with perfect ease (Fig. 8). After the pole is mobilized a small strip of thyroid is left to form the upper part of the remnant in order to protect the recurrent laryngeal nerves which are the most vulnerable in this area of the thyroid field. It is believed that dividing the branches of the superior thyroid artery rather than the main artery or mass ligation of the superior pole has many safeguards. It avoids a mass ligature which often must be placed with poor exposure and under tension thus lessening the chance of immediate or post-operative hemorrhage from the superior thyroid vessels. We believe this prevents injury to the blood supply of the parathyroid because of the absence of permanent tetany in more than 4,000 of our operative cases. It also safeguards the internal branch of the superior laryngeal nerve which is now known to contain motor fibers to the

the wound This dressing is covered by two pieces of sterile cotton and the entire dressing is bound snugly to the neck by means of a gauze bandage

On the day following operation the dressing is removed and every other skin clip is removed. The pressure dressing is replaced by a flat gauze dressing After 48 hours the remaining skin clips are removed while after the fourth or fifth post-operative day the dressing may be disposed of entirely

The patients are discharged in from 8 to 10 days after operation, this period of time being necessary for the symptoms of hyperthyroidism to quiet down Hospital morbidity is thus from 3 to 7 days less than for previous methods.

SUMMARY

The technique of subtotal thyroidectomy as performed in this clinic, and as shown by the illustrations and the description has proved satisfactory.

The use of silk in thyroid surgery is entirely justified by the results that have been obtained in wound healing

Fig. 16. Illustrating the method of dressing the wound

(Fig. 11) All vessels are ligated with fine Dek-natol or a German made white silk. The remnant is fairly dry and is dropped into the thyroid bed while the remaining lobe is removed in a similar way. Two rows of interrupted fine silk sutures are placed in the cut surface of the remnant in the long axis of the neck for hemostasis and not too deeply placed to protect the nerves and parathyroids (Fig. 12). The remnants are then drawn to the midline and sutured by fine silk to the fascia of the trachea and the thyroid tissue is left along the trachea. The thyrohyoid muscles are then brought back to their original location and sutured together and to the lower portion of the remnant. This is an additional aid to complete hemostasis (Fig. 13). Closure is accomplished by

using interrupted fine silk sutures (Fig. 15). When the sternohyoid muscles have been divided the severed ends of the anterior jugular veins are ligated separately by transfixion sutures and then the edges of the muscles are sutured together by interrupted sutures (Fig. 14). The skin edges are brought into exact approximation and Van Wachenfeldt clips are applied (Fig. 16, 1). Beneath the flanges of the clips on either side a saline soaked gauze is then placed over the closed wound as shown in Figure 16, 2, and the entire wound is covered by a flat dry gauze dressing (Fig. 16, 3). An ordinary flat rubber sponge with notches cut in the upper edge to permit molding to the neck is placed as in Figure 16, 4, for distribution of pressure over the entire area of

Fig. 17. Illustration of the condition of the wounds on the fourth postoperative day

Fig. 18. Showing the condition of the wounds on the seventh postoperative day

infection does not go by way of the blood stream or lymphatics but travels along the cavity of the uterus to the tubes

As a result of this study, 5 conclusions were reached (1) When a patient had a complete occlusion at the uterine end of the tube, tubal infection did not recur and pus tubes did not develop, (2) that the uterus was the necessary avenue through which the infection reached the tubes from the cervix and the external genitalia, (3) that even in the presence of the uterus, a total absence of infection from the internal os downward prevented re-infection, (4) the cured infected tube did not spontaneously re-infect itself, (5) salpingitis did not develop in those patients in whom the connection between the uterine cavity and the tubes had been broken in spite of a gonorrheal infection of the lower genital tract

It was then argued that if these conclusions were correct, 1 of 4 procedures could be followed in order to prevent re-infection of the tubes. (1) Clear up all foci of infection and not allow sex trauma, (2) do a hysterectomy, (3) remove the infected tubes with or without fundectomy, or (4) resect the tubes at the cornu of the uterus

Which procedure should be followed? Procedure 1 could be followed if the patients would co-operate, but it is usually impossible to prevent sex trauma. Infections have occurred in some cases following sex trauma where one could absolutely exclude re-infection from the consort. As a result of the impossibility of control the first procedure, although it can be carried out, is usually doomed to failure

Procedure 2, or hysterectomy, is rather radical surgery for infected tubes, patients will not submit to it, the mortality and morbidity is too high, and it breaks every principle of preserving as much of the pelvic organs as possible

Procedure 3, or the removal of the tube with or without resection of the fundus, is an excellent procedure but still somewhat radical. In removing the tubes with or without a piece of the fundus, the blood supply to the ovaries may be interfered with, and those patients on follow-up frequently present ovarian cysts with associated symptoms

Procedure 4, or the resection of the tubes, carries with it a minimum of surgery, and if it will clear up the condition and prevent re-infection, it should be the method of choice

Tubal resection is indicated in those patients who have had repeated attacks of salpingitis covering a period of one year with a relative disability or incapacity for work during this time. They should give a history of sterility during this

Fig 1 Figure-of-8 suture A, B, C, D, E, inserted through the cornu of the uterus, clamp F applied to uterine end of tube. V shaped excision of the uterine end of tube. The mesosalpinx is cut close to the tube so as to free slightly the uterine end of the tube

period and on vaginal examination should show persistent palpable masses

Surgically the requirements are that the patient be a good surgical risk as far as her other vital organs are concerned. She must have had a normal temperature for at least 14 days with a leucocyte count of less than 10,000 and a sedimentation time longer than 30 minutes for 18 millimeters in the Linzenmeyer tube

TECHNIQUE OF THE OPERATION

The abdomen is opened by a left paramedian incision from the symphysis to the umbilicus. After insertion of the self-retaining retractor, 3 laparotomy pads are placed so as to pack away the omentum and intestines. The adhesions of the omentum and small intestines to the pelvic organs are severed by blunt or sharp dissection. The fundus of the uterus is identified and the adnexa are inspected. *The condition of the ovaries is the deciding factor for the type of operation to be performed.* If ovarian pathology such as abscess or cyst is found, a salpingo-oophorectomy is performed. If no ovarian pathology is found, a resection of the tube can be carried out

A figure-of-8 stitch (Fig 1, A-B-C-D-E) is inserted in the uterine horn, proximal to an artery clamp (Fig 1, F) placed on the uterine end of the tube. A V shaped excision of the uterine end of the tube is carefully made so as not to injure the underlying ovarian branch of the uterine artery. The proximal end of the tube is then freed from its mesosalpinx by cutting the mesosalpinx close to the tube for a distance of about 1 centimeter. The figure-of-8 suture, A to E, in the uterus is tied, left long, and a clamp is applied

TUBAL RESECTION AS A TREATMENT FOR RECURRENT GONORRHEAL SALPINGITIS

HENRI C. FALK, M.D., F.A.C.S. and GEZA WEITZNER, M.D.
New York, New York

SALPINGITIS is a well defined clinical entity and constitutes one of the most important chapters in gynecology. The salpingitides are divided on an etiological basis into 3 groups: gonorrheal salpingitis, septic salpingitis, and tuberculous salpingitis. In this discussion the term recurrent salpingitis will be used as a synonym for recurrent gonorrheal salpingitis.

Practically every case of primary gonorrheal infection of the tube can be cured if reinfection can be prevented. A woman who is financially able to take care of herself and who is willing to follow instructions carefully can be promised an almost complete recovery under proper medical treatment. The difficulty in any large city lies in the following facts: first, the patients not understanding the seriousness of their condition will not follow the instructions given them; second, if they understand the seriousness of the condition and desire to follow the instructions, they cannot because of their financial condition which requires them to return to work too soon; and lastly, most of these patients have to support themselves, therefore they cannot interrupt their periods of occupation too frequently or they lose their positions. As a result of these factors a great many patients in our city institutions must be operated upon not because of the pathology present but to prevent frequent attacks of incapacitating symptomatic salpingitis.

What operative procedure shall be the one of choice in these cases? Salpingectomy is a relatively safe and useful operation if practised in accordance with the principles laid down by Simpson and Curtis. Yet it has several disadvantages: (1) It has a primary mortality of 1 per cent and a fairly high percentage of postoperative morbidity. (2) The technical difficulties encountered during the operation frequently leads to radical surgery of the ovaries and uterus producing a surgical menopause which is contrary to all principles of conservative gynecology. (3) Postoperative exudates or indurations may require prolonged treatment or even a secondary

operation (Norris 58 per cent). Postoperative cyst formation in the ovaries due to impaired circulation and postoperative adhesions producing symptoms do occur. (4) The loss of the fallopian tubes occasionally has a bad psychological effect on some patients.

The operation to be described is presented as a conservative procedure to prevent the above described sequelae. It retains the tubes and prevents their reinfection. The observations (2) which furthered the belief that this procedure would and could prevent reinfection of chronically infected tubes were that:

1. In spite of the known fact that a gonorrheal infection of the tubes is always bilateral, patients were seen frequently who had a pus tube on one side and a fairly normal tube on the other. As a result of this observation several of these apparently normal tubes were removed and examined. It was found that the apparently normal tube there always had obstruction at the uterine cornu, whereas the tube on the other side, the connection with the uterine cavity seemed to be maintained.

2. When a hysterectomy was performed on a patient with chronic bilateral tubal infection, the inflammation disappeared and reinfections did not occur. In looking over the literature, hysterectomy is found to be described as a treatment for pus tubes (4).

3. When a patient with quiescent pus tubes was adequately treated so as to remove all gonorrheal infection from the lower genitalia (cervix, urethra, etc.) and she was separated from her contact to prevent reinfection, the tubal infection as a rule cleared up and did not recur.

4. Simpson and Curtis have shown that gonorrheal salpingitis is a self-limited disease and the organisms die in the tube 2 weeks after the temperature is normal. As a result the tube cannot re-infect itself; the infection must come from without the tube.

5. Those patients whose tubes had been resected close to the uterus for sterilization purposes never developed salpingitis in spite of a gonorrheal infection of the lower genital tract (cervix, urethra, etc.) thus showing that gonorrheal

Read before the Section of Obstetrics and Gynecology of the 46. Army of Medicine, New York, Oct. 20, 1937.

5 patients had small masses, 6 patients had larger masses

Clinical 76 patients reported themselves clinically cured or asymptomatic; 13 patients had slight symptoms, 6 patients had definite symptoms

Economic 83 patients were able to perform their usual work, 12 patients had sufficient symptoms to interfere with work

No patients have had to be re-admitted for severity of the symptoms or for a recurrence of a salpingitis. There have been no re-operations on account of pelvic disease. One patient who had a bilateral resection was re-operated upon 14 months later for intestinal obstruction. The obstruction was due to upper abdominal pathological conditions. A negative pelvis was found

CONCLUSIONS

Cornual resection of the tubes is offered as a surgical procedure for the cure of recurrent gonorrheal salpingitis. It involves a minimum of surgical trauma and in 112 cases gave the follow-

ing results: (1) no primary mortality, (2) no primary pelvic morbidity, (3) 70 per cent perfect, 14 per cent good, and 7 per cent fair anatomical results; (4) 79 per cent symptom free patients, 21 per cent with slight symptoms; (5) 87 per cent fit for manual labor, 13 per cent with only partial incapacity, (6) no re-operations for pelvic disease, and (7) no re-admissions for recurrent salpingitis

Fig 2 1 Cornual figure of 8 suture tied. Ligature placed around uterine end of tube B and tied. Long end of suture threaded on a needle and passed through posterior wall of the uterus C, from medial to lateral under the round ligament of ovary.

Fig 3 All sutures tied. Litterine end of tube inverted covering all raw areas.

A ligature is then applied to the cut end of the tube (Fig 2, B) and the clamp is removed. The long end of this suture is threaded on a needle which is passed through the posterior wall of the uterus below the round ligament of the ovary (Fig 2 C) and tied. This automatically causes the cut end of the tube to be inverted under the tube itself (Fig 3, B). The same procedure under the same conditions is carried out on the other side.

RESULTS

In this series 112 patients have been operated upon. The first operation was performed May 17, 1934, the last included in this series was done on November 28, 1936.

Pre-operative data. The youngest patient was 20 years old, the oldest was 42. 87 patients were in the 20 to 29 year group, 23 in the 30 to 39 year group, and only 2 were 40 years or over. The shortest pre-operative stay in the hospital was 2 days, the longest period 60 days, and the average was 17.3 days. All patients complied with the routine conditions and indications for the operation.

The operations performed were as follows: bilateral resection in 5 patients, left salpingo-oophorectomy, right tubal resection in 37, right salpingo-oophorectomy, left tubal resection in 28, ovarian suspension in 18, uterine suspension in 92, and appendectomy in 70.

The following pathological lesions were seen at operation and allowed to remain in the pelvis: A small mass, the tube measuring up to 2 centimeters was found 51 times; a medium sized mass pyosalpinx, the tube measuring 3 to 4 centimeters was seen 35 times, a large mass, the tube measuring more than 4 centimeters in diameter, occurred 26 times.

In 106 patients the operations were performed as the operation of choice, on 6 occasions they were performed as operations of necessity. In these latter cases the surgeon's intention was to do some other type of procedure but the difficulties encountered made it advisable to shorten the operation. As a result a cornual resection was resorted to instead of the usual salpingectomy or salpingo-oophorectomy. The 106 operations of choice were performed without operative complications and without drainage. The 6 operations of necessity were all drained: 4 abdominally and 2 vaginally.

POSTOPERATIVE COURSE

In the group of the 106 cases one patient had a pulmonary complication which delayed the patient's discharge until the twentieth postoperative day. All other patients were discharged on the twelfth to the fourteenth day. There were no wound infections. In the 6 patients in whom the operation was one of necessity, all were discharged from the thirteenth to the twenty-ninth day.

Follow-up. Ninety-five patients or 85 per cent of those operated upon have been seen in the follow-up clinic one or more times. The duration of observation ranged from 2 to 30 months. All patients are usually seen 6 weeks after the operation and thereafter at bi-monthly intervals. Some patients have been seen only once, most of them on several occasions.

The results have been tabulated on an anatomical, clinical, and economic basis.

Anatomical. 67 patients had an absolutely negative pelvis, 17 patients had induration only.

5 patients had small masses, 6 patients had larger masses

Clinical 76 patients reported themselves clinically cured or asymptomatic, 13 patients had slight symptoms, 6 patients had definite symptoms

Economic 83 patients were able to perform their usual work, 12 patients had sufficient symptoms to interfere with work

No patients have had to be re-admitted for severity of the symptoms or for a recurrence of a salpingitis. There have been no re-operations on account of pelvic disease. One patient who had a bilateral resection was re-operated upon 14 months later for intestinal obstruction. The obstruction was due to upper abdominal pathological conditions. A negative pelvis was found.

CONCLUSIONS

Cornual resection of the tubes is offered as a surgical procedure for the cure of recurrent gonorrheal salpingitis. It involves a minimum of surgical trauma and in 112 cases gave the follow-

ing results (1) no primary mortality, (2) no primary pelvic morbidity, (3) 70 per cent perfect, 14 per cent good, and 7 per cent fair anatomical results, (4) 79 per cent symptom free patients, 21 per cent with slight symptoms, (5) 87 per cent fit for manual labor, 13 per cent with only partial incapacity, (6) no re-operations for pelvic disease, and (7) no re-admissions for recurrent salpingitis

ENCAPSULATED INTRAMEDULLARY TUMOR INVOLVING THE WHOLE SPINAL CORD FROM MEDULLA TO CONUS COMPLETE ENUCLEATION WITH RECOVERY

GILBERT HORRAN, M.D., F.A.C.S. and DONALD G. HENDERSON, M.D. Boston, Massachusetts

ALTHOUGH individual case reports are seldom of sufficient interest to warrant special and detailed tabulation, it so happens that occasionally a patient comes under observation with a condition so unique that one is urged from this standpoint alone to make a note of it if for no other purpose than to put it on record in medical literature. Besides this, in the present instance we feel that there are at least 2 additional points to which attention should be drawn, namely the possibility of doing an almost complete laminectomy and, secondly, the surprising extent of recovery of function following what amounted to a practically complete anteroposterior transection of the spinal cord throughout its entire length.

CASE HISTORY

A young woman 29 years of age was referred to The Lahey Clinic and the New England Deaconess Hospital on December 6, 1936 complaining of paralysis of the legs and difficulty with her bowels and bladder. The salient features of her past history were these. She had been admitted to a hospital in another city on September 18, 1930 at which time she had been having high dull backache and for one year was unable to use her legs. Because of her painful symptoms lipiodol was injected and this was said to have shown a block in the upper dorsal region. Laminectomy was performed on September 29, 1930 at which time the cord was exposed from the level of the seventh cervical to the fourth dorsal vertebra. No pulsation was seen. The dura was opened and the cord appeared edematous. Nothing further was done; the dura and muscles were closed and the condition was thought to be a myelitis. A cord bladder developed for which a suprapubic cystostomy was instituted.

The patient showed practically no change for about 1 year and then began to have some warning of micturition and a little motion in her legs developed. In January 1932 the cystostomy tube was removed and she was able to void voluntarily. Gradually during the next 2 years the strength of her legs returned and in the spring of 1934 she resumed her former position as cashier in a theater. She was able to walk to and from her work, went to dances and seemed perfectly well for about 1 year. During 1935 she again began having difficulty in walking and this increased to such a degree that by April 1936 she was once more confined to a chair. On November 3, 1936 she was readmitted to the same hospital where she had been before and was transferred from there to Boston. There ultimately

her blood and spinal fluid Wassermann tests had been negative repeatedly.

When admitted to the New England Deaconess Hospital on December 6, 1936 she presented the following clinical picture. She was a well nourished young woman lying in bed without any great degree of discomfort. Cerebration was normal and her cranial nerves were normal throughout.

Motor system. Both legs were almost completely paralyzed although a very slight amount of extension at the knees was possible if the legs were held flexed by the examiner. Both arms and both hands retained fairly good strength, the left being slightly weaker than the right. There was some involuntary flexion of the thighs upon stimulation with a pin point over various areas of the legs or the dorsum of either foot.

Sensation. The patient showed a sensory level at the third rib anteriorly and the third dorsal spine posteriorly below which pain and temperature sensations were almost wholly lost, the loss of pain being the more complete of the two. There was marked hypoesthesia to pain and temperature on the medial aspects of both arms and both hands. Light touch was fairly well preserved over the area just described, there being more diminution of this type of sensation over the lower extremities than the upper. Deep pressure pain was lost in the legs but was present in the arms. Vibratory sensation was lost below the hips, diminished in the left arm and present in the right arm (Fig. 2).

Reflexes. All deep reflexes were bilaterally overactive except the Achilles jerks which were absent. There was at times a positive Babinski on the left but no sustained ankle clonus.

Sphincters. She had been having difficulty with voluntary control of both bowels and bladder but this loss of function was not complete.

Lumbar puncture was carried out on December 9, 1936. The spinal dynamics showed a complete block. The lipiodol which had been injected previously could not be made to pass upward beyond the body of the eleventh dorsal vertebra.

Spinal fluid examination showed deeply xanthochromic fluid with a total protein of 1200 milligrams.

First stage operation. December 10, 1936. A cervicodorsal laminectomy was carried out and the spines and laminae from the axis to the seventh dorsal vertebra inclusive (the first to third dorsal had been removed at her operation elsewhere) were removed. Upon incision of the dura over this area the whole length of exposed cord appeared greatly widened and thinned out, the pect being that of a huge cystic cord. The blood vessels on the surface were spread apart and the cord had a grayish color. On the assumption that the condition was syringomyelia a fine needle attached to a syringe was inserted into the widest part of the cervical region but when suction was made no fluid was obtained.

The dorsal a pect of the cord was therefore incised in the midcervical region and at a depth of 2 to 3 millimeters

the surface of an apparently encapsulated intramedullary tumor was encountered. The growth was quite firm and of a brownish-gray color. The incision in the cord was now carried upward to the lower end of the medulla and downward to the inferior end of the dural opening. There was a tendency for the tumor to bulge through this incision. Growth could be separated from the attenuated cord on either side by gentle retraction and dissection with small moist cotton pledgets, and in this way it was followed upward to its superior pole at the lower limits of the medulla. When this upper pole was freed it could be grasped with a forceps and lifted outward, thus making it possible to peel the tumor out of its bed by gently brushing away the slightly adherent cord tissue below it. In this way it was enucleated down to the lower end of the cord incision at about the level of the fifth dorsal vertebra (Fig 2). Here a silk ligature was tied around the growth and it was divided just above the ligature, the remaining tumor below this (of unknown extent at this time) being left to be taken out at a second stage operation, since the present procedure had lasted some 5 hours or longer. The patient on the whole was in very good condition although toward the latter part of the operation her blood pressure had dropped to about 80 millimeters systolic and 55 millimeters diastolic. She was given a transfusion of 250 cubic centimeters of blood.

The tumor was cylindrical and a little over 2 centimeters in diameter (Fig 3). It almost bisected the cord anteroposteriorly so that along the anterior aspect of its bed there could be seen only 1 to 2 millimeters of cord substance and at some points only the pia and arachnoid had been left.

Second stage operation, December 16, 1936 At this session the spines and laminae of the remaining dorsal vertebrae as well as the first and second lumbar were removed. After the dura was opened over this area the dorsal aspect of the cord was incised from the lower end of the previous operation down to the end of the conus, thus exposing the remaining portion of tumor which extended the entire length of the cord. This lower end of growth was peeled out in the same manner as at the primary operation. A portion of this lower end of tumor proved to be cystic but with a

definite capsule and not merely a syringomyelic cavity (Fig 4). The cystic contents were first removed so as to gain room and make less damage to the cord, then the capsule of the cystic portion was grasped, lifted outward, and gently dissected free from its bed (Fig 5). The dura and muscles were then closed in the usual careful layers.

Pathological report The specimen consisted of 2 parts, roughly cylindrical, and its total length was 38.5 centimeters (Fig 6). The upper piece had a diameter of 2.2 centimeters for a distance of 5 centimeters then gradually narrowed to 1.5 centimeters for the middle 19.5 centimeters. The lower portion of 14 centimeters was a thin walled, tube-like structure 0.5 centimeter in diameter.

ENCAPSULATED INTRAMEDULLARY TUMOR INVOLVING THE WHOLE SPINAL CORD FROM MEDULLA TO CONUS COMPLETE ENUCLEATION WITH RECOVERY

GILBERT HORRAX M.D. I.A.C.S. and DONALD G. HENDERSON M.D. Boston, Massachusetts

ALTHOUGH individual case reports are seldom of sufficient interest to warrant special and detailed tabulation, it so happens that occasionally a patient comes under observation with a condition so unique that one is urged from this standpoint alone to make a note of it if for no other purpose than to put it on record in medical literature. Besides this in the present instance we feel that there are at least 2 additional points to which attention should be drawn, namely, the possibility of doing an almost complete laminectomy and, secondly the surprising extent of recovery of function following what amounted to a practically complete anteroposterior transection of the spinal cord throughout its entire length.

CASE HISTORY

A young woman 20 years of age was referred to The Lahey Clinic and the New England Deaconess Hospital on December 6, 1936 complaining of paralysis of the legs and difficulty with her bowels and bladder. The salient features of her past history were these. She had been admitted to a hospital in another city on September 18, 1930 at which time she had been having high dull backache and for one year was unable to use her legs. Because of her spinal symptoms lipiodol was injected and this was said to have shown a block in the upper dorsal region. Laminectomy was performed on September 29, 1930 at which time the cord was exposed from the level of the seventh cervical to the fourth dorsal vertebra. No pulsation was seen. The dura was opened and the cord appeared edematous. Nothing further was done. The dura and muscles were closed and the condition was thought to be a myelitis. A cord bladder developed for which a suprapubic cystostomy was instituted.

The patient showed practically no change for about a year and then began to have some warning of micturition and a little motion in her legs developed. In January 1932 the cystostomy tube was removed and she was able to void voluntarily. Gradually during the next 2 years the strength of her legs returned and in the spring of 1934 she resumed her former position as cashier in a theater. She was able to walk to and from her work, went to dances and seemed perfectly well for about a year. During 1935 she again began having difficulty in walking and this increased to such a degree that by April 1936 she was once more confined to a chair. On November 2, 1936 she was readmitted to the same hospital where she had been before and was transferred from there to Boston. The results of

her blood and spinal fluid Wassermann tests had been negative repeatedly.

When admitted to the New England Deaconess Hospital on December 6, 1936 she presented the following clinical picture. She was a well nourished young woman lying in bed without any great degree of discomfort. Cerebration was normal and her cranial nerves were normal throughout.

Motor system. Both legs were almost completely paralyzed although a very slight amount of extension at the knees was possible if the legs were held flexed by the examiner. Both arms and both hands retained fairly good strength, the left being slightly weaker than the right. There was some involuntary flexion of the thighs upon stimulation with a pin point over various areas of the legs or the dorsum of either foot.

Sensation. The patient showed a sensory level at the third rib anteriorly and the third dorsal spine posteriorly below which pain and temperature sensations were almost wholly lost, the loss of pain being the more complete of the two. There was marked hypoesthesia to pain and temperature on the medial aspects of both arms and both hands. Light touch was fairly well preserved over the area just described, there being more diminution of this type of sensation over the lower extremities than the upper. Deep pressure pain was lost in the legs but was present in the arms. Vibratory sensation was lost below the hips, diminished in the left arm and present in the right arm (Fig. 1).

Reflexes. All deep reflexes were bilaterally overactive except the Achilles jerks which were absent. There was at times a positive Babinski on the left but no sustained ankle clonus.

Sphincters. She had been having difficulty with voluntary control of both bowels and bladder, but this loss of function was not complete.

Lumbar puncture was carried out on December 9, 1936. The spinal dynamics showed a complete block. The lipiodol which had been injected previously could not be made to pass upward beyond the body of the eleventh dorsal vertebra.

Spinal fluid examination showed deeply xanthochromic fluid with a total protein of 1200 milligrams.

First stage operation. December 10, 1936. A cervicodorsal laminectomy was carried out and the pines and laminae from the axis to the seventh dorsal vertebra inclusive (the first to third dorsal had been removed at her operation elsewhere) were removed. Upon incision of the dura over this area the whole length of exposed cord appeared greatly widened and thinned out, the pect being that of a huge cystic cord. The blood vessels on the surface were pressed apart and the cord had a grayish color. On the assumption that the condition was syringomyelia a fine needle attached to a syringe was inserted into the widest part of the cervical region but when suction was made no fluid was obtained.

The dorsal aspect of the cord was therefore incised in the midthoracic region and at a depth of 2 to 3 millimeters

Fig 6 Photograph of the entire tumor, pieced together

charge she had begun to move the toes of both feet and the ankle on the right side, and slight flexion was possible at the right knee. She had regained the function of bowels and bladder which had been lost completely after operation, and was up in a chair several days before leaving. On January 30, 1937 she was discharged to her home, 6½ weeks after her second operation (Fig 9).

Follow-up notes. The patient has reported from time to time by letter indicating her progress. She has slowly regained almost full use of her right hand and both arms but the left hand is still somewhat weak. Both legs regained strength slowly, and on June 2, 1937, 6 months after operation, she was able to stand with support. Her back has never given her any trouble from weakness. By July 13, 1937, she was able to take a few steps with support and her letter of October 4, 1937, stated that she was standing and taking steps with support every day, the right leg being much better than the left. Her last letter, February 2, 1938, 14 months after operation, was most encouraging. To quote "I walk every day with help on each side of me. The right leg is wonderful. I think it is almost back to normal (Fig 10). The left leg has to be pushed along but sensation seems to be better all through the left side."

DISCUSSION

A fairly complete review of the literature has revealed only 2 instances of intramedullary tumors, which were encountered at operation and removed, at all comparable in size and length to that of our patient. The first of these was reported by Cushing in 1927.

This tumor was an ependymoma in a girl 8 years of age, and it extended from the medulla to the second thoracic level. The dorsal aspect of the cord was incised as in our case and the growth, which was soft, removed by suction. At this first operation a laminectomy from the atlas to the second thoracic vertebra inclusive was performed. Thinking that the tumor extended below this lower level, a second stage operation was carried out removing the remaining thoracic and the first 2 lumbar laminae. Only a hydromyelic cavity, however, was found throughout this lower end of the cord. The child made an excellent recovery, and was practically normal for 5 years.

The other instance in which a long intramedullary growth was operated upon was Case 3 reported by Foerster and Bailey in 1936. The tumor extended from the first cervical to the ninth thoracic level. It was removed piece-meal at operation, but unfortunately the patient died the following day. The tumor was an astrocytoma.

Several instances of long, intramedullary growths, which were discovered at necropsy, are quoted by Foerster and Bailey in the important article in which they report their own experiences. These are the cases of Hatschek, a myxoglioma of the entire cord, of Miura, a glioma extending from the midcervical to the lower lumbar region, of Nonne, a sarcoma involving the first cervical to the tenth dorsal segments, of Schueppel, a gliomyxoma extending from pons to conus, of Schultze, a gliosarcoma from bulb to conus, of Taterka, a fascicular glioma from bulb to the twelfth thoracic

after removal. It was from this portion that the cystic fluid had been evacuated at operation and when distended its diameter was fully equal to the upper end of the growth.

The tumor grossly had a delicate capsule intact except for small foci of traumatic disruption. A surface network of hyperemic fine blood vessels was apparent throughout and an occasional superficial minute hemorrhage was noted. The upper 24.5 centimeters was soft gray and the cut surface showed the center softer and more hemorrhagic than the periphery. Delicate longitudinal striations were faintly visible in the deeper portions. The tube-like structure was collapsed; it had a smooth white lining, a homogeneous elastic wall and a finely shaggy surface.

Microscopically, with hematoxylin-eosin and phosphotungstic acid-hematoxylin, the sections showed no definite capsule but surface layers that were interlacing and gave the appearance of being compressed. The bulk of the tumor was well vascularized. Large cells having scanty cytoplasm and oval nuclei with heavy chromatin network tended to arrange themselves about blood vessels; they were mostly unipolar with the processes extending toward the perivascular spaces (Fig. 2). Between these rosette-like arrangements, smaller cells were growing singly and an occasional star cell could be determined. The stroma was scanty and blepharoplasts were definite but minimal. Mitotic activity was absent (Fig. 8). An occasional small empty canal lined by ependymal cells was present but that was a minor feature. Necrosis was absent. The lower sac-like portion had both inner and outer lining surfaces to be composed of compressed small cells having longitudinally interlacing processes, scanty cytoplasm and oval deeply stained nuclei. The wall was homogeneous and consisted of similar though larger cells. Microscopically the tumor corresponded to Kernohan's cellular type of ependymoma.

Postoperative course. The patient recovered promptly from each of her 2 long laminectomies. Her arms and hands were at first not as strong as they had been before operative intervention but they began to show improvement before she left the hospital. Likewise by the time of her dis-

It might be asked whether merely splitting the whole length of the cord posteriorly and leaving the dura open might not have given her more prompt and complete recovery than she has shown up to the present time. This is a possibility, but in that case she would still retain her tumor and at some future time would have to undergo the same extensive operative procedures with perhaps even greater technical difficulties than at the original session. It does not, therefore, seem to us that such a course would have been advisable.

Another subject which should be mentioned is the ability to recover from a complete antero-posterior transection of the spinal cord. In our own patient this transection was complete in certain places in the cervical region where only the pia arachnoid was visible anteriorly, and throughout the entire cord there were probably only 1 to 3 millimeters of cord substance remaining anterior to the tumor. As told in the patient's follow-up reports, she has recovered the motor function of her right leg almost completely, but sensation is poor in this leg, whereas with the left leg the reverse is true. In Foerster and Bailey's Case 3 a similar complete transection was made, but the ability to recover could not be followed up owing to the death of the patient within 24 hours. No mention was made as to the completeness of the spinal cord transection in the other cases which have been reviewed.

From the pathological standpoint the incidence of primary ependymomas to other intramedullary spinal cord tumors has not been accurately deter-

mined, but in a series of 51 cases Kernohan, Woltman and Adson found that they represented 42 per cent. Of the gliomas in the region of the cauda equina the incidence rises to 68 per cent (8). This type of tumor is relatively slow growing and has not been observed extending outside nervous tissue. The sections of the specimen reported here show no definite capsule, but the compressed surface layers, lack of mitotic activity, and presence of well differentiated cells, all indicate low invasive tendencies.

vertebrae of Thielen, a neuro-epithelioma gliomatousum from the upper cervical region to the conus and of Zinn another neuro-epithelioma gliomatousum from the first cervical to the conus.

The second question which would seem appropriate to discuss in connection with the case reported here has to do with the actual operation performed. The propriety of removing intramedullary tumors completely has been questioned, since at times more damage may be done to the cord by radical removal than would have been the case had the dorsal columns merely been incised, the tumor allowed to extrude partially, and then more or less completely removed at a secondary operation. This method was advocated by Elsberg in 1925 and doubtless has its advantages in soft infiltrating tumors. Furthermore, it has been held as almost axiomatic that an attempt to extirpate intramedullary growths involving the fourth cervical segment should not be made because of the grave danger of respiratory cessation.

So far as both these questions are concerned there is now considerable evidence in the literature, including our own case, to make us believe that in the encapsulated tumors such as the ependymoma here reported a careful complete extirpation no matter what the level is the procedure of choice. This attitude is taken by

Fig. 10 Snapshots of the patient at her home March 16 1938

Kernohan, Woltman and Adson (6) and re-emphasized by Adson (1935) in his discussion of the important paper by Kernohan and Fletcher Kernohan (7). Mention has been made already of the patient operated upon by Cushing in 1927 in which no untoward feature occurred during the removal of the cervical portion of an extensive ependymoma. Other cervical intramedullary growths which have been extirpated radically without serious respiratory upset were reported by Cairns and Riddoch (1931) by Adebstein and Paterson (1934) and by Foerster and Bailey (Case 7) 1936. On the other hand in Case 4 of Foerster and Bailey death was caused by respiratory paralysis.

An interesting point in reviewing our own case comes out in the extraordinary relief of symptoms which the patient obtained after her original small exploratory laminectomy in 1930. It will be remembered that at this time the dura under the upper 3 thoracic vertebrae was opened, the cord inspected and the dura again closed. She remained paraplegic for approximately a year, then gradually improved for 2 years and during the year 1934 she resumed her usual work walking about going to dances and so forth. It is difficult to explain this improvement on the basis of the operation but it may be that during the ensuing year there was sufficient atrophy of the vertebrae by pressure from the tumor to give a spontaneous decompression to the cord.

At the time of our operation patient was paraplegic with beginning sphincteric incontinence

Fig 1 a, left, Fresh fracture, immobilization in non-padded plaster for 6 weeks, time off from work 8 weeks b, Appearance after 6 weeks

first hour after injury. Early recognition and treatment thus being made possible, open reduction of any fractured bone was the exception, because of the ease of closed reduction in an early case. We maintain that the practice of waiting overnight or days later to accomplish a reduction is a serious mistake and conducive to unfavorable results. The newer school advocates open operation with bone graft inlay for these fractures and reports good results in all cases. About one third of this series of scaphoid fractures were simply immobilized upon cock-up splints in a position of moderate dorsiflexion and slight radial flexion. In the latter two thirds we applied unpadded plaster casts with the wrist in the same position, and with the thumb fully abducted and incorporated in the cast. The plaster extended only to the distal palmar crease, thus allowing full movement of the fingers. The fact that end-results in all cases were the same argues for the belief that early treatment is the keynote, not the method nor the fixation in any exaggerated position. There can be no question concerning the efficiency of unpadded plaster in satisfying the third requirement of adequate fixation. Immobilization was generally maintained for 6 to 8 weeks depending upon the extent of healing shown by x-ray examination, although our results show the average entire compensable time to be 6.62 weeks. In 2 cases the patients were foremen and returned to work in 9 and 16 days respectively, while 2 others returned to light work as watchmen in 2½ and 3½ weeks, with their casts on and still under treatment. The

average length of treatment was about 10 weeks.

Roentgenograms were taken at the time these men were rated by the Industrial Accident Commissions of Nevada or Arizona, usually 3 to 4 months after they had returned to work. Only 2 of the 16 failed to show bony union. The criteria for bony union were complete obliteration of the fracture line, with the proximal fragment showing the same density as the distal. One of the 2 cases of non-union had also a comminuted fracture of the radius and a fractured hamate. After reduction the wrist was held in slight palmar flexion and in a mid position between ulnar and radial deviation with the thumb partially adducted. This would seem to indicate the importance of position in healing of the scaphoid, if it could be shown that position alone brings as high a percentage of bony union. We have had experience with only one old non-union of a scaphoid. This was seen by one of us in private practice.

The patient, one year after the original injury, complained of a painful wrist. He was doing his regular work, but felt that he could not do it as well as he had previously. Tenderness and slight swelling were present in the anatomical snuff box and x-ray films showed a fracture of the proximal third of the scaphoid with some cystic rarefaction about the site of the fracture. The apposition and alignment of the fragments were good. After the method described by Haldeman and Soto Hall, horizontal incision was made over the scaphoid which was exposed. Several drill holes were made through the fragments, the wound was closed, and a non-padded plaster cast was applied with the wrist in the dorsal ulnar position. This cast was left on for 14 weeks and the patient was returned to light work 2

ACUTE FRACTURES OF THE CARPAL SCAPHOID

RUSSELL F. JAEHLF, M.D. and ALBERT C. CLARK, M.D., San Francisco, California

In handling a large number of fractures during the construction period at Boulder Dam we were quite interested in observing that our percentage of fractures of the carpal scaphoid was high as compared to other bony injuries about the wrist. The statistics regarding the percentage of these fractures reported by other authors have varied considerably, but we feel that our statistics may be considered as typical for purely industrial practice.

A comparison of fractures of the carpal scaphoid with other more common fractures is given here with carpal scaphoid 17, humerus 25, radius 63, clavicle 16, femur 21, tibia 85, fibula 78, os calcis 43.

The literature on this subject is somewhat disconcerting. Cravener, reporting on fractures of the carpal scaphoid, states that non union is very prone to occur in fractures through the waist, while fractures through the tuberosity are of relatively little importance. Murray states that fractures of the tuberosity always unite satisfactorily and that fractures through the waist if immobilized early, will also give satisfactory results. Both of these authors are inclined to believe that non union is due to delayed immobilization. Boehler also reports satisfactory results with immediate fixation. Hosford agrees with the above authors on the results obtained with immediate immobilization, except he states that fractures through the proximal third of the bone have a tendency to non union due to the interference with the blood supply. Scudder is more radical recommending total excision of the involved bone whenever there is a comminuted fracture. When immobilization without open reduction is done it is generally advised that this immobilization be maintained for a period of 6 to 8 weeks. Almost all positions have been advised for the immobilized wrist. Boehler recommends dorsal ulnar flexion. Speed recommends a slight volar and radial flexion and Soto Hall and Haldemann advise a dorsal radial position. As far as reported results are concerned it is difficult to arrive at any definite conclusions because of the fact that the final results are not uniformly rated but are merely said to be good, fair or poor. This type of information is not always helpful.

From the first aid service Six Companies Hospital, Boulder City, Nevada

DIAGNOSIS

The history of these cases is that of a fall on the hyperextended hand with resultant pain and some swelling in the wrist at the base of the first metacarpal. It can be unequivocally stated that any painful or so called sprained wrist occurring after a fall on the outstretched hand should always be x-rayed. On physical examination we have almost always found tenderness and occasionally swelling in the anatomical snuff box. Motion of the wrist is not limited except by moderate pain. Many authors have reported that the diagnosis is confirmed by percussion on the head of the second metacarpal when the fist is clenched. This is supposed to elicit pain in the region of the scaphoid. Frankly we have never used this test and have always found the diagnosis to be easy enough provided the possibility of such a fracture has been considered.

It has also been mentioned frequently that the x-ray is not infallible. It is particularly misleading when one simply has an anteroposterior view and a lateral view made such as one would desire for a possible Colles fracture. It is advisable to take at least one view with the wrist ulnar deviated and in questionable cases, a stereoscopic view should be taken with the wrist in this position. Some roentgenologists advise the use of a magnifying lens when studying these films. Wet films should never be used in determining the presence of these fractures. In the final analysis we believe that if the physician calls the attention of the roentgenologist to the possibility of a fractured carpal scaphoid these fractures will not be missed frequently on the x-ray plate.

TREATMENT

The results of treatment of any fracture are enhanced by (1) early recognition (2) early treatment and (3) adequate immobilization for a sufficient time to allow healing. Because of the nature of cancellous bone (its location, structure and blood supply) when fractured it is difficult to obtain healing and these factors assume increased importance.

We have nothing new to offer in treatment but only wish to emphasize the important part early treatment has played in our results. Because of an ideal setup for medical care at Boulder Dam our patients were almost always seen within the

immobilization in the accepted position with unpadded plaster for 7 to 8 weeks, one can expect no total permanent disability and 87½ per cent of bony union

These results in acute fractures and in the one old case of non-union which we report, plus the numerous other excellent results obtained in the treatment of old non-unions by drilling or grafts, we believe should definitely contra-indicate excision of the carpal scaphoid under any condition

CONCLUSIONS

- 1 Immediate immobilization is stressed.
- 2 Failure of bony union occurred in only 2, or 12½ per cent of the acute fractures.
- 3 Disability ratings in the acute fractures, including the 2 cases lacking bony union, have been uniformly zero

Fig. a Non union of fracture 1 year old b Appearance 10 weeks and c 30½ weeks after drilling Patient's wrist was in non padded plaster 14 weeks and he was away

from work 16 weeks No disability Note fracture line disappearing and the gradual return of blood supply as evidenced by decreasing density of the proximal fragment

weeks later Bony union was partially completed when the last roentgenogram was taken 6½ months after the operation The patient has full range of motion of the wrist and has no subjective complaints

RESULTS

From a practical standpoint the results were perfect in all cases since there was a normal range of motion without pain and with full strength of the wrist when these men were rated Uniformly there was no permanent disability awarded The average time lost from work was 66 weeks which is less than we would allow for any individual case without the exceptions here noted

In sharp contrast to the conservative treatment, we present one case treated in the hospital by another surgeon In this case radical excision of the fragments was done This patient was on total temporary disability for 8 weeks and returned to a foreman's job requiring only moderate use of the hand Eventually he was rated at a 35 per cent loss of function of the hand

It is difficult to compare the results offered by different authors because of their various ways of reporting such results We believe that inasmuch as the majority of these cases are industrial are treated by industrial surgeons and are finally rated by industrial accident commissions they should be reported by the disability rating awarded This in turn would make these reports a basis for both the insurance carriers and the industrial surgeons to use in making a preliminary

estimate of possible resultant disability in any particular type of fracture We realize that different accident commissions and medical referees will report in different degree on the same disability But in general we believe that experienced commissions and referees will not vary appreciably in their decisions We also realize that in fractures of bones when considerable variation in the type of injury may occur the disability will vary accordingly

In a previous paper however, which considered fractures of the os calcis we attempted to show that the type of injury and fracture may be so classified that a fairly accurate idea of the resulting disability could be estimated upon a preliminary examination of the injury and of the first roentgenograms, provided a certain line of treatment were carried out Fractures of the carpal scaphoid are not so varied as to require any classification Although we know that we may obtain fractures of the tuberosity fractures of the waist and fracture dislocation of the scaphoid we find no need to classify these separately because the results with proper and immediate treatment have been uniformly good Where poor results are obtained namely painful non union we are inclined to believe that they were caused by delayed immobilization as a result probably of delayed diagnosis

The economic value of this survey means that for any individual case, with early recognition and

immobilization in the accepted position with unpadded plaster for 7 to 8 weeks, one can expect no total permanent disability and 87½ per cent of bony union

These results in acute fractures and in the one old case of non-union which we report, plus the numerous other excellent results obtained in the treatment of old non-unions by drilling or grafts, we believe should definitely contra-indicate excision of the carpal scaphoid under any condition

CONCLUSIONS

- 1 Immediate immobilization is stressed.

Fig 2. a Non union of fracture 1 year old. b Appearance 50 weeks and c 30½ weeks after drilling. Patient's wrist was in non padded plaster 14 weeks and he was away

from work 16 weeks. No disability. Note fracture line disappearing and the gradual return of blood supply as evidenced by decreasing density of the proximal fragment.

weeks later. Bony union was partially completed when the last roentgenogram was taken 6½ months after the operation. The patient has full range of motion of the wrist and has no subjective complaints.

RESULTS

From a practical standpoint the results were perfect in all cases, since there was a normal range of motion without pain, and with full strength of the wrist when these men were rated. Uniformly there was no permanent disability award. The average time lost from work was 6.62 weeks which is less than we would allow for any individual case without the exceptions here noted.

In sharp contrast to the conservative treatment we present one case treated in the hospital by another surgeon. In this case radical excision of the fragments was done. This patient was on total temporary disability for 5 weeks and returned to a foreman's job requiring only moderate use of the hand. Eventually he was rated at 1.35 per cent loss of function of the hand.

It is difficult to compare the results offered by different authors because of their various ways of reporting such results. We believe that inasmuch as the majority of these cases are industrial and are treated by industrial surgeons and are finally rated by industrial accident commission they should be reported by the disability rating awarded. This in turn would make these reports a basis for both the insurance carriers and the industrial surgeons to use in making a preliminary

estimate of possible resultant disability in any particular type of fracture. We realize that different accident commissions and medical referees will report in different degree on the same disability. But in general we believe that experienced commissions and referees will not vary appreciably in their decisions. We also realize that in fractures of bones when considerable variation in the type of injury may occur the disability will vary accordingly.

In a previous paper however which considered fractures of the os calcis we attempted to show that the type of injury and fracture may be so classified that a fairly accurate idea of the resulting disability could be estimated upon a preliminary examination of the injury and of the first roentgenograms provided a certain line of treatment were carried out. Fractures of the carpal scaphoid are not so varied as to require any classification. Although we know that we may obtain fractures of the tuberosity, fractures of the waist and fracture dislocation of the scaphoid we find no need to classify these separately because the results with proper and immediate treatment have been uniformly good. Where poor results are obtained, namely painful non union, we are inclined to believe that they were caused by delayed immobilization as a result probably of delayed diagnosis.

The economic value of this survey means that for any individual case with early recognition and

tion is insignificant in relation to the surgical aspects of this entity. In this series corpus luteum cysts comprised 75 per cent of cases and the follicle cysts 25 per cent.

SURGICAL PATHOLOGY

The occurrence of intraperitoneal hemorrhage arising from ovarian retention cysts is now well established. The usual findings of a gross tear or rupture in the wall of these cysts explain in most cases the origin of the hemorrhage. In such instances the cyst cavity usually contains blood which may be clotted and around which a small steady ooze or a larger spurting vessel may be found. In some cases it is impossible to demonstrate the vessel from which the bleeding occurs, and the opening on the surface of the ovary may be so minute as to leave one in doubt as to the ovarian origin of the intraperitoneal hemorrhage. This is not surprising since nature attempts to wall off the troublesome area and lay down a zone of fibrin so as to close the point of hemorrhage.

VerBruggen reports a case of massive intraperitoneal hemorrhage wherein at operation he found a small bleeding point on the right ovary. Although the abdominal cavity was thoroughly explored, no other point of hemorrhage could be found. The surgeon in this instance felt that the minute point of hemorrhage in the ovary did not explain the massive intraperitoneal bleeding. In 2 of our patients, one of whom was almost exsanguinated, no point of rupture could be seen although the assumption was made that the hemorrhage came from a cystic ovary filled with blood. It was removed and the pathologist proved it to be the source of the hemorrhage although he was unable to demonstrate a point of rupture. Apparently a massive intraperitoneal hemorrhage may take place as the result of a small tear in one or the other type of ovarian retention cysts, and no point of rupture may be demonstrable even by microscopic examination.

Emil Novak states that the occurrence of hemorrhage will depend largely on the location of the rupture of the cyst structures in relation to its blood vessels. If they lie near the surface when it ruptures, an extensive hemorrhage will then result, whereas a rupture in a relatively avascular area might produce very little bleeding. Our series confirms this statement.

Occasionally, these cysts may produce an abnormal type of vaginal bleeding which is on a hormonal basis. We refer to the vaginal spotting which is sometimes seen and simulates the spotting associated with ectopic pregnancy. Such bleeding is most likely explained on the basis of

Fig 1. Photomicrograph of graafian follicle cyst removed from Case 2, Mrs. B.L. Section shows multiple follicle cysts without hemorrhage and a large central cyst filled with blood. This larger cyst had ruptured producing a moderate hemorrhage simulating acute appendicitis.

an excess of estrin secreted by the abnormal cyst. There is proof offered by various writers that a follicle cyst may secrete an excess of estrin (7, 8). One of the actions of estrin is to produce an increased vascularity of the uterine endometrium which may produce continuous spotting. This was noted in 4 of our cases and suggested tubal pregnancy. In one of the cases the spotting continued following the resection of the cyst but stopped on the administration of prolan in the form of antuitrin-S.

THEORIES AS TO MECHANISM OF RUPTURE

In discussing the mechanism of rupture in these cysts, the question arises as to whether spontaneous intracystic bleeding is a forerunner to rupture, or whether bleeding is the result of rupture produced by other extracystic factors. Theoretically, it is conceivable that hormonal influences might play a part in the production of spontaneous bleeding into these cysts. The general increased vascularity of the pelvic organs at such a time may easily explain the intracystic hemorrhage and subsequent rupture. The occurrence during sound sleep of a rupture, which is not infrequent, can be

INTRAPERITONEAL HEMORRHAGE FROM RUPTURED OVARIAN RETENTION CYSTS

Corpus Luteum and Graafian Follicle Cysts

FRANKLIN I HARRIS, M.D., F.A.C.S., and MORRIS J. GROFF, M.D.
San Francisco, California

DURING the last few years rupture of ovarian retention cysts has received more frequent recognition in the differential diagnosis of acute surgical abdominal conditions. The consideration of this diagnosis as to its importance had not been emphasized previously. The description of characteristic clinical symptoms produced by a rupture of an ovarian retention cyst is difficult to find in any text book or current surgical literature. Cope, in his excellent and adequate work on the diagnosis of the acute abdomen, does not mention this subject. Individual case reports are frequently noted and a few papers have appeared covering larger series. To date a total of 367 cases have been reported in the literature. This condition is not the rarity it was formerly thought to be but its recognition and pre-operative diagnosis still remain difficult.

In an attempt to classify the clinical picture of this surgical entity the authors have reviewed a series of 45 patients with ruptured ovarian retention cysts who were admitted to the surgical service of the Mount Zion Hospital during the years 1926 to 1938. The study of this group of cases has shown remarkable variations in the pathology, the clinical diagnostic features and the etiology. The one characteristic feature of all these cases, however, has been the constant finding at operation of intraperitoneal hemorrhage in varying amounts. It is our belief that the variations in the pre-operative picture are directly dependent upon the severity and degree of intraperitoneal bleeding and that a clinical classification with adequate features may be described on this basis.

PHYSIOLOGY AND PATHOLOGY

To understand properly the clinical course of a ruptured ovarian retention cyst it is essential to review briefly the normal physiology of ovulation and the deviations which result in pathological ovarian cyst formation. Without attempting to

describe the minute histology of the ovary it is sufficient for our purposes to review the normal sequence of events connected with ovulation. The ovarian stroma contains an innumerable number of primordial cells which vary greatly in degree of maturity. As an individual ovum matures it is seen to be deeply situated within a cyst like structure lined by granulosa cells first described by de Graaf and now referred to as a graafian follicle. It is generally considered that during the middle of the menstrual cycle the matured graafian follicle ruptures to expel the ovum. The follicle fills with blood and fibrin and the granulosa cells are transformed to large luteal cells as organization proceeds. Later the corpus luteum shrinks in size and terminates as an orange pigmented scar.

The graafian follicle and corpus luteum found in this normal process are minute structures hardly visible to the naked eye and it is improbable that clinical disturbances of surgical significance are produced in this cycle. If hypersecretion into the graafian follicle occurs at some stage in its development, a pathological condition results which produces an abnormal enlargement of the follicle so that there occurs a cyst formation which has been called a graafian follicle cyst. Failure of the corpus luteum to regress and disappear might likewise result in the formation of a cyst which is referred to as a corpus luteum cyst. In such a cyst the wall may be 1 to 3 centimeters in thickness so that the cavities vary proportionately. Occasionally the ovary may be completely replaced by the cyst although a small nodule of ovarian parenchyma remains near the pedicle.

Basically both these types of cyst have the same origin. Microscopically they differ slightly in their structure. For simplicity in their clinical classification as well as to describe their common origin, they may be referred to as ovarian retention cysts (5). We advocate the use of this terminology for clinical discussion on this subject. There appears to be considerable confusion in the literature in reporting these cases as to whether the author is describing a rupture of a corpus luteum or graafian follicle cyst. This differentia-

From the Surgical Service of Dr. Harold Brunn, Mount Zion Hospital.

On examination one is impressed by the fact that these patients do not appear sick. There is no change in the pulse or temperature. Muscle guarding may be present but is not well defined or constant, and true rigidity is never seen. Tenderness is present at some time during repeated examinations on such a patient but may be absent at other times. It is not pronounced and when felt is always in the lower abdomen. Auscultation of the abdomen shows normal or slightly increased peristalsis.

Pelvic examination may occasionally show the presence of a small cystic protuberance in one or the other ovary. When such positive findings are present and the patient is conservatively treated, check-up examination after the disappearance of the symptoms may reveal normal ovaries with no evidence of the cyst previously noted.

The blood count in the mild cases usually shows essentially normal findings. No anemia is noted and leucocytosis is not the rule although an occasional case has shown a rise in the white blood count to as high as 15,000.

GROUP 1: ILLUSTRATIVE CASES OF MILD HEMORRHAGE

Mrs S. N. (No. 22834), age 24 years, entered the hospital on April 9, 1936. She was complaining of pain in the lower abdomen of 4 days' duration. The pains were described as being originally referred to the pit of the stomach and were not severe. The last 2 days they had centered in the lower abdomen. There was no history of vomiting but she had noticed occasional slight nausea. Her last menstrual period was approximately 2 weeks before on March 23, 1936.

Examination showed a patient apparently not sick looking, temperature 37 degrees C, pulse 80. On examination of the abdomen there was found tenderness in both lower quadrants. No rigidity was found but there was slight muscle guarding present. There was no distention of the abdomen and peristalsis was active. A pelvic examination showed tenderness in both fornices but no masses were palpable.

Laboratory work White blood count, 10,400, polymorphonuclears, 69 per cent, hemoglobin, 79 per cent, red blood count, 4,200,000.

A tentative diagnosis of subacute appendicitis was made. At operation approximately 100 cubic centimeters of blood tinged fluid was found in the pelvis and there was a cystic right ovary with a rupture of a small cyst about the size of a cherry which was still oozing blood. The appendix was essentially negative.

This case illustrates a time interval of 4 days from onset of the pain to the time she sought medical advice. The persistent indefinite abdominal pains made the surgeon suspicious of appendicitis. The onset of her pain, approximately 2 weeks after her last period, suggests that it was a rupture of a follicle cyst, although the surgeon described it as a ruptured corpus luteum cyst. The common error of diagnosing subacute

appendicitis is also illustrated by this case. Had the exact diagnosis been made the patient would probably not have needed surgery.

Mrs. O. M., age 23 years, entered the hospital on November 14, 1937. She stated that immediately following the act of defecation early that morning she was seized with a cramp-like pain that doubled her up. This pain lasted about 1½ hours and was located deep in her lower abdomen. There was no nausea, no vomiting, nor had she felt faint or dizzy. Her last menstrual period was about 3 weeks previous. She stated that she expected to menstruate in a few days.

Examination showed a patient who did not appear sick, temperature, 37 degrees C, pulse 96. The abdomen showed tenderness in the right lower quadrant and suggestive rebound tenderness over McBurney's point. There was moderate muscle guarding but no true rigidity and peristalsis was very active. Pelvic examination showed a suggestive tender cystic mass in the right fornix.

Laboratory work White blood count, 7,300, polymorphonuclears, 79 per cent, red blood count, 3,860,000.

Subsequent course In 36 hours the abdominal pains completely disappeared. The patient was discharged from the hospital with a diagnosis of a ruptured corpus luteum cyst. She was examined in the physician's office 10 days later and the cystic mass noted in the right fornix had disappeared although the ovary could be easily palpated.

This case illustrates the suddenness with which the onset of the pain appeared in relation to the act of defecation, suggesting a rupture of a retention cyst. Because of the proximity of her next menses the cyst was probably a corpus luteum. She was treated conservatively with complete relief and the disappearance, on subsequent pelvic examination, of the cystic mass found during the acute attack.

Group 2 The onset of pain is not unlike that described in Group 1, and bears a similar relationship to the menstrual cycle. Usually there is a history of sudden sharp pain in the lower abdomen but the duration following the onset is longer. Although there may be a cessation of symptoms for a period of hours, the return of pain within a short time is the rule. The pain is more definitely localized to either the left lower quadrant or the right lower quadrant and simulates more closely the pain of acute appendicitis, particularly pelvic appendicitis, when localized to either the left lower quadrant, as Brunn has so well described. On continued observation the pain shifts to the upper quadrant of the abdomen but is not colicky in nature and is described as a severe discomfort. Seldom is a narcotic required. When questioned many of these patients will recall or complain of pain in one or the other shoulder which is pathognomonic of the presence of sufficient blood to cause diaphragmatic irritation. Nausea is noted as frequently as in Group 1, and vomiting is occasionally present but is not noteworthy. Symptoms of mild shock are noted in many

Fig. 2 Drawing from specimen removed at operation from Case 32 Mrs. S. R. Pre operative diagnosis of ectopic pregnancy. Drawing shows point of hemorrhage that is sealed over by fibrin and a large thick walled corpus luteum cyst which grossly simulated an ovarian pregnancy.

explained only on the basis of spontaneous intracystic bleeding. This has been noted in this series as well as in other reports.

In the majority of these cases, however, there is usually a history which suggests a more than casual relationship to some exciting traumatic factor. Most authors have therefore, assumed that the rupture precedes and is the cause of the bleeding. Our series demonstrated a high percentage of the cases wherein the history suggests extracystic factors of the type of direct or indirect trauma.

In this category we place cases which are antedated in the occurrences of their symptoms by a history of (1) a pelvic examination (2) a direct blow on the abdomen (3) coitus (4) straining at stool lifting heavy objects and vomiting as examples of increased intra abdominal pressure (5) acute appendicitis and appendiceal colic are occasionally etiological factors probable on the basis of the pain associated with these conditions increasing intra abdominal pressure.

CLINICAL ASPECTS

The degree of intraperitoneal hemorrhage determines the characteristic clinical features of this condition. This study of 45 cases suggests the division for descriptive purposes into 3 groups: (1) those suffering from mild hemorrhage by which is meant the finding at operation of an amount of blood or blood tinged fluid of less than 100 cubic centimeters (2) those suffering from moderate hemorrhage amounting to between 100 and 500 cubic centimeters and (3) those suffering from massive hemorrhage of from 500 to as much as 1500 cubic centimeters.

Fig. 3 Photomicrograph of specimen shown in Figure 2. The corpus luteum is a thick walled cyst with the center of the cyst filled with old and recent hemorrhage. There is moderate edema of the ovarian stroma.

Group 1 is characterized by mild intraperitoneal bleeding with minimal symptoms. In this group the pain is extremely variable and depends on various factors. There may be a history of a sudden sharp pain of momentary duration in either the right lower quadrant or the left lower quadrant which is due to the actual rupture of the cyst. This momentary pain may be followed by complete relief. A few hours to a few days later there may be noted the appearance of vague lower abdominal pains which are fleeting and ill defined. The patient is not sick enough to be confined to bed but has a definite feeling of discomfort in the lower abdomen. These patients are often admitted to the hospital for observation on suspicion of a possible acute surgical abdomen and are discharged within 24 to 72 hours because of lack of further positive findings. Occasionally they are returned in another 48 to 72 hours for exploratory operation due to the persistence of these vague abdominal pains. Shoulder pain has not been noted in this group. Nausea of mild degree is occasionally present but vomiting is seldom seen. Symptoms of mild shock are absent.

The history of the onset of these symptoms can always be traced to a definite relationship with the menstrual cycle and is of the utmost significance. Pain occurring in the lower abdomen at or after the middle of the intermenstrual period suggests probable follicular origin. Pain appearing just preceding the onset of the menses is due to hemorrhage from a corpus luteum cyst.

with maximum tenderness in the lower abdomen. Muscle guarding is definite but no rigidity is noted. Peristalsis in this advanced bleeding type may also be absent. On percussion of the abdomen a definite area of dullness may be noted in the lower part. Pelvic examination will show fluctuation in the cul-de-sac suggestive of fluid which is easily interpreted as being blood in view of the general appearance and condition of the patient. The blood count is of help in these cases as it shows a definite drop in hemoglobin and an increase in leucocytes.

GROUP 3: ILLUSTRATIVE CASES OF MASSIVE HEMORRHAGE

Miss T. G. (No. 22143), age 18 years, single, entered the hospital on September 18, 1935, complaining of an attack of sudden severe pain in the right lower quadrant of her abdomen which had increased in severity over the past few hours. She had a severe pain in her right shoulder and some upper abdominal discomfort. The patient had not vomited but was nauseated.

On examination the patient definitely appeared sick, pale, and worried; temperature, 37.3 degrees C, pulse, 98. There was noted some moderate distention and generalized, extreme tenderness in both lower quadrants of her abdomen which was dull to percussion and on auscultation no peristalsis was heard. Rectal-pelvic examination revealed tenderness in the cul-de-sac and the suggestion of a mass. Her last period was 3 weeks previous. During about 6 hours' observation the patient's pulse became more rapid and she showed more pronounced symptoms of shock.

Laboratory work: Hemoglobin, 50 per cent, red blood count, 3,650,000, white blood count, 12,500.

A tentative diagnosis of ruptured ovarian retention cyst with massive intraperitoneal hemorrhage was made. At operation over 1,000 cubic centimeters of blood was aspirated from the peritoneal cavity and retransfused into the patient. A cystic mass, the size of a small orange completely filled with clotted blood and representing a hemorrhage into a corpus luteum cyst of the right ovary, was removed. The patient made an uneventful recovery.

This case illustrates the severe type of hemorrhage that may occur as the result of a comparatively small tear or rupture in an ovarian retention cyst. Although a massive hemorrhage was found it was difficult to demonstrate either macroscopically or microscopically the exact point of rupture. The variability of the abdominal pains, its complete disappearance and reappearance at intervals, as well as frequent change in location, are characteristic.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

This condition occurs in women of the second and third decades of life. No single feature or symptom is characteristic but its variable manifestations strongly suggest the diagnosis. The variability of the abdominal pains, their complete disappearance and reappearance at intervals, as well as frequent changes in location, are charac-

teristic. The initial pain may be severe although momentary and may be associated with trauma. Even without a history of trauma this pain may be of such severity as to awaken a patient from sound sleep. When the pain reappears later it is changed in character, it is dull, described as an abdominal discomfort, it is not colicky and seldom requires a narcotic. *The pain is sufficient to put both the doctor and the patient on guard but is insufficient to clearly define the type of pathology that is within the abdomen*, unless one has a "high index of suspicion." Many of the minor attacks of unexplained abdominal pains in female patients are probably on the basis of mild intraperitoneal bleeding. The abdominal tenderness present in these patients is as variable in its degree and location as the symptoms of pain. When found in the lower abdomen it is usually at a low level close to Poupart's ligament. Muscle guarding is present in proportion to the peritoneal irritation because of bleeding. Rigidity is seldom seen. Hyperactive peristalsis is an important accessory diagnostic finding.

Rupture of an ovarian retention cyst is most frequently diagnosed as acute appendicitis. This was the pre-operative diagnosis in 54 per cent of our series. Hoyt and Meigs report a similar diagnosis in 56 per cent of their cases. The onset of the pain in ruptured cysts is usually sudden and momentary, compared to the gradual and constant pain of appendicitis. The variability in duration and variation in location of the abdominal pain is unlike the steady and more definite location of appendicitis. On abdominal examination tenderness may be elicited only over the right lower quadrant and strongly suggests appendicitis. It later tends to shift to other parts of the lower abdomen more frequently than is seen in appendicitis. With increased bleeding abdominal tenderness becomes more generalized. *Even when the tenderness remains located in the right lower quadrant, careful examination will disclose that tenderness is just above the inguinal region in contrast to the periumbilical or McBurney tenderness of appendicitis.* The total white blood count and in particular the differential polymorphonuclear count are higher as a rule in acute appendicitis.

The next most frequent mistake in the diagnosis of this condition is its confusion with ruptured ectopic pregnancy. The occasional presence of continued vaginal spotting associated with retention cysts is probably due to an excess of estrin derived from the cyst and might lead to an erroneous diagnosis of ectopic pregnancy. The occurrence of massive hemorrhage with signs and symptoms of shock further confuses the picture. Differentiation in such cases depends on a careful

patients and are characterized by dizziness, faintness, and a feeling of weakness. These symptoms are particularly pronounced if the patient has been ambulatory.

On examination these patients appear worried and somewhat sick looking. No noticeable alteration in pulse or temperature is observed. Abdominal tenderness, however, is a constant finding. It is limited to the lower abdomen but shifts to the upper quadrants frequently. This shifting tenderness is strongly suggestive of moderate intraperitoneal bleeding. The tenderness may be quite exquisite, particularly in the inguinal regions. To the experienced surgeon it is not, however, the abdominal tenderness of an acute infectious peritonitis. Muscle guarding is pronounced and in most of these cases may even suggest true surgical rigidity. On auscultation peristalsis is very active and will help in differentiating from the silent abdomen of more serious conditions. Pelvic examination may or may not reveal a palpable cystic mass in either one ovary or the other. Occasionally, however, a doughy fullness may be felt in the cul de sac suggestive of an accumulation of blood or blood clots. The blood count is quite variable with a greater tendency to leucocytosis. No change is noted in the hemoglobin of sufficient importance to be of clinical value.

GROUP 2 ILLUSTRATIVE CASES OF MODERATE HEMORRHAGE

Miss M. F. age 20 years a graduate nurse entered the hospital on January 20, 1935, stating that early that morning she was awakened from her sleep by a sharp severe pain in the lower abdomen which seemed more intense in the right lower quadrant. She became very nauseated but did not vomit. Her last menstrual period was approximately 3 weeks previous.

On examination the patient appeared sick and worried. Temperature 37.3; degrees C. pulse 84. The abdomen showed no rigidity but there was marked tenderness over the entire abdomen particularly more pronounced over McBurney's point. Auscultation showed very active peristalsis. There was mild muscle guarding over the entire abdomen.

Laboratory work. White blood count 7,480 polymorphonuclears 68 per cent.

After 24 hours observation the clinical picture had not changed. The abdominal pains although varying considerably in severity were still present. As her tenderness seemed definitely localized to the right lower quadrant a diagnosis of acute appendicitis was made and surgery advised. Operation was performed through a McBurney incision and when the peritoneum was opened a considerable amount of bright red blood was found. A normal appendix was quickly removed through this incision and it was then closed and a midline incision made. On exploration of the abdomen approximately 500 cubic centimeters of bright red blood was seen and a ruptured cyst the size of a walnut was found still oozing blood from the left ovary. The cystic portion of the left ovary was resected and plastic

closure of the remaining stroma made with interrupted silk sutures. The patient's convalescence was uneventful.

This case illustrates a more severe type of pain simulating appendiceal colic. The diffuseness over the abdomen on continued observation and the active peristalsis without a rise in temperature or white blood count after 24 hours should have made one suspicious that the diagnosis was not acute appendicitis.

Mrs. M. O. age 35 years a housewife was seen at home on November 27, 1936. Of interest in her past history is that she had her appendix removed at the age of 15. The patient stated that for the past 3 days she had had indefinite pains in her lower abdomen which were similar in nature to the pains she remembered having during her attack of appendicitis a few years previous. She said the pain disappeared and reappeared and in the last 24 hours had increased in severity so that she felt it advisable to remain in bed. She also complained of slight dizziness and weakness when she was on her feet. On direct questioning she complained of pain in her right shoulder.

Abdominal examination showed a soft abdomen with tenderness in all quadrants particularly in the right lower quadrant. There was no rigidity nor muscle guarding and active peristalsis was heard. Pelvic examination showed the right ovary to be enlarged with a suggestion of a small cystic mass attached to it which was very tender. Her last menstrual period was 2 weeks previous.

A tentative diagnosis of a ruptured follicle cyst was made and the patient was advised to remain in bed with ice packs to the lower abdomen. She made a complete recovery in about 3 days and reported to the office for a check up pelvic examination on December 14, 1936 at which time no evidence was found of a cystic mass attached to the right ovary nor was any tenderness present.

This case illustrates a classical picture of a ruptured follicle cyst. The previous removal of her appendix aided in the diagnosis. Characteristic right shoulder pain suggestive of moderate intraperitoneal hemorrhage and the finding of a cystic mass connected to the right ovary which disappeared over the subsequent period of observation was further confirmation. Such a case affords one who has a high index of suspicion a fine opportunity of studying the progress of ruptured ovarian retention cyst under conservative management.

Group 3. These patients show signs and symptoms which are typical of massive intraperitoneal hemorrhage. They constitute the smallest percentage. The onset of the pain is definitely more severe and constant in its character. There is no period of relief rather an increase in its severity. The pain is localized across the entire lower abdomen but in a few hours it involves the upper abdomen and there is characteristic pain in either one or the other shoulder. Nausea is more frequently seen as well as vomiting. These patients show definite evidence of shock which may be profound. Abdominal tenderness is generalized

clinical aspects of this entity are determined by the amount of intraperitoneal bleeding

4 The mechanism of rupture may be due to increased intracystic pressure from spontaneous bleeding into the cyst, or increased extracystic pressure from trauma of various types.

5 The diagnosis of the condition is dependent upon time relation to the previous menstruation, characteristic variation in abdominal pain and tenderness, the presence of active peristalsis, and frequently positive pelvic findings. A "high index of suspicion" aids materially in the diagnosis.

6 Rupture of an ovarian retention cyst must be differentiated from (1) acute appendicitis, (2) ectopic pregnancy, (3) pelvic inflammatory disease, and (4) torsion of an ovarian cyst.

7 The majority of these cases can be treated by conservative observation after the proper diagnosis is made. The tendency to recurrent attacks is rare but does occur, and the possibility of treatment by endocrine therapy is suggested in such cases.

8 Rupture of ovarian retention cysts seems to have a high incidence among nurses.

9 When surgical intervention is necessary, the entire ovary should not be sacrificed. Plastic resection of the cyst and preservation of normal ovarian tissue is advocated.

analysis of the menstrual cycle. In contrast to ectopic pregnancy there is usually no history of a missed or late period. The use of the urine pregnancy test is of considerable value in differentiation as it always is negative with ruptured cysts, and so frequently positive in ectopic pregnancy.

Occasionally this condition is confused with acute or subacute pelvic inflammation. This differentiation should be easily made because of the absence of high fever and the fact that these patients are not as sick as those with pelvic inflammation. Rigidity is not usually found in this condition. The sedimentation time is always normal in contrast to the rapid sedimentation time of pelvic inflammation.

Twisted ovarian cyst is usually a more sudden and severe emergency which on examination presents a well defined tender pelvic mass the presence of which has usually been known to the patient for some time past.

Endometriosis which clinically is a rather rare entity, may simulate this condition but the close relation of its symptoms to the onset of menstruation should aid in the differentiation.

Treatment will depend largely upon the acuity of the clinician. If a correct differential diagnosis has been made and it is found that the patient is suffering from mild or moderate intraperitoneal bleeding conservative observation is indicated. Such observation necessitates repeated examinations of the patient. With the proper diagnosis the greater majority of these cases will not need surgical intervention. It is our belief that many of the patients whom we operated upon in our series would spontaneously have stopped bleeding and reabsorbed the intraperitoneal blood. With greater experience and a more careful study of this subject we have found that we are operating less frequently. Pratt has reported a similar experience and recommends conservative observation.

Surgery should be performed if there are signs or symptoms of increasing or massive intraperitoneal hemorrhage, or when the diagnosis remains doubtful after a reasonable period of conservative treatment. A low midline incision is usually made and if a bleeding cyst is found it is resected and as much as possible of the good ovarian stroma is preserved. The ovary in such cases is usually resutured with fine silk. It is strongly urged that a McBurney incision should not be used in a female when there is any reasonable doubt of the diagnosis of acute appendicitis.

REMARKS

In the larger majority of our cases there does not appear to be a tendency to recurrence of this

condition. However, there is a smaller group in which the condition seems to recur at frequent intervals. One of our patients had recurring attacks at every intermenstrual period for 6 consecutive months. These attacks were more definite than the so called 'Mittel Schmerz' so frequently described in foreign literature but so infrequently seen in this country. She was given a course of endocrine therapy in the form of emmenin with a remarkable and complete disappearance of her attacks. Such a case suggests the probability that some of the new endocrine preparations may be of value in treatment when the condition is recurrent. In other cases in which the patients had been operated upon and appendectomy performed as well as plastic resection of the affected ovary, the recurrent attack was treated conservatively because of the certainty of the diagnosis. To re-operate upon such a patient might mean the sacrifice of the involved ovary. Our policy has been to err on the side of conservatism and never remove the entire ovary in the young patients.

It is interesting to note that there were 4 patients who had recurring attacks. These were all nurses. Of the total series of 45, 11 of the patients or approximately 25 per cent were nurses. It is possible that their type of work which necessitates long hours in the upright position and often requires lifting of heavy patients may predispose to ruptured cysts. Certainly the high incidence among nurses should be emphasized in relation to diagnosis.

The occurrence of proven appendicitis in 6 cases of this series in conjunction with a ruptured cyst is of interest. This finding has been noted in other reports (2, 6, 9, 10). One can theorize that the cyst rupture is a secondary and incidental accompaniment of the appendix attack and probably would not have occurred otherwise. There must be an increase in intra abdominal pressure with the pain of acute appendicitis particularly the obstructive type which produces a rupture of a pre-existing cyst.

CONCLUSIONS

1. For clinical purposes the term ovarian retention cyst is advocated in the discussions of rupture of graafian follicle and corpus luteum cysts.
2. Intraperitoneal hemorrhage from rupture of an ovarian retention cyst has not received sufficient recognition in the differential diagnosis of acute surgical abdominal conditions.
3. A classification into 3 groups of mild moderate, and massive hemorrhage resulting from rupture of ovarian retention cyst is described. The

clinical aspects of this entity are determined by the amount of intraperitoneal bleeding

4 The mechanism of rupture may be due to increased intracystic pressure from spontaneous bleeding into the cyst, or increased extracystic pressure from trauma of various types

5 The diagnosis of the condition is dependent upon time relation to the previous menstruation, characteristic variation in abdominal pain and tenderness, the presence of active peristalsis, and frequently positive pelvic findings. A "high index of suspicion" aids materially in the diagnosis

6 Rupture of an ovarian retention cyst must be differentiated from (1) acute appendicitis, (2) ectopic pregnancy, (3) pelvic inflammatory disease, and (4) torsion of an ovarian cyst

7 The majority of these cases can be treated by conservative observation after the proper diagnosis is made. The tendency to recurrent attacks is rare but does occur, and the possibility of treatment by endocrine therapy is suggested in such cases

8 Rupture of ovarian retention cysts seems to have a high incidence among nurses

9 When surgical intervention is necessary, the entire ovary should not be sacrificed. Plastic resection of the cyst and preservation of normal ovarian tissue is advocated

THE CONSERVATIVE SURGICAL TREATMENT OF NON-CALCULOUS HYDRONEPHROSIS

JAMES T. PRIESTLEY, M.D. F.A.C.S., Rochester, Minnesota

INTERFERENCE with the flow of urine from a kidney, which persists for any appreciable length of time, invariably causes some degree of hydronephrosis. The extent of pyelectasis and caliectasis which results varies and depends upon the degree and duration of obstruction, the presence of infection, the status of renal function and other related factors. The conservative surgical procedure which is indicated to relieve symptoms and prevent further damage to the renal parenchyma must be altered according to the exact anatomical relationships that are present.

Many advances have been made during the past 20 years in the conservative surgical treatment of hydronephrosis so that now many kidneys are preserved which previously would have been considered irreparably damaged and removed. As experience with this type of surgery has grown, the results both immediate and ultimate have become increasingly more satisfactory. (10) The present discussion will be limited entirely to the conservative surgical management of hydronephrosis. Symptoms, diagnosis, indications for operation, significance of infection and other aspects of the subject will not be discussed. No attempt will be made to discuss the historical development of the conservative surgical treatment of hydronephrosis nor to review the current literature on the subject.

CAUSES AND SURGICAL PROCEDURES

Anomalous vessels. Anomalous blood vessels directed to the lower pole of the kidney constitute one of the abnormalities first described as a cause for hydronephrosis (1-6). For many years the etiological relationship of these vessels to hydronephrosis remained unquestioned. In recent years, however, certain authors have expressed the belief that aberrant vessels of this type are only of secondary importance and are not primarily responsible for the hydronephrosis (11). At present there is therefore some divergence of opinion regarding the importance of these vessels in the production of hydronephrosis. It is certainly true that the mere presence of anomalous vessels to the lower pole of the kidney is of no

definite significance unless it can be clearly demonstrated that they interfere with drainage from the kidney.

Rather than formulate a dogmatic opinion regarding all anomalous vessels it appears more reasonable to judge each case individually. At the time of operation, when actual anatomical relationships can be accurately ascertained, marked variations are noted in different cases. The responsibility for determining the exact factors concerned in the production of the hydronephrosis therefore resides with the surgeon. In some cases there seems to be no possibility that aberrant vessels to the lower pole interfere with drainage from the renal pelvis. In these cases the anomalous vessels are not even in contact with the ureter or pelvis. In other cases it seems equally apparent that these vessels are a definite factor in the production of hydronephrosis although it is realized that their apparent importance may be accentuated as the pelvis gradually increases in size. One may find the ureter sharply angulated or flattened against the pelvis by pressure of the vessels. Active peristalsis may be seen in the pelvis and upper portion of the ureter, but despite this fact the pelvis remains distended. After the vessels are severed and pressure on the ureter is released the pelvis empties readily.

If anomalous vessels are present and one demonstrates to his satisfaction that they are of importance in the production of hydronephrosis, one of several surgical procedures may be necessary. The vessels may first be temporarily occluded to determine their importance in the blood supply of the lower pole of the kidney. If no undue change in color takes place during compression for several minutes the vessels may be severed with impunity. Should the lower pole become very dark and should a sharp line of demarcation appear between the main portion of the kidney and the lower pole the vessels cannot be divided without producing an infarct in the portion of the kidney which they supply. Under these circumstances, if the vessels are definitely compressing or angulating the ureter, it may be necessary to sever the ureteropelvic junction and reimplant the ureter into the pelvis on the opposite side of the vessels (4). At times such a pro-

cedure may be indicated when the ureter has been inserted high up on the pelvis and has been compressed against the pelvis by aberrant vessels. At the time of re-implantation the ureter is then placed dependently in the renal pelvis (Fig. 1).

If the pyelectasis found to be associated with anomalous vessels is very extensive and if the pelvic wall is thin and flabby and apparently contains little if any musculature capable of effective peristalsis, resection of the pelvis may be performed (Fig. 2). This procedure has been employed frequently by Walters (9). It is realized that the main object of any operation for hydronephrosis is to improve drainage from the kidney and not primarily to decrease the size of the extrarenal pelvis. If a very large redundant pelvis is present, however, it seems quite possible that urine might stagnate there because of the excessive size of the pelvis and its inability to empty. It has been stated that resection of the pelvis interferes with normal peristalsis (5), however, experience with this type of operation has demonstrated that emptying of the pelvis under certain circumstances may be improved by this procedure. If the pelvis is not too large and if it appears to have active peristalsis, it will usually empty itself satisfactorily after the obstruction has been removed, and resection of the pelvis is not necessary.

High insertion of ureter into renal pelvis. One of the common abnormalities found associated with hydronephrosis is high insertion of the ureter into the renal pelvis. Obviously, when this anatomical abnormality exists, dependent drainage of the pelvis is lacking. It may be stated that such a relationship between the pelvis and ureter is merely the result and not the cause of the hydronephrosis and it is difficult actually to prove or disprove this contention. It is true, however, that pyelectasis and varying degrees of caliectasis are not infrequently found to exist when there is no explanation for their occurrence other than the fact that the ureter leaves the pelvis in its middle or upper portion. Undoubtedly, this abnormality can sometimes be rendered more important in its appearance as the size of the pelvis increases. It seems very probable, however, that in certain cases this faulty anatomical relationship is primarily responsible for the production of the hydronephrosis. Frequently, as stasis occurs and as the pelvis gradually enlarges, the upper portion of the ureter is compressed by lateral pressure from the distended pelvis. This results in further interference with drainage. Occasionally fibrous bands hold the ureter closely pressed against the pelvis. Under such circumstances one

is usually surprised that urine leaves the kidney as well as it does. The ureteropelvic juncture may be on the posterior or anterior surface of the pelvis, but it is usually located on the medial aspect of the pelvic wall.

The correction of high insertion of the ureter may be accomplished by a variety of surgical procedures, 3 of which are illustrated in Figures 3, 4 and 5. In general, an operation which does not entirely sever the ureter from the pelvis is to be preferred, when feasible, as the blood supply and nerve supply to the upper portion of the ureter are not disturbed by this type of operation. One of the simplest and most satisfactory procedures consists of simple anastomosis between the ureter and pelvis, so called ureteropyeloneostomy (Fig. 3). In this operation a new opening is made between the most dependent portion of the pelvis and the ureter at the corresponding level.

A second procedure that may be employed, which is quite similar in principle to the one just described, is illustrated in Figure 4 (5). The adjacent portions of the ureter and pelvis are incised in a straight line and the cut edges are then united, posterior edge of pelvis to posterior edge of the ureter and anterior edge to anterior edge, which is similar in principle to the Finney pyloroplasty.

Another procedure which I have not seen described in the literature but which I have employed with satisfactory results in cases of high insertion of the ureter is illustrated in Figure 5. In this operation a longitudinal incision is made in the upper portion of the ureter which lies adjacent to the pelvis. This incision is carried down to a level which corresponds with the most dependent portion of the pelvis, which is near (approximately 1 centimeter) the renal parenchyma of the lower pole. The dependent portion of the pelvis which lies between the lower pole of the kidney and the ureter is then resected in a wedge shaped manner, with the base of the wedge directed downward and the apex reaching upward to the level of, or a little above, the ureteropelvic juncture. The anastomosis between the remaining portion of the pelvis and the longitudinal incision in the ureter is then completed in the usual manner. This procedure has the advantage of bringing the ureteropelvic juncture close to the kidney in a dependent position, creating a funnel shaped pelvis, and furthermore removes the excess portion of the pelvis that usually remains when an ordinary anastomosis is performed without removal of tissue. The operation described by Foley may also be used in cases of this type, although it was described for use in

cases of stricture at the ureteropelvic junction.

Somewhat less conservative operations may at times appear advisable. Occasionally it may seem necessary to sever the ureteropelvic junction completely, resect the upper portion of the ureter which lies adjacent to the pelvis and reimplant the upper end of the ureter in the lowest portion of the pelvis. This may or may not be combined with resection of the pelvis. If the pelvis is resected, the line of incision may be carried to within 1 centimeter of the renal parenchyma both on the anterior and posterior walls. The ureter is then inserted at the lower angle of the pelvis. This procedure, as utilized for stricture of the ureteropelvic junction is illustrated in Figure 6. This type of operation is best reserved for cases of large hydronephrosis in which there is a very thin, markedly dilated pelvis which has flattened and narrowed the upper portion of the ureter. Accurate anastomosis between ureter and pelvis is desirable. The upper end of the ureter may be incised downward for a short distance in order to increase the diameter of the resulting ureteropelvic junction if it appears advisable.

Narrowing at ureteropelvic junction. Hydronephrosis may be caused by narrowing of the lumen of the ureteropelvic junction as a result of scar tissue, trauma of one form or another, inflammatory reaction, fibrous bands, idiopathic stricture, or other causes. Many types of surgical procedures have been employed for the correction of this condition with variable results. Employment of the principle of the Heineke-Mikulicz operation for pyloroplasty known as the 'Fenger operation' is one of the simplest procedures technically, however ultimate results following this type of procedure which utilizes a longitudinal incision through the strictured region closed transversely have not been so satisfactory.

Schwytzer modified Fenger's operation by using a Y shaped incision the diverging limbs of the Y being placed on the pelvis above the ureter and the descending limb being extended down the ureter. This incision is closed so that the dependent point of the triangular flap created on the pelvis is approximated to the lower end of the incision in the ureter. The diameter of the ureteropelvic junction is thereby increased with some redundancy in the upper end of the ureter opposite the anastomosis. Foley modified this operation by placing the diverging limbs of the Y incision downward on the lower portion of the pelvis directly opposite the upper end of the ureter. The straight incision in the ureter is made somewhat longer than in the Schwytzer operation and

on the side of the ureter adjacent to the pelvis. The dependent tip of the flap on the pelvis is approximated to the lower end of the incision in the ureter and the anastomosis is completed accordingly. This provides a large ureteropelvic junction with a funnel shaped opening into the pelvis. Satisfactory results have been reported following this procedure.

If the pelvis is unusually large and the upper portion of the ureter somewhat redundant, resection of the renal pelvis and upper portion of the ureter and reimplantation of the ureter usually gives very satisfactory results (Fig. 6). This procedure is especially advantageous when a more conservative operation without resection would leave an excessively large renal pelvis and give doubtful results. In this type of operation it is especially important to leave the ureteral "splint" catheter in place for an adequate length of time.

Square shaped pelvis with medial insertion of ureter. Occasionally one finds hydronephrosis with a square shaped extrarenal pelvis and a ureteropelvic junction (of adequate lumen) situated dependently on the medial aspect of the pelvis. The ureter is then a considerable distance from the lower pole of the kidney. It is difficult to determine just how an anatomical arrangement of this type might be responsible for the development of the hydronephrosis. It may often appear as though the relationship were merely secondary, the hydronephrosis having developed from some undetermined cause. Whichever the case may be the late results obtained following operation make it appear worth while in some of these cases to resect a wedge shaped portion of the lower part of the pelvis situated between the ureter and lower pole of the kidney. The base of the wedge is excised from the lowermost portion of the pelvis and the apex is directed upward. Such a procedure brings the ureter and ureteropelvic junction close to the lower pole of the kidney and makes the dependent portion of the pelvis more funnel shaped and less flat. Such an arrangement some times appears to enhance drainage.

Hydronephrosis associated with movable kidney. That most cases of slightly abnormal renal ptosis or mobility are of clinical significance seems highly improbable and I believe that such a viewpoint will avoid many unnecessary operations. That certain cases of abnormal renal ptosis associated with some degree of hydronephrosis and pain which appears to be of renal origin are of clinical significance seems almost equally certain. I do not think there are many such cases but one is occasionally encountered. If the clinical diagnosis has been established with as much

Fig 1 Hydronephrosis associated with aberrant vessels and high insertion of ureter, a, left, high insertion of ureter into the enlarged pelvis, upper portion of ureter compressed by aberrant vessels running to lower pole of kidney, and b, resection of upper portion of ureter and re-implantation into dependent portion of pelvis. The aberrant vessels could not be severed without causing an infarct in lower pole of kidney

Fig 2 Hydronephrosis associated with aberrant vessels, a, left, compression of ureteropelvic junction by aberrant vessels, and b, aberrant vessels severed and enlarged extrarenal pelvis resected

certainly as possible and if definite stasis has been actually demonstrated, a pleasing result may follow immobilization of the kidney in an appropriate position so that undue angulation or kinking of the ureter or ureteropelvic juncture does not occur. If such a condition is found in the right kidney of a patient who has a low lying liver as is often the case, one need not attempt to maintain the kidney in an anatomically high position where with each inspiration the liver will push down on the upper pole. All that is actually necessary is to fix the kidney in a relatively high position so that it does not descend unduly when the patient is standing. The details of performing nephropexy will not be discussed except to say that elaborate methods of fixation are unnecessary. One does not need to operate on many kidneys which have been subjected to a previous operation before realizing that nature does a very good job of fixing the kidney following almost any type of renal operation.

Hydronephrosis resulting from other causes
Hydronephrosis which results from various abnormalities in the lower portion of the urinary tract, and from pathological conditions entirely extrinsic to the urinary tract is not at all uncommon. Tumor of the ureter, ureteral stricture, vesical neoplasm, obstruction in the neck of the

bladder and so forth, and numerous pelvic conditions such as tumors, inflammatory processes and trauma in one form or another may result in obstruction of one or both ureters. Likewise abdominal or retroperitoneal tumors which cause pressure on the ureter or renal pelvis may result in varying degrees of pyelectasis and caliectasis. The treatment of hydronephrosis resulting from these causes will not be discussed since the primary concern under these circumstances is the original lesion responsible for the secondary effects on the kidney. In cases of this type local conservative operation on the kidney is seldom indicated.

Hydronephrosis of indeterminate origin
Occasionally one encounters definite hydronephrosis without an adequate anatomical explanation for its development. Sometimes the hydronephrosis may be unilateral at other times bilateral. In children bilateral hydronephrosis without evidence of organic obstruction is not uncommonly seen. It seems possible that disturbances of function may eventually cause an anatomical abnormality for which there is no recognizable organic lesion. Although the exact cause for such hydronephroses to my belief has never been conclusively demonstrated, the current tendency is to explain them on the basis of neuro or neuro-

Fig 4 Hydronephrosis associated with high insertion of ureter, a, left, high insertion of ureter into dilated pelvis, b, anastomosis between dependent portion of pelvis and adjacent portion of ureter

Fig 5 Hydronephrosis associated with high insertion of ureter, a left, high insertion of ureter into enlarged pelvis, b, wedge shaped resection of lower portion of pelvis and ureteropelvic anastomosis

muscular dysfunction. Obviously when no actual obstruction is present little benefit may be expected from any type of plastic operation. The ultimate results of various types of operative procedures carried out on the autonomic nervous system in a large series of cases remain to be seen. Individual cases and small groups of cases have been reported with reputed benefit following denervation of the renal pedicle, ureterolysis, section of the ureteropelvic sphincter, and resection of the presacral nerves. Experience has been limited with all of these procedures and they will not be discussed in detail at this time. Suffice it to say that further experience both experimental and clinical, is desirable before definite conclusions can be drawn.

Hydronephrosis in kidney with duplicated pelvis
Duplication of the pelvis of one or both kidneys is one of the most frequent congenital abnormalities that occurs in the urinary tract. Often such a condition causes no symptoms as both segments of the kidney function normally and there is no superimposed disease or abnormality. At times however, hydronephrosis or other changes may develop, usually in one but occasionally in both segments of the kidney. When hydronephrosis

develops in one segment only and the other half of the kidney is functioning normally, a conservative operation rather than nephrectomy is desirable.

If hydronephrosis occurs in one segment of a kidney with double pelvis it is usually in the upper half, and it may be caused by a variety of factors such as ectopic lower opening of the ureter or other anatomical abnormality, a kink or sharp angulation in the ureter, narrowing of the ureter by pressure and so forth. For the conservative surgical correction of such a condition a number of different procedures have been utilized with varying degrees of success. Heminephrectomy is the operation which has given the most uniformly satisfactory results at The Mayo Clinic (Fig. 7). In this operation the diseased portion of the kidney and at least a portion of the attached ureter are removed. This procedure is usually not difficult and in a majority of cases can be performed with a low risk and a good result. Complete ureterectomy is not necessary even if marked ureterectasis is present unless there is definite obstruction in the lower portion of the ureter. Ligation of individual blood vessels to the involved portion of the kidney and temporary com-

Fig 7 Hydronephrosis in upper segment of duplicated kidney, a, redundant hydro-ureter, the lower half of kidney is normal, and b, heminephrectomy, removing upper half of duplicated kidney

pression of the renal pedicle with a rubber covered clamp facilitate the procedure. The line of resection should be placed so that neither a calyx nor a pelvis is opened. By making a wedge shaped excision of the involved segment, the edges of the defect in the remaining portion of the kidney can be approximated. Large individual vessels seen on the cut surface of the kidney may be ligated with interrupted mattress sutures. Following this the edges of the kidney may be approximated with similar sutures tied over muscle tissue and finally covered with a pad of fat held in place by a continuous running suture through the renal capsule.

Other operations which are described for hydronephrosis in half of a duplicated kidney include mere ligation of the ureter from the involved segment, various types of anastomoses of the ureters and pelves of the 2 segments, and re-implantation of the involved ureter into the bladder in case it has an ectopic opening. The

enlarged renal pelvis may be anastomosed to the one of normal size. The ureter of the involved segment may be joined to the normal pelvis or ureter. As a general rule, results following these operations are less satisfactory than following heminephrectomy. Occasionally, if it is essential to preserve all possible functioning renal parenchyma, some type of anastomosis or a re-implantation may be advisable.

Hydronephrosis in a unilateral fused kidney. Occasionally a unilateral fused kidney presents definite hydronephrosis in one segment with resultant symptoms. Generally this may be treated in the same manner as hydronephrosis in one segment of a duplicated kidney. The exact procedure that is necessary will change with the individual patient, depending on the anatomical and functional relationships encountered.

Hydronephrosis in an ectopic kidney. Hydronephrosis sometimes develops in an ectopic kidney. This may be caused by pressure on the

ureter from an abnormal blood supply (which is the rule rather than the exception under such circumstances) or by some other cause of ureteral obstruction such as acute angulation, redundancy with kinking, or external pressure on the ureter. In the surgical treatment of kidneys of this type which are producing symptoms, nephrectomy gives the most uniformly satisfactory results provided the other kidney is in good condition. Because of the abnormal position of the kidney and its unusual blood supply, conservative plastic operations are less often successful than in cases in which the kidney is normally placed. They may at times be necessary, however, because of bilateral renal disease. The exact type of procedure that is indicated will vary from case to case and depends on the cause of obstruction and for this reason no universally applicable procedures can be described. In general if a conservative operation is performed the same surgical principles should be utilized as in dealing with a kidney in a normal position.

Hydronephrosis in a horseshoe kidney. The horseshoe kidney which shows evidence of hydronephrosis usually presents a very clear cut problem at the time it is exposed surgically. It has been our preference at the clinic to utilize the ordinary posterolumbar incision in these cases, continued somewhat more anteriorly than usual, with the patient placed at an angle of 45 degrees with the table. This type of incision and position provide adequate exposure. Obstruction to the free drainage of urine from the pelvis is usually caused by high insertion of the ureter or pressure on the ureter from aberrant blood vessels, the lower pole of the kidney or the renal isthmus. Occasionally angulation of the ureter by fibrous bands may be present.

Depending upon the etiological factors responsible for the hydronephrosis, the surgical indications will vary. Ordinarily plastic operations on the ureter and pelvis can be as easily performed on a horseshoe kidney as on a single kidney. The pelvis is commonly found to lie anteriorly which compensates for the fact that renal mobility is somewhat limited because of direct attachment to the opposite kidney. In case the hydronephrosis is caused by high insertion of the ureter into the pelvis ureteropyelostomy (Figs. 3 and 4) usually gives a good result. In case the renal isthmus causes pressure on the ureter which I believe is uncommon it is necessary to divide the isthmus so that the ureter is not compressed as it passes downward. When this is done it is often essential to fix the lower pole of the kidney laterally to the lumbar muscles in order to avoid

pressure by the lower pole on the ureter. In the limited group of cases of hydronephrosis in horseshoe kidneys in which conservative operations have been performed, the ultimate results have been equally as satisfactory as following operations on single normally placed kidneys.

GENERAL CONSIDERATIONS

Certain general surgical considerations that seem important in obtaining satisfactory results following plastic operations on the kidney might be mentioned. Absorbable suture material is universally employed, because non absorbable sutures may readily form the nidus for crystalline deposit, especially when infection is present. Personally, I prefer a single row of interrupted catgut sutures for closing the pelvis. There may be some slight leakage of urine during the early postoperative period with this type of closure but this does no real harm and affords an additional safety valve in case of increased intrapelvic pressure. Additional rows of suture are unnecessary and only increase the amount of local reaction and tissue that subsequently will slough.

Drainage by nephrostomy is widely recognized as a valuable adjunct to practically every plastic operation performed on the ureteropelvic junction. With such provision for immediate drainage during the early postoperative period the incidence of secondary nephrectomy and functional failure of operation is definitely reduced.

When any procedure has been carried out at the ureteropelvic junction the use of an indwelling catheter which traverses the lower pole of the kidney, lower calyx, pelvis, ureteropelvic junction and ureter in order so called 'ureteronephrostomy' is of definite value. A small, soft rubber catheter size 10 to 14 French is preferred to the commonly employed harder smaller ureteral catheter. An extra hole is cut in the portion of the catheter that remains in the pelvis so that there may be free drainage of urine through the catheter either outward to the collecting bottle or downward to the bladder. The catheter should be passed down the ureter a sufficient distance so that it will not be easily dislodged. This catheter serves to maintain an adequate lumen of the ureter at the site of operation and in addition discourages undesirable angulation of the ureter which might otherwise occur during the early postoperative period. The length of time that the catheter and nephrostomy tube are left in place varies with the individual case. If an extensive plastic operation has been performed such as complete resection of the renal pelvis and reimplantation of the ureter, it may

be advisable to leave the tube in place for as long as 3 months. If a less extensive type of procedure has been carried out, 3 weeks may be ample. In general it is wiser to err on the side of leaving the tubes in place for too long rather than too short a time. As healing occurs and as the resultant scar tissue contracts, the lumen of the ureteropelvic juncture may be narrowed unless the catheter remains in place.

It is generally advisable to fix the kidney in a position which is most favorable to good drainage at the conclusion of a plastic operation. This does not mean that the kidney must always be fixed in exactly the same position nor in the same manner. The most desirable position must be ascertained in each individual case and the kidney then immobilized in this position. The wound should always be drained.

COMMENT

As one can readily surmise from a brief review of the many different surgical procedures that have been suggested and tried in the conservative treatment of hydronephrosis, the surgical management of this condition is far from standardized. Although it is more than 50 years since the first plastic operation on the kidney was reported (8), relatively few operations of this type were performed until 20 years ago. Since then this field of surgery has expanded greatly and, at present, many plastic operations are performed on the kidney each year. Some of the earlier procedures have been discarded and certain newer ones have been developed. As more time elapses,

evaluation of ultimate results will become more accurate. At some time in the future the technical aspects of conservative renal surgery will undoubtedly become more standardized, and perhaps certain of the procedures which are utilized today will be altered or discarded.

"DECOMPRESSION" OF THE INTESTINAL TRACT

ACCORDING to Paine, the first stomach tube was probably made and used by John Hunter in the latter part of the eighteenth century. Shortly thereafter improvements in the types of tubes were reported in the United States, France and England. Kussmaul rediscovered the stomach tube in 1863 and it is due in no small part to him that it was popularized as a diagnostic and therapeutic instrument. Ewald and Oser in 1874 described stomach tubes made of soft rubber and with a smaller lumen and showed that they could be introduced without using stylets.

Most of the pioneer work on the development of the duodenal tube was performed in America. Turck and Hemmeter described tubes with which the duodenum had been intubated. Shortly thereafter Finhorn and Gross independently simplified and improved them. Gross recommended that the patient should lie on the right side after the tube had been

swallowed in order to facilitate passage into the duodenum. Levin in 1921 described the smooth catheter tipped duodenal tube which could be passed through the nares. Many other types have been described but extensions in the indications for usage have greatly outstripped the improvements in construction.

Whereas the duodenal tube was employed almost exclusively as a diagnostic procedure for many years, it is being used more and more in recent times as a therapeutic agent and particularly in the treatment of intestinal distention. Approximately 25 years ago, its use for continuous siphonage drainage was advocated by Westermann and Karpis in the treatment of distention associated with peritonitis. Kanavel and Matas made contributions to this subject. The work of McIver and his associates in which they showed the important role played by swallowed air in the genesis of postoperative distention has extended the indications for decompression therapy. Many surgeons have treated postoperative distention and other conditions by the use of the duodenal tube as a siphon. Ward of San Francisco was the first to employ continuous suction to the duodenal tube in the treatment of peritonitis. Wangensteen was the first to use the principle of continuous suction applied to the duodenal tube in the treatment of some types of mechanical obstruction of the small intestinal tract. The popularization and perfection of this therapeutic procedure is due largely to Wangensteen and Paine. Whereas siphonage is efficient in the drainage of the urinary bladder and other closed cavities of the body, they showed that the difference in the effectiveness of siphonage drainage of the gastro intestinal tract as contrasted with the

other cavities is dependent on the presence of gas as well as fluid which enters the tube and stops its action. Siphonage is dependent on the difference in the heights of two columns of water and the presence of a moderate quantity of gas destroys its effectiveness. Continuous mild suction is a better means of removing the combination of gas and fluid. Wangenstein and Paine have shown that, when the obstruction is due to adhesions and is accentuated by the accompanying distention, it may be relieved permanently by suction applied to a duodenal tube. Further, they showed that deflation of the stomach and upper part of the small intestines renders the operation, if such is necessary, less dangerous and easier to perform. In this connection, it may not be amiss to state in a short-circuiting operation in which collapsed and distended loops of intestine are anastomosed that one should be certain that the collapsed intestine is not that which has been decompressed by the tube and hence is proximal to the point of obstruction.

However, there are a good many patients in whom gastroduodenal suction is not successful in relieving the distention. Furthermore, even though the distention is relieved by the duodenal suction, the location and nature of the lesion may still be unknown. It is in these cases that the intestinal intubation method of Miller and Abbott may achieve gratifying results. In principle, the method consists of passing through the nose into the small intestinal tract a double lumen tube or a pair of tubes, the larger opening being used for aspiration purposes and the smaller one for the inflation of a rubber balloon which surrounds its distal end. With the combination of aspiration of the intestinal contents and of inflation of the balloon, peristalsis carries the tube down the intestinal tract. This takes place whether the obstruction is mechanical or paralytic. It offers an interesting and new method for

many physiopathological studies on man and animals. Striking results following its use in patients with distention due to several causes have been reported by Abbott and Johnston, Penberthy, Noer and Kenning, and by others. In a number of instances, decompression has released the obstruction and operation has been unnecessary. The tube usually advances until the tip reaches the point of obstruction. Under these conditions, examination of the aspirated material and the injection of an opaque suspension combined with x-ray studies may reveal the location and the nature of the lesion.

The men who have developed the methods for decompression of the intestinal tract are quite conservative in their claims. It is emphasized that this therapy should not be used in cases of strangulation of any part of the intestinal tract and in instances of obstruction of the large bowel. Since strangulated external hernias usually present no difficulty in diagnosis, costly mistakes are most apt to occur in instances of volvulus, internal hernia, and intussusception. Since early operation is urgently indicated in patients with strangulation, the time required for the passage of the tube is not permissible. The greatest difficulty usually lies in getting the tube to pass through the pylorus into the duodenum but it is likely that better methods for doing this will be evolved. In general it may be stated that a trial with suction is permissible in those cases in which clear indications for immediate operation do not exist. It cannot be emphasized too strongly that the person who elects to treat a patient with mechanical obstruction by non-operative means must use the x-ray in following the results of the therapy. If suction does not result in decompression in 24 to 36 hours, an operation is indicated. Prolonged non-operative management is apt to be especially dangerous in the absence of a

history of previous abdominal operations since under these conditions adhesions are not so likely to be the cause of the obstruction.

If the contra indications to the use of intestinal intubation are understood fully and, if the patients are chosen properly, the method may offer many advantages. It may make an operation unnecessary by relieving the distention above the point of obstruction with a resulting re establishment of the normal intestinal continuity. Even if an operation is necessary, it may be used in preparing the patient by relieving the distention, making for an easier procedure both for the patient and the surgeon. It offers a non operative means of combating the distention in paralytic ileus. Conditions other than mechanical obstructions in which the employment of suction may be indicated include the physiological obstructions whether they accompany operations, infection, or a variety of conditions including the distention accompanying uremia, pneumonia, and fractures. The work of Fine, Sears, and Banks indicates that the inhalation of oxygen may be effective in combating the distention associated with some of these conditions. Intestinal intubation offers a means of supplying fluids when they are needed urgently. It affords a possible method for determining the location and nature of the lesion in the intestinal tract. It may be used to diminish the tension on sutures in the intestinal tract or to permit a greater delay in the making of an opening in an exteriorized portion of the intestines. Following eviscerations through incisions, it may be employed in combating distention. Duodenal suction alone will be effective in many of these conditions but the use of the double tube with the balloon increases the area which is accessible.

The therapeutic procedures enumerated are relatively new and undoubtedly many improvements in the methods now used will be

made. Since they offer such bright possibilities, it is hoped that indiscriminate and ill advised usage will not retard their development. It seems quite likely that the decreasing popularity of enterostomy in the treatment of ileus, paralytic and otherwise, will decrease still further as a result of the effectiveness of these non operative means of therapy.

ALFRED BLALOCK

HYDATIDIFORM MOLE AND CHORIO-EPITHELIOMA

A STUDY of the extensive papers on hydatidiform mole and chorio epithelioma written prior to 1930 (the year in which the Aschheim Zondek test became of practical use) reveals that the mortality rate for mole was approximately 12 per cent and that of chorio epithelioma 60 per cent. During that period hydatidiform mole was usually not diagnosed until hydatid vesicles were demonstrated, and the presence of chorio epithelioma was not suspected until metastases had appeared. A recent five year survey of these two diseases on the Pacific coast and a review of the world's literature for 1935, 1936 and 1937 shows that the mortality rate for hydatidiform mole and for chorio epithelioma has dropped to 2 per cent and 10 per cent, respectively. Analysis of the recent literature points to the fact that the decreased mortality is the result of early diagnosis by means of the various biological pregnancy tests which have come into vogue and early treatment by hysterectomy.

At the present time there is sufficient evidence in the literature to show that it is wise to leave the ovaries when hysterectomy is performed. The exceptions to this rule would be, of course, primary chorio-epithelioma of the ovary following ovarian pregnancy, pri-

mary chorio-epithelioma of the ovary due to a chorio-epitheliomatous growth in a teratoma, or actual metastases which seriously involve the ovary. Torsion of an ovary containing lutein cysts or enormous enlargement of an ovary as a result of lutein cysts would probably necessitate removal of the involved ovary.

In order that even better results may be obtained, loose concepts must be abolished, more exact knowledge and better interpretation of the tests for gonadotropic hormone must be had, and a technique better than is at present extant is needed so that the most minute amounts of living chorionic tissue can be detected. And it is to be hoped that pathologists by more extensive and more painstaking

examination of the mole will ultimately be able to formulate criteria that will establish potential malignancy and thus enable us to prophesy the advent or to determine the existence of chorio-epithelioma. The highest percentage of cures will be obtained when there is judicious correlation of the clinical history, verification of the histological examination, and intelligent interpretation of the biological pregnancy tests. It would appear if modern criteria are used, early diagnosis made, and early operative treatment instituted that the woman with chorio-epithelioma will have approximately a 95 per cent chance to get well and keep her ovaries.

ALBERT MATHIEU

THE fourth edition of Boyd's *Surgical Pathology*¹ exhibits no departure from the highly satisfactory method of presentation found in the preceding editions. The treatise is divided into thirty-seven chapters which are carefully selected, and comprise practically all of the more commonly encountered diseases in the realm of surgery. An interesting introductory chapter on surgery and pathology, omitted for the first time from the third edition, has been reinserted. Included among the new subjects are lymphogranuloma inguinale, primary thrombosis of the axillary vein, glomus tumor, pilonidal cyst, Hashimoto's disease, parathyroid tumor, regional ileitis, the pathology of the intervertebral discs, Gradenigo's syndrome, and tumors of the islets of Langerhans.

The rewriting of the chapter on diseases of the rectum has vastly improved the section on ulcers and fistulas. The pathogenesis of these conditions is discussed in a manner quite commensurate with the contemporary understanding of the subject. In the chapter on appendicitis, considerable attention is paid to the work of Wangenstein and Bowers demonstrating that obstruction plays an all important rôle in appendicitis. The author declares that in recent years much progress has been made in the study of neoplasia. He points out the significance of the phenathrene ring in the experimental production of cancer. New material is also included on the relation of the hypothalamus to gastric ulcer, the pathogenesis of renal calculi, and the relation of chronic mastitis to carcinoma of the breast.

No effort is made to have the experimental work on any subject complete. The author, instead, carefully selects what, in his opinion, is significant. By this method the material is brought quite well up to date, and the size of the book is prevented from becoming unreasonable. The text reads easily and is very fresh and alive, due most probably, to the discussions on pathologic physiology. This is correlated with the gross and microscopic pathology and the symptomatology in such a way as to make an extremely elucidating and interesting work. The author's style is direct and concise and possesses unusually good literary form for a medical book. The volume should certainly be in the library of every surgeon and pathologist.

ALEXANDER SLIVE

EVERYONE who has used carbon dioxide and oxygen for therapeutic purposes should read Henderson's *Adventures in Respiration*² Why? Because the book is written by the discoverer of the therapeutic use of carbon dioxide and oxygen in such a clear and interesting manner that every physician and medical student can comprehend and enjoy reading the facts regarding the acapnia theory, the theory upon which the therapy is based. It is only

with such information in mind that the therapy can be most rationally used. The author's method of "resuscitation from asphyxia" has undoubtedly saved many lives. The facts upon which this accomplishment is based are presented truly as the author states, "as a simple story of adventures adventures in respiration as I have myself experienced and enjoyed them."

A C IVY

PROCEDURES for practically all situations in plastic surgery are included by Barsky in his recent book³ and, according to the preface, these procedures have been evaluated and have been successful in his hands and the hands of his colleagues. The usual diagrams of methods of closure of small defects are outlined along with type of anesthesia used. The section on free skin grafts lacks photographs of results obtained which would make the text inadequate were it not for the fact that further details of grafting appear under other chapter headings. One is especially surprised in examining the diagram showing the thickness of various grafts to find that the same mistake has been made as in other texts for example, a split or thick Thiersch graft is shown being cut through the basal layer of the epidermis. The author states in the text, however, that the split graft is cut one-half to three-fourths the thickness of the skin. Apparently he has not correlated this statement with the mistaken idea shown in the illustration.

An upper lip mucous membrane flap is recommended for a small vermilion loss on the lower lip but no mention is made of the method employed by New and others, simply to mobilize the mucous membrane on the inside of the same lip and advance it. In the chapter on jaws, the subcutaneous section of the ramus for retrusion is credited to Padgett instead of to Blair.

Nose operations are quite fully described and there is a wealth of material in the book, but one might surmise that the subject of plastic surgery needs a larger text if the entire field is to be covered. The book should receive a good reception by the increasing demands of surgeons who find it difficult to obtain the scattered articles in the literature that describe the procedures now in general use.

JAMES BARRETT BROWN

THE authors—professor and associate professor, respectively, of pathology in Temple University School of Medicine—of *Essentials of Pathology*⁴ present what they consider fundamental and essential in pathology by a new method. In general outline, the familiar and orthodox division into general pathology, tumors, and systematic or special pathology is followed. But within the several chapters "a concise discussion" of each specific pathological condition or disease is followed by one or more "carefully

¹SURGICAL PATHOLOGY. By William Boyd, M.D., LI.D., M.R.C.P. (Ld.), F.R.C.P. (Lond.), Dipl. Psych., F.R.C.S. 4th rev. ed. Philadelphia and London: W. B. Saunders Co., 1938.

²ADVENTURES IN RESPIRATION. Modes of Asphyxiation and Methods of Resuscitation. By Yandell Henderson. Baltimore: Williams and Wilkins Co., 1938.

³PLASTIC SURGERY. By Arthur Joseph Barsky, M.D., D.D.S. Philadelphia and London: W. B. Saunders Co., 1938.

⁴ESSENTIALS OF PATHOLOGY. By Lawrence W. Smith, M.D., and Edwin S. Gault, M.D. With a foreword by James Ewing. New York and London: D. Appleton-Century Company, Inc., 1938.

selected case histories complete with their associated gross and microscopic pathology' Dr James Ewing in his foreword expresses the belief that this case history method is one of the most successful of the

various devices that have been employed to take the teaching of pathology out of the realm of abstract philosophy and make it an effective force in the professional equipment of the medical student. This method of the clinicopathological conference has been employed in teaching of junior and senior medical students and graduate physicians for many years but this is the first attempt to use it in present the first or elementary course in pathology. How successful this method will prove in this new field remains to be seen. It should yield satisfactory results for it does possess advantages. In the first place it gives pathology a practical value—an expression that has a large appeal to medical students and graduate physicians. The clinical history with the essential associated and adventitious pathological changes in each case impresses the student with the fact that any one section represents only a part of the entire disease process and thus enables him to gain a broader concept of pathology and its relation to the science and art of medicine. The descriptions of microscopic pathology in specific cases should by example aid students in making adequate records of their own observations in studying and describing their own microscopic slides.

A certain amount of the philosophic basis and general principles of pathology must be presented if the student is to acquire an adequate knowledge of the clinical side of medicine and is to meet successfully the serious emergency problem of passing state and national board examinations. For he who can load his facts on the wheel of theory will be able to carry more facts than if he has to handle each one in an isolated package. In general the concise discussion of each subject in this volume is perhaps adequate for both these purposes. In some instances for example, the explanation of the mechanisms of the different types of edema on page 46 the discussions are too brief to meet these requirements.

Certain sections merit special commendation. The important tropical diseases and those due to animal parasites are treated in an especially satisfactory manner. Tumors are likewise emphasized to a rather greater extent than is customary. The general discussion of this subject covers 163 pages with 133 illustrations. The authors insist that cancer is not a single disease but a generic term applied to a variety of conditions of different etiology, running typical specific courses affecting particular organs and tissues and having but one property in common—the autonomous new growth of cells. The leucemias (pp 300-308) and Hodgkin's disease (pp 295-296) are placed frankly among the malignant tumors. The statement that in Gruskin's test (intracutaneous injection of extracts of certain fetal tissues) for carcinoma and sarcoma, well over 90 per cent accuracy has been established (p 229) will doubtless meet with considerable skepticism.

Satisfactory discussions, excellent illustrations and interesting case reports of the rare tumors of the ovary—arrhenoblastoma granulosa or theca cell carcinoma and Brenner's tumor—are given on pages 717-720. But there is no description of the changes in the endometrium during the various phases of the menstrual cycle.

This volume contains 865 pages of text with 679 illustrations, reports of 295 cases and an adequate index of 18 pages arranged in three columns to the page. The typography is excellent with the case reports in small but clear type. The pages measure 8½ by 11 inches and are therefore larger than those of most textbooks. But the printed material is arranged in two parallel columns each 3 inches wide and this makes for easier reading. The illustrations—gross specimens, roentgenograms and photomicrographs—are on the whole excellent. Reproductions of the 12 colored plates are worthy of special notice.

The numerous carefully selected illustrative clinical histories with microscopic and in many cases gross and x ray illustrations of each case together with the rather more than usual success in correlating clinical and pathological findings should render this volume both useful and interesting to clinicians and medical students alike. J P SIKOROS

DR KARSNER'S textbook *Human Pathology*¹ first printed in 1926 now appears in a fifth edition following the fourth edition after an interval of 4 years. That the book should go through five editions in the 12 years since its first appearance and its continuous inclusion among the texts recommended for students in most of our medical schools indicates that Dr Karsner's text is accepted by his pathologist colleagues as well as by others as a reliable and useful book.

Though the book is designated as a new edition there are but few changes. It could perhaps as well be designated a revision as a new edition. Little new material has been added. While it is stated in the preface that no chapter has escaped alteration in many of the chapters the alterations consist of a few changed words or sentences. A few paragraphs have been rewritten.

Physically the fifth edition is practically identical with the fourth. The arrangement of material and chapter sequence remains unaltered. A few unnumbered photomicrographs are added and some new illustrations are substituted for old ones. The text continues to be well illustrated. The bibliography has received revision and continues to be excellent.

Dr Karsner's gross and histopathological descriptions are concise, clear and effective. While anatomic changes are clearly presented, too often an equally clear concept of the disease as an entity of disordered physiology does not emerge. This apparently too exclusively anatomical viewpoint is further stressed

EXPERIENCES WITH EMPLOYMENT OF SUCTION IN THE TREATMENT OF ACUTE INTESTINAL OBSTRUCTION

A Reiteration of the Indications, Contra-Indications, and Limitations
of the Method

OWEN H. WANGENSTEEN, M D , F A C S , CHARLES E. REA, M D ,
BAXTER A SMITH, Jr , M D., and HANNS C SCHWYZER, M D ,
Minneapolis, Minnesota

SEVEN years ago, one of the authors reported the successful decompression of 3 instances of acute mechanical intestinal obstruction by continuous suction applied to an indwelling tube (18). It was then indicated that the chief rôle of conservative decompression in the management of mechanical obstruction of the bowel would probably be found to be in instances of adhesive obstruction in which drainage of the bowel would permit automatic re-establishment of luminal continuity. It was asserted then also that colonic obstruction accompanied by great distention and strangulating obstructions were absolute contra-indications to attempts at achieving release of the obstruction by suction. In the intervening years, a number of expressions have come from this clinic upon the management of bowel obstruction (19, 20, 21, 22, 23, 24). Save for an analysis of the experience gained dur-

ing the first 2 years (25), no systematic study of the rôle and the successes and failures of the suction management of acute mechanical obstruction of the intestine has been made since in this clinic. The invitation to review the experience of this clinic with the method is, therefore, not only welcomed but recognized as a duteous obligation.

As explained in the initial communication, the idea that the small bowel when obstructed could be decompressed by an indwelling duodenal tube was no accidental observation but the outgrowth of quantitative determinations of the gas and fluid escape through enterostomy tubes following operative relief of obstruction. As soon as drainage of the bowel proximal to the obstruction permits re-establishment of intestinal continuity, the escape of gas and fluid through the enterostomy usually ceases.

The indications and the contra-indications for the employment of suction applied to an indwelling duodenal tube in the management of acute obstruction have remained essentially the same during these 7 years. These have

From the Department of Surgery, University of Minnesota Medical School

This study was supported by a grant from the graduate school. Presented at the meeting of the Western Surgical Association, Omaha, Nebraska, December 1938.

been described so often that they will not be repeated here. The relative indications for the employment of suction are so many that it would be well to reiterate a warning which has been uttered on other occasions, namely, "The practice of employing suction as a test procedure to indicate whether operation will be necessary leads only to deferment of appropriate treatment." Neglect of this admonition is the most mischievous error into which one may fall in the application of suction to patients with intestinal obstruction.

It is to be admitted freely that suction in such instances is a "blind method" far more dum sighted than "blind enterostomy," in the use of which method, at any rate, the abdomen is opened. It is highly important, therefore, that he who uses the method be acquainted not only with its shortcomings, but also with the intricacies and limitations of diagnosis of acute abdominal disorders. Bearing in mind the significance of *intestinal colic*, the absence or presence of demonstrable peritoneal tenderness, the character of the gastric aspirations and the disclosures of the scout film of the abdomen, the trained clinical observer can tell usually with high accuracy (1) whether obstruction is present, (2) whether the obstruction is simple or strangulating in character, (3) where the obstruction is and (4) whether it is complete or incomplete. Often he cannot say what the causative agency is or just how the bowel is obstructed. Determination of the exact pathological mechanism of the obstruction without operation is, therefore, almost invariably conjectural. Yet except for rare occurrences of enteric intussusception or obstruction by gall stones, deductions made from a summation of the clinical and roentgenographic evidence in instances of simple obstruction are ordinarily accurate. He who elects to employ suction in the presence of *intestinal colic* accompanied by rebound tenderness of the abdominal wall does it at the great risk of treating a patient conservatively who has a strangulating type of obstruction. The only source of error is that such a patient may have a simple mechanical obstruction as a consequence of an inflammatory lesion which provokes tenderness. This differentiation unfortunately can

not be made always. It is no idle academic discussion, for many an inflammatory lesion is extended by invading the peritoneal cavity unnecessarily. At the same time, it is foolhardy and dangerous to treat conservatively a patient who may have a strangulating type of obstruction.

Furthermore, patients with strangulated gut, who are observed only after the elapse of some time, may be incorrectly identified as instances of peritonitis of inflammatory origin. Untrained observers particularly are likely to fall into this error. With the escape of fluid into the peritoneal cavity, the *intestinal colic* becomes less and less a prominent feature and may be elicited with the stethoscope only after long periods of waiting and listening at the bedside. Yet, observant attention to the story and the lending of a careful and attentive ear for the presence of abdominal sounds and noises over protracted periods of time, should serve to eliminate this potential source for tragic blunder. It is an error which hedges about the recognition of the presence of bowel obstruction rather than over choice of treatment.

The trained observer is more likely to err in overextending the relative indications for suction than he is in misapplying suction to a patient with a strangulated gut in whom exploration is mandatory. Untrained observers may fail to identify strangulating obstructions and confuse them with primary inflammatory lesions. Such has been the experience in this clinic.

EVALUATION OF RESULTS

The strength and weakness of a therapeutic measure can be appraised only by extensive trial and a study of the results. The scheme employed in the report (25) of 1933 will be followed in the evaluation of the suction method. That study included a few patients seen in consultation in other hospitals in the metropolitan area of the Twin Cities. This study relates only to patients admitted to the University Hospital in the 7 year interval between June 1, 1931 and June 1, 1938. In the earlier study all patients were seen by 2 observers (Faine and Wangenstein). This study parallels more closely common hospital

practice in which the responsibility for observing and treating the patient is shared by a much larger group of men. While the senior author of this paper has been responsible for outlining the general policy of management and a large number of the patients have come under his immediate attention, somewhat more than a dozen staff members and surgical residents have shared the responsibility of determining the choice of a therapeutic procedure in the series of cases reported herewith and of performing the necessary operations.

DIVISION OF CASES

The tabulated results include all patients with acute mechanical obstruction of the small intestine that have been observed at the University Hospital in the interval between June 1, 1931, and June 1, 1938. To be certain, suction applied to an inlying duodenal tube has played no significant function as a sole agent in such cases as strangulated hernias and intussusception. Yet, it has appeared important to consider all patients with obstruction of the small intestine in this study to indicate more accurately what the rôle of suction is considered to be. Patients with obstruction of the colon have been excluded from this study for, as has already been stated, conservative decompression concerns essentially obstruction of the small intestine. Only those patients with colonic obstruction in whom distention is not a prominent feature are suitable for attempts at decompression by an inlying duodenal tube. In all patients in whom great distention of the colon exists, immediate operative decompression is indicated. It should probably be said, however, that 6 patients with acute colonic obstruction in whom the distention was only of moderate grade have in this interval of time been treated by an inlying duodenal tube and suction, thereby avoiding colostomy as an initial operative procedure. There were no deaths in this group. The experience of any clinic in the management of acute bowel obstruction cannot be sampled adequately unless all types of cases are recorded. Even though the employment of suction does not relate significantly to the treatment of patients with acute obstruction of the large bowel save as a

secondary auxiliary factor, the experience of this clinic in the management of such cases also will be detailed briefly. Patients with inflammatory intraperitoneal lesions in whom distention occurred and other types of physiological ileus, in the relief of which suction is an important therapeutic agency, are not considered in this study save in those few instances in which the presence of mechanical obstruction to intestinal continuity was affirmed on good factual data.

The cases have been grouped as follows

1. *The suction group*

A. Patients in whom suction applied to an inlying duodenal tube was the only treatment directed at the relief of the obstruction (no operation).

B. Patients decompressed by suction but operated upon subsequently because of demonstrated or conjectured persistence of obstructive mechanism.

C. Patients in whom suction was unsuccessful in effecting decompression and in whom operation became necessary for satisfactory relief from acute obstruction.

2. *Patients treated by immediate operation*

A. Intraperitoneal obstructions.

B. Strangulated hernias.

C. Intussusceptions.

3. *A miscellaneous group in which no therapy directed at the relief of obstruction was carried out because the patient was*

A. Moribund or dead on arrival at the ward.

B. The obstruction had righted itself spontaneously.

C. The presence of obstruction was not recognized.

RESULTS

The results are to be noted in the tables for each group. A brief synopsis is to be found in Table VIII. The salient information regarding all patients who died is tabulated briefly. The case records of fatal cases are, in the main, far more deserving of study and at the same time more instructive than are the successes.

In the calculation of mortality a "corrected factor" has been introduced to denote those patients who died of intestinal obstruction. In a series such as this a number of patients are observed with terminal carcinomatosis or extraperitoneal infection in whom acute mechanical obstruction occurs as an incident. If the management of the distention failed to relieve the obstruction, the death is counted as being due to obstruction; if on the con-

Classified also in Group 2 (death No. 10)			1					

Deaths in Group 1

The first 6 deaths are considered as unrelated to the obstruction

1 E.D. No 624561 female aged 74. Patient had generalized carcinomatosis primary in the ovary and partial intestinal obstruction. Relief was secured by suction applied to an intying duodenal tube but patient could not tolerate clamping of the tube. Patient died 31 days after admission.

2 F.E. No 623097 male aged 50. Patient had a perforated peptic ulcer repaired eleven years previously. He came in for treatment of bilateral emphysema and lung abscesses. During the hospital stay patient developed small and large bowel obstruction controlled by suction. The patient died of toxemia due to abscesses and emphysema and of respiratory embarrassment. Autopsy also showed adhesive bands.

3 O.H. female aged 18. Patient had an 11-day history of symptoms of small bowel obstruction on an adhesive basis. Suction gave partial relief in 24 hours and complete decompression in 48 hours. Duodenal tube was removed in 144 hours. The patient was symptom free for 3 days and then died suddenly. The mode of death strongly suggested suicide by poisoning. However this was not proved.

4 C.S. No 662462 male aged 62. History was unreliable. Patient had had chills, sweats, cough, obstipation, considerable vomiting, and increasing abdominal distention for 6 or 7 days. Mass was palpable in the left lower quadrant. X-ray findings after an Ambrothor meal were interpreted as obstruction in the upper small bowel probably due to carcinoma. The patient refused surgery despite frequent urging and was treated with moderate relief by suction. The patient expired on the fourteenth hospital day, 11 days after surgery was advised. Autopsy was refused.

5 O.M. No 66054 male aged 61. This patient had had resection of carcinoma of the sigmoid colon done eleven years before admission. At the time of admission he had had quite severe back pain for 4 months and had lost 20 pounds during this period. On the fourth hospital day the patient developed partial intestinal obstruction and was treated by means of duodenal suction for 11 days. The obstruction seemed controlled. The patient died on the thirty-fourth hospital day of carcinomatosis. There

was no distention of bowel found at autopsy. The tube was removed after 11 days.

6 R.B. No 618098 female aged 6 days. The patient was a 6-day-old baby who was admitted because of persistent vomiting and a walnut sized mass at the base of a necrotic umbilical stump. Intestinal contents drained at the umbilicus and with probing of the wound drainage became free and the emesis ceased. X-ray examination revealed complete obstruction at the cecum. The patient was treated with suction and para-enteral fluids alternating with concentrated predigested food. The fistula was frequently probed to permit drainage and stop vomiting so that feeding could be done. Gangrene of the arm developed necessitating amputation. Patient expired the thirtieth hospital and second day following amputation. Autopsy revealed the fistula to be in the terminal ileum with many adhesions in this region the adhesions apparently causing the obstruction. There was also a congenital stricture of the cystic duct.

The following case histories involve deaths related to obstruction.

7 E.R. No 060151 male aged 54. Patient had had vague gastro-intestinal distress almost all his life, more marked for the 3 to 5 years prior to admission. His pain had been constant for the 4 months prior to admission and he had been largely incapacitated. There was a history of recent red blood in the stools. The patient had had abdominal cramps, vomiting and obstipation. He had been treated in another hospital for 10 days for an intra-abdominal condition the diagnosis of which was reserved. There had been shoulder strap pain for 24 hours. The patient had had appendectomy 30 years before admission. At the time of admission there was marked distention of the abdomen with extreme tenderness in the upper abdomen but no definite rebound tenderness. The abdomen was silent. X-ray examination revealed distention of small and large bowel and some loss of peritoneal markings but no free gas. Diagnosis made was possible perforated ulcer but this was indeterminate. The patient was treated conservatively with suction and transfusions. He expired on the 11th hospital day. Autopsy revealed strangulation obstruction due to visceroparietal adhesions at site of old appendectomy. There was peritonitis but no definite perforation. There was a duodenal ulcer not perforated.

8 H O, No 662246, male, aged 19 This patient had had appendectomy 6 months before admission No gross abnormality had been found On the day of the present admission the patient suffered sudden, severe abdominal pain accompanied by vomiting He had been given 2 injections of what was believed to be morphine Upon admission, examination of the abdomen revealed no distention, and the abdomen was soft There was some tenderness in the right lower quadrant with slight spasticity there The patient was heavily narcotized The abdomen was quiet to auscultation X-ray examinations were inconclusive, and the diagnosis was reserved The patient was treated conservatively and under observation The temperature rose and distention appeared and increased The patient became irrational within 48 hours (temperature 99.6 degrees R and pulse 110) and from that time on he removed the duodenal catheter frequently He died the sixth hospital day with the diagnosis of peritonitis, cause undetermined Autopsy revealed strangulation obstruction under an adhesion and peritonitis There was a Meckel's diverticulum of no note

9 A H, No 601060, female, aged 66 Patient had had a 30-year history of cholecystitis Cholelithiasis had been diagnosed by x-ray examination and surgery had been advised, but was refused She was admitted 1 year later complaining of pain in the upper abdomen and in the back This attack was of 25 days' duration at the time of admission She had medical management for 8 days during which time she had barium by mouth upon 2 occasions In the latter examination it was noted that there was a spontaneous cholecystoduodenal fistula and that the gall stones were in the pelvis They completely obstructed the flow of barium There was distention of the small bowel by gas, and the patient was transferred to the surgical service The patient was a very poor surgical risk, among other things, she had retained practically nothing by mouth for over 1 month It was hoped that the stones would pass and the patient was treated conservatively with suction, paracentral fluids, and hot packs The distention was relieved

trary, the obstruction is relieved satisfactorily and the patient survives for a reasonable period of time to die of the initial primary condition, such patients are omitted in the calculation of the "corrected mortality" Inasmuch as a few patients were obstructed more than once, both a patient and case mortality are listed

COMMENT

Obstruction of the bowel embraces a large number of rather diverse pathological conditions which bring about similar end-effects One of the surprising findings brought out in this review of the experience of this clinic in the treatment of acute bowel obstruction is how large a number of the patients exclusive of strangulated hernias, intussusception, and acute obstructions of the large bowel, have been treated entirely or primarily by suction There have been a few glaring mistakes made (Group 1, A, deaths Nos. 7 and 8 Group 1,

and the stones did move slightly the first few days After that, however, they remained stationary and the obstruction persisted, but was controlled by conservative management of alternating suction and feeding The patient died on the fifty-fifth hospital day, the forty-seventh day on the surgical service Autopsy revealed a cholecystoduodenal fistula and intestinal obstruction of a chronic nature due to impaction of a mass of gall stones This mass could not be moved forward or backward in the bowel Two sharp projections had perforated the bowel wall and there was localized peritonitis When the mass of stones was removed, it could not be broken by moderately vigorous manipulation There were impacted stones in the common duct

10 E C, No 615599, female, aged 52 The patient weighed 375 pounds She had a ventral hernia of 20 years' duration with a second defect of 10 years' duration, the latter the result of an attempted repair of the former The patient was admitted with a history of pain in the region of the hernias, abdominal pain of a cramp-like character, and nausea and vomiting for 6 days prior to admission Examination of the abdomen revealed obesity, 2 ventral hernias filled with bowel from which gas could be expressed There was some tenderness over the hernias There were no borborygmi noted at the acme of pain The patient's systolic blood pressure was 55 millimeters of mercury the day of admission In spite of the possibility of strangulation, it was deemed advisable to treat the patient conservatively This was done The patient expired on the third hospital day At autopsy all the small intestine was found free in the peritoneal cavity proper The hernias were filled with colon Almost all the terminal ileum was strangulated with perforation of the anti-mesenteric border in one spot There were adhesions present, most of which were not related to the peritonitis found at autopsy It was believed that strangulation had taken place in one of the hernial sacs and that the bowel had returned to the peritoneal cavity after death, judging from the findings at autopsy

C, death No 6) in extending the indications for suction¹ When these cases are reviewed critically in the light of the significant evidence abstracted from the case records, it is only fair to say that the fault lay largely in

¹In the discussions of the Western Surgical Association for 1937 which have been printed since this paper was written is contained the suggestion that the so called conservative management of mechanical obstruction is *expectans morlem* treatment And so it may well be, when applied to unsuitable cases Yet, in the experience of this clinic, suction has proved a worth while adjunct as well as a valuable direct, single, therapeutic agent in the treatment of certain types of bowel obstruction

There have been no injuries noted in the pharynx, larynx, esophagus, or stomach of any of the patients reported in this series One patient in the series had a duodenal tube down constantly for purposes of feeding or suction for 47 days (Group 1, A, death No 10) Two patients have been observed at the University Hospital with injury to the arytenoid cartilages following prolonged intubation One of these was our own patient After drainage of the abscess the condition cleared quite satisfactorily The other patient was admitted here with edema of the arytenoid cartilages and larynx for which tracheotomy was done He, too, recovered but with residual limitation of motion of one of the vocal cords In the 7 years during which suction has been applied frequently to intubing duodenal tubes, probably more than 5,000 patients in this hospital have earned such tubes for variable periods of time

The pathologists of the metropolitan area of the Twin Cities have been interrogated with reference to traumatic lesions from duodenal tubes at various times and none has been reported to us save an occasional small erosion of the gastric mucosa Inasmuch as our pathologists do not examine routinely the nasopharynx, larynx and upper reaches of the esophagus, it is of course not unlikely that in this region, where such pressure effects are most likely to arise, several have escaped notice

Deaths in Group 1B

1 D.K., No. 616766, female aged 32. This patient returned 3 days after having been successfully decompressed by suction. She had recurrence of symptoms and findings. There was 4 plus distention and loops of small bowel were palpable and visible. There was no tenderness or rigidity. The small bowel was completely decompressed by suction in 48 hours and suction was continued intermittently for 36 hours more. Surgery had been advised following decompression during the former admission but was refused. Surgery was accepted this time and was carried out. On

exploration no obstructive mechanism was found and the obstruction was believed to be spastic in nature. A presacral neurectomy was done. This procedure was accompanied by bleeding severe enough to warrant packing. The patient convalesced well for 4 days when she began to have fever.

The patient died suddenly on the seventh post-operative day following removal of packing. No autopsy was obtained but pulmonary embolism was believed to be the cause of death. Exploration of the wound revealed no evidence of hemorrhage.

each instance with the observers who noted the findings accurately enough but who interpreted them badly. Patients like the 3 referred to, who entered the hospital with a strangulating type of obstruction and who already had transudation of fluid into the peritoneal cavity, are less likely to have *intestinal colic* as a prominent finding than are patients with simple obstruction. Yet, careful auscultation of the abdomen at the bedside over protracted periods of time has invariably in the experience of the senior author of this paper, revealed recurrent intestinal gurgling. To be certain if the strangulation has been present for some time and if the patient has been heavily narcotized *intestinal colic* is by no means a prominent feature and it is difficult on this basis alone to decide that a strangulating obstruction is present. For even

patients with peritonitis of inflammatory origin do have intestinal gurgling occasionally. Yet the tell tale evidence of the history of gas pains and vomiting, the uniform presence of tenderness and the character of the gastric aspirations are extremely helpful. Another significant but less frequent occurrence is the unrelenting and unusually severe character of the pain which overshadows the earlier intermittent crampy pain.

This study indicates that the differential criteria which have been described to distinguish simple and strangulating obstructions are reliable. It is to be admitted freely, however, that now and then due to increase of intraluminal pressure alone the gut of simple obstruction will weep, and fluid will transude into the peritoneal cavity giving rise to abdominal tenderness. In this series of cases

‡During an enterostomy four days after reduction of intussusception, the patient (death No. 10) died. Peritonitis was present. The enterostomy was not completed.

Deaths in Group 1C

The first 4 deaths are considered as unrelated to the obstruction.

1 J.L., No. 646685, male, aged 54. This patient had been admitted 1 year before for probable alcoholic gastritis and enteritis and was treated conservatively. He was admitted with a week's history of vomiting, abdominal pain, and constipation. There was some small bowel distention which refused to clear up completely with long tube but was improved. Eleven days after admission, patient was explored with tentative diagnosis of chronic obstruction probably due to adhesions following an old appendectomy. Tuberculous peritonitis was found and biopsied. He died 13 days later of tuberculous peritonitis, atypical fibroid pulmonary tuberculosis with miliary nodules, and hypostatic pneumonia.

2 H.W., No. 646386, male, aged 37. This patient had a chronic history of over 3 weeks' duration of intestinal obstruction with a gastro-intestinal study having been done outside. He was treated 6 days with suction with no relief.

The abdomen was explored and metastatic carcinoma was found. Enterostomy was done. The patient improved, then obstruction recurred and 10 days later a permanent ileostomy was done, 9 days after which the patient died. No autopsy was obtained.

3 G.S., No. 664482, female, aged 64. This patient was discharged from gynecological service 1 month before admission. At that time she had carcinoma of the ovary with metastases and had had surgery. Symptoms of obstruction present upon second admission were not relieved entirely by duodenal tube well into jejunum, so enterostomy was done 6 days after admission. Patient died 55 days later of carcinomatosis and cachexia. No distention was present at death.

4 I.F., No. 608342, female, aged 30. Patient had had radiation therapy for carcinoma of the cervix 1 year before admission. She was admitted with signs of pelvic peritonitis and obstruction, with cramp-like pain, and borborygmi present. Conservative treatment relieved the pain but distention was not completely relieved so enterostomy was

done 8 days later. The patient continued her febrile course and died 14 days later. Autopsy revealed that the carcinoma had perforated into the rectum causing the peritonitis.

The following deaths were related to obstruction:
 5 CW No 654754 male aged 59. Onset of symptoms of obstruction occurred 5 days before admission. There were no previous operations. Patient was struck in the abdomen by a baseball many years before. A similar attack occurred 8 years before. The bowel was partially decompressed by suction (tube in duodenum next day). X ray third and fourth days showed increased distention and the tube in the stomach. No gas in the colon so the patient was explored (fourth day). Tenderness was not noted. Bowel was too distended for exploration so enterostomy was done. Patient had 2 attacks of acute distention of the stomach. He died the ninth postoperative day of peritonitis atelectasis and hydrothorax. Autopsy showed obstruction to be due to an adhesive band 16 inches below the enterostomy. Exploration rather than blind enterostomy would have obliterated outcome.

6 MS No 663126 female aged 56. The patient was admitted with a 36 hour history of cramp-like abdominal pain and constipation with similar attacks over the preceding few years. The abdomen was very tender and distended at the time of admission. There was no rectal tenderness. Temperature 100 degrees pulse 126 respiration 20. She was treated conservatively. The next morning (14 hours after admission) temperature was 103.4 (R) pulse 140 respirations 22 and abdomen was tender. Exploration (2 hours duration) revealed strangulation of the distal 6 feet of ileum by an adhesive band across the mesentery. Bowel could not be exteriorized because cecum would not deliver so the distal end was resected and the cecum dropped back and the ileum was brought out with a Fayr clamp and an enterostomy was done on the exteriorized ileum. Patient died 12 hours later. The temperature had risen to 106 patient was cyanotic and gasping for breath. Ten minutes before death much fluid was aspirated from trachea and pharynx. Autopsy was refused. Irolonged operative procedure contributed materially to outcome.

7 EM No 661383 female aged 13. This patient had had appendectomy for ruptured appendix and 18 days later she developed obstruction and an enterostomy was done. She was discharged in satisfactory condition. Three weeks later she was admitted with strangulation obstruction due to adhesive bands which were divided and an enterostomy was done. Convalescence was satisfactory and pneumoperitoneum was done 9 days later. Sixteen days after enterostomy the obstruction recurred. Conservative treatment was carried on for 24 hours but the abdomen remained tender and rigid so patient was explored at which time no obstruction was found. There was fibrin on the peritoneum and loops of bowel were adherent to each other. Enterolysis was done. The patient developed a gangrenous wound infection with a doubtful positive culture for gas bacillus and died the second postoperative day.

8 ON No 665195 male aged 52. The patient presented a 3 weeks history of cramp-like abdominal pain vomiting and constipation and had lost 25 pounds in weight. He was followed 2 days in the Out patient Department where he was thought to be a psychoneurotic. He was transferred to surgery the day after admission with complete decompression accomplished in 3 days but the obstruction recurred after ingestion of fluid and so the patient was explored 6 days after admission. The obstruction was found and was thought to be due to carcinoma inflammation or foreign body in the terminal ileum. In attempting to free it up the bowel was accidentally perforated with resultant spillage. Enterostomy was done. The patient died of peritonitis and bronchopneumonia 6

days later. Simple enterostomy would have avoided this unfortunate occurrence.

9 FB No 633028 male aged 57. The patient was admitted with a one week's history of distention occasional abdominal pain (crampy) and constipation. There was an incisional hernia of 8 years duration partially reducible. X ray examination revealed distention of bowel. He was given 24 hours of conservative treatment with decrease in distention of bowel. Under local anesthesia a needle then a trocar then a catheter were inserted into the bowel in the hernial sac and purse string sutures were taken about the catheter. No relief was obtained by this combined with suction. Five days later an enterostomy was done. The patient died the next day with a picture of circulatory collapse. Autopsy was done and revealed gangrenous small bowel and hepatic flexure with perforation of both in the hernial sac. Enterostomy on strangulated segment failed to relieve because of presence of hernia en W (De Beule).

10 LC No 610990 female aged 27. The patient spoke only Mexican and was 4 to 5 months pregnant. History was of cramp-like abdominal pain and vomiting of 3 days duration. Suction was instituted and fluids were given. After 24 hours rebound tenderness appeared, distention had not decreased. The abdomen was explored and an enteric intussusception was reduced. Cultures taken at time of reduction showed peritonitis to be present. Suction was continued. Patient did not improve appreciably and 4 days later became more distended. An enterostomy under local anesthesia supplemented by ethylene was attempted. Patient died suddenly on the table. Peritonitis was present and was the cause of death. There was active tuberculosis in both apices at autopsy. No perforation was found but bowel wall was thinner than normal and the mucosa was ulcerated.

11 JD No 627736 male aged 34. The patient was admitted 7 months after appendectomy for ruptured appendix. The history was 16 hours of crampy abdominal pain nausea and obstipation of sudden onset. Examination of the abdomen revealed tenderness no peristaltic rushes and no distention of note. Conservative treatment was employed without relief for 2 days when rebound tenderness appeared. Patient was explored and strangulation obstruction due to adhesive bands was found and some (but not all) of bands were freed and an enterostomy was done. Patient died 40 hours later with gas bacillus infection of right chest wall (jaundiced). Autopsy revealed gas bacillus infection peritonitis and strangulation obstruction of lower 8 to 10 feet of ileum caused by an adhesive band across the mesentery. The discovery of the strangulation mechanism entailed 45 minutes of searching at autopsy.

12 FC No 6240 female aged 60. Seventeen days prior to admission the patient had black stools and was placed on a milk and cream diet. Four days later she felt ill and had abdominal cramps. She ate no food for 3 days when she resumed her diet. Distention along with intermittent pain was noted a week prior to admission. Distention continued to the time of admission. Two days before admission an enema was given with no results. Abdomen was distended there was no tenderness or borborygmi. Diagnosis was probable spastic ileus. Conservative treatment was employed for 24 hours without relief. Duodenal tube would not enter duodenum even with the fluoroscope as a guide. Abdomen was explored under spinal anesthesia and gas was found in the colon. No obstruction was found but sterile fluid was present. Enterostomy was done. (At the time of admission there was no elevation of white blood count hemoglobin reported 65 per cent and 49 per cent.) Patient died 4 days later. Autopsy revealed

a mass of white stool in the sigmoid colon with perforation, hemorrhage, and beginning peritonitis. No obstruction was found but there was ileus. Acute duodenal ulcer and atelectasis of both lower lobes were found. This was in all probability a case of spastic ileus of the colon with perforation.

13 J.A., No. 643016, male, aged 73. This patient presented a 9 day history of obstruction. There was a 4 plus distention. He was treated conservatively for 17 days with no improvement, so was explored. Cholecystenteric fistula with gall-stone impaction in the terminal ileum was found. The gall stone was removed and enterostomy was done. Spinal anesthesia was used and resuscitation was necessary at the completion of the operation. He died suddenly the evening of operation, apparently a delayed spinal anesthesia death. See also below Table IV, Case 2.¹

¹For more than 4 years now inhalation anesthesia has been employed in all operations for acute intestinal obstruction save in a few instances

14 M.F., No. 611402, male, 22. This patient had cramp-like abdominal pain, nausea, and vomiting for 4 days prior to admission. Appendectomy (drained) had been done 1 year before. Abdomen was 3 plus distended and there was some rebound tenderness. He was treated conservatively for 2 days and the tube was in the duodenum, bowel was partially decompressed. His temperature had risen to 101 degrees F., and there was some rebound tenderness. No gas was in the colon as determined by x-ray examination. The abdomen was explored and a loop of small bowel was found pinched off by an adhesion, but the blood supply was satisfactory. Spillage occurred in dividing the adhesion. The perforation was sutured and an enterostomy was done. The patient died 3 days later of peritonitis.

in which local infiltration with procaine was employed. The patient's stomach is evacuated with an inlying duodenal tube before as well as during operation.

there have been quite a number in which this occurrence was observed during the course of suction treatment. As soon as tenderness supervenes (which should be looked for by experienced examiners every 4 to 6 hours), operation should be done. No deaths occurred in such cases in this series and no disappointment was felt in failing to find a strangulating type of obstruction. The only reason that has been justified for treating patients with acute obstruction of the small bowel presenting abdominal tenderness conservatively has been repeated obstruction in the same patient.² A few such patients appear in this series, none of whom came to harm through this apparent unwarranted departure from established procedure. The only defense for this seeming liberty is the anxiety of the surgeon to postpone operation in such instances until the more complete operation of enterolysis can be done in an unobstructive phase. The persistence of tenderness in such instances, however, indicates that operation is in order, an occurrence which has urged operative intervention occasionally in this type of case.

It is not as easy to define exactly the contraindications for continuance of suction or the criteria which suggest necessity for operation in simple acute obstruction of the small intestine as it is for strangulating obstructions or acute occlusion of the colon with great distention. Disappearance of gaseous distention of the small intestine and reappearance of gas in

the colon (in complete obstruction) herald a successful issue. The consideration which must be kept in mind always is that the longer suction is continued, the greater hazard to the patient if suction fails. The importance of effecting a happy compromise between achieving decompression by suction within a reasonable period or resorting to operative relief is, therefore, the wisest rule to follow. Postponed operations will mean operations of necessity (enterostomy) rather than operations of election. Yet, our own experience with enterostomy in late, adhesive, non-strangulating obstructions has been satisfactory (Table III).

DUODENAL INTUBATION

Our practice has been to introduce the catheter into the stomach. Suction is then applied and the patient is placed in various positions until it is reasonably certain that the stomach has been evacuated. The source of suction is then temporarily cut off, the patient is requested to drink a glass of water and is placed in the lateral decubitus with the right side down. The duodenal tube is advanced about an inch every 5 minutes. After about 30 minutes the cut-off on the suction is released and if the intestinal distention has not been great enough to divert the course of the tube, it is observed usually that bile is aspirated. It is a good plan at this juncture to fluoroscope the patient or take a bedside film to check on the position of the tube. In the main, this method has been quite as successful for the catheterization of the pyloric

²Two female patients with plastic pelvic masses, which caused protracted intestinal obstruction, were treated successfully by inducing hyperpyrexia in a fever chamber, suction being maintained over long periods to an indwelling duodenal tube. Operative intervention in such instances not uncommonly extends the peritoneal infection.

dome 8 days later. The patient continued her febrile course and died 14 days later. Autopsy revealed that the carcinoma had perforated into the rectum causing the peritonitis.

The following deaths were related to obstruction:

5 C.W. No 054754 male aged 59. Onset of symptoms of obstruction occurred 5 days before admission. There were no previous operations. Patient was struck in the abdomen by a baseball many years before. A similar attack occurred 8 years before. The bowel was partially decompressed by suction (tube in duodenum next day). X-ray third and fourth days showed increased distention and the tube in the stomach. No gas in the colon so the patient was explored (fourth day). Tenderness was not noted. Bowel was too distended for exploration so enterostomy was done. Patient had 2 attacks of acute dilatation of the stomach. He died the ninth postoperative day of peritonitis atelectasis and hydrothorax. Autopsy showed obstruction to be due to an adhesive band 16 inches below the enterostomy. Exploration rather than blind enterostomy would have obviated outcome.

6 M.S. No 063126 female aged 56. The patient was admitted with a 36 hour history of cramp-like abdominal pain and constipation with similar attacks over the preceding few years. The abdomen was very tender and distended at the time of admission, there was no rectal tenderness. Temperature 100 degrees pulse 126 respiration 20. She was treated conservatively. The next morning (14 hours after admission) temperature was 103.4 (R) pulse 140 respiration 22 and abdomen was tender. Exploration (2 hours duration) revealed strangulation of the distal 6 feet of ileum by an adhesive band across the mesentery. Bowel could not be exteriorized because cecum would not deliver so the distal end was resected and the cecum dropped back and the ileum was brought out with a Payr clamp and an enterostomy was done on the exteriorized ileum. Patient died 12 hours later. The temperature had risen to 106 patient was cyanotic and gasping for breath. Ten minutes before death much fluid was aspirated from trachea and pharynx. Autopsy was refused. Prolonged operative procedure contributed materially to outcome.

7 E.M. No 061383 female aged 13. This patient had had appendectomy for ruptured appendix and 18 days later she developed obstruction and an enterostomy was done. She was discharged in satisfactory condition. Three weeks later she was admitted with strangulation obstruction due to adhesive bands which were divided and an enterostomy was done. Convalescence was satisfactory and pneumoperitoneum was done 9 days later. Sixteen days after enterostomy the obstruction recurred. Conservative treatment was carried on for 24 hours but the abdomen remained tender and rigid so patient was explored at which time no obstruction was found. There was fibrin on the peritoneum and loops of bowel were adherent to each other. Enterolysis was done. The patient developed a gangrenous wound infection with a doubtful positive culture for gas bacillus and died the second postoperative day.

8 O.N. No 065195 male aged 37. The patient presented a 3 weeks history of cramp like abdominal pain vomiting and constipation and had lost 25 pounds in weight. He was followed 2 days in the Outpatient Department where he was thought to be a psychoneurotic. He was transferred to surgery the day after admission with complete decompression accomplished in 3 days, but the obstruction recurred after ingestion of fluid and so the patient was explored 6 days after admission. The obstruction was found and was thought to be due to carcinoma inflammation or foreign body in the terminal ileum. In attempting to free it up the bowel was accidentally perforated with resultant spillage. Enterostomy was done. The patient died of peritonitis and bronchopneumonia 6

days later. Simple enterostomy would have avoided this unfortunate occurrence.

9 F.B. No 033028 male aged 57. The patient was admitted with a one week's history of distention occasional abdominal pain (crampy) and constipation. There was an incisional hernia of 8 years duration partially reducible. X-ray examination revealed distention of bowel. He was given 24 hours of conservative treatment with decrease in distention of bowel. Under local anesthesia a needle then a trocar then a catheter were inserted into the bowel in the hernial sac and purse string sutures were taken about the catheter. No relief was obtained by this combined with suction. Five days later an enterostomy was done. The patient died the next day with a picture of circulatory collapse. Autopsy was done and revealed gangrenous small bowel and hepatic flexure with perforation of both in the hernial sac. Enterostomy on strangulated segment failed to relieve because of presence of hernia in (de Beule).

10 L.C. No 010990 female aged 27. The patient spoke only Mexican and was 4 to 5 months pregnant. History was of cramp like abdominal pain and vomiting of 3 days duration. Suction was instituted and fluids were given. After 24 hours rebound tenderness appeared distention had not decreased. The abdomen was explored and an enteric intussusception was reduced. Cultures taken at time of reduction showed peritonitis to be present. Suction was continued. Patient did not improve appreciably and 4 days later became more distended. An enterostomy under local anesthesia supplemented by ethylene was attempted patient died suddenly on the table. Peritonitis was present and was the cause of death. There was active tuberculosis in both apices at autopsy. No perforation was found but bowel wall was thinner than normal and the mucosa was ulcerated.

11 J.D. No 027736 male aged 31. The patient was admitted 7 months after appendectomy for ruptured appendix. The history was 16 hours of crampy abdominal pain nausea and obstipation of sudden onset. Examination of the abdomen revealed tenderness no peristaltic rushes and no distention of note. Conservative treatment was employed without relief for 2 days when rebound tenderness appeared. Patient was explored and strangulation obstruction due to adhesive bands was found and some (but not all) of bands were freed and an enterostomy was done. Patient died 40 hours later with gas bacillus infection of right chest wall (pneumothorax). Autopsy revealed gas bacillus infection peritonitis and strangulation obstruction of lower 8 to 10 feet of ileum caused by an adhesive band across the mesentery. The discovery of the strangulation mechanism entailed 45 minutes of searching at autopsy.

12 E.C. No 01470 female aged 60. Seventeen days prior to admission the patient had black stools and was placed on a milk and cream diet. Four days later she felt ill and had abdominal cramps. She ate no food for 3 days when she resumed her diet. Distention along with intermittent pain was noted a week prior to admission. Distention continued to the time of admission. Two days before admission an enema was given with no results. Abdomen was distended there was no tenderness or tortuosity. Diagnosis was probable spastic ileus. Conservative treatment was employed for 24 hours without relief. Duodenal tube would not enter duodenum even with the fluoroscope as a guide. Abdomen was explored under spinal anesthesia and gas was found in the colon. No obstruction was found but sterile fluid was present. Enterostomy was done. (At the time of admission there was no elevation of white blood count hemoglobin reported 85 per cent and 49 per cent.) Patient died 4 days later. Autopsy revealed

Deaths in Group 2B

All deaths are considered as related to the obstruction.

1 A R., No. 663930, female, aged 55. Patient had a 24 hour history of vomiting and of pain in an incisional hernia which she was unable to reduce. At the time of admission her systolic blood pressure was 80 millimeters of mercury and bronchopneumonia was present. She was given a blood transfusion and intravenous fluids before operation. Slight cyanosis was present when the operation was begun. The strangulated ileum was reduced and the normal color of the bowel returned. The patient was placed in an oxygen tent after operation and a blood transfusion and parenteral fluids were given. She improved temporarily, but died the evening of operation. Autopsy showed hypertensive heart with dilation of the right ventricle, edema of the lungs, and bronchopneumonia.

2 C W., No. 632311, female, aged 53. Patient had an incisional hernia which had been incarcerated for 1 month. She had had pain, nausea, and vomiting for several days before admission. At operation there was gangrene of 15 centimeters of ileum, perforation had occurred and the gangrenous bowel was exteriorized and an enterostomy was done on the proximal loop. She died 21 days after operation of sepsis following parotid abscess, submental abscess, and wound infection.

3 M D., No. 640364, female, aged 51. This patient had a femoral hernia which had been incarcerated for 3 days before admission. At operation the bowel was strangulated, but was thought to be viable. The patient died the day following operation of peritonitis, atelectasis, and bronchopneumonia. No perforation was found at autopsy, but there were small areas of focal necrosis of the bowel wall.

4 J B., No. 663086, female, aged 47. Patient had had 4 abdominal operations, 3 of which were for intestinal ob-

struction. She had had abdominal pain and vomiting for 7 hours before surgery. She had an incisional hernia in which the ileum was incarcerated. Two feet of the ileum were gangrenous, strangulation was caused by an adhesive band in the hernial sac. The gangrenous bowel was exteriorized. Convalescence was stormy but satisfactory until the seventh day when the patient's temperature and pulse rose very high and she expired. Autopsy examination done through the operative incision did not reveal enough peritonitis to warrant death, the immediate cause of death was thought to be bronchopneumonia.

5 J R., No. 651256, female, aged 76. Patient had a strangulated incisional hernia. The hernia was surgically reduced and an enterostomy was done proximal to the strangulated segments of bowel. Auricular fibrillation was noted the second postoperative day. Death was due to cardiac failure (left and right) and bronchopneumonia occurred the fifth postoperative day.

6 J T., No. 659832, male, aged 67. This man spoke no English. According to the history obtained, the patient was stepped on by a cow 5 days prior to admission. An incarcerated inguinal hernia was present and the patient was in a state of shock. Eight hours were spent combating the shock. At operation the bowel was found to be strangulated and perforated and peritonitis was present. He died on the first postoperative day.

7 N J., No. 654542, female, aged 64. This patient had a femoral hernia with strangulation and gangrene of a loop of ileum and a Meckel's diverticulum. The loop was exteriorized. The patient died the fifth postoperative day of peritonitis and pulmonary atelectasis.

8 See Group 1A, death No. 10, in which the patient had 2 ventral hernias.

9 See Group 1C, death No. 9, a case in which enterostomy on strangulated segment failed.

TABLE 11.—GROUP 2.—PATIENTS TREATED BY IMMEDIATE OILRATION

A. Intraperitoneal obstructions

Procedure	Patient	Case	Death	Percent mortality		Unrelated deaths	Corrected mortality percent	
				Patent	Case		Patient	Case
Enterostomy	1	6	1	40	33.3	1	20	16.6

Enterostomy	3	1	1		100	0		100
Enterostomy	4	1	0		0	0		0

One patient was later seen in Group C

Deaths in Group 2 A

Death No. 1 is considered as unrelated to the obstruction. 1. A.H. No. 59706 female aged 74. Patient had a long history of constipation and diarrhea. She had had rather severe lower abdominal pain, obstipation and vomiting for 12 days before admission. Examination revealed marked distention of the abdomen with rebound tenderness in the lower abdomen. A hard nodular mass was palpable per rectum. The abdomen was explored and the ileum was found obstructed by adhesions about a mass in the pelvis. Enterostomy was done. The patient had a stormy course and died the eighth postoperative day of pelvic peritonitis due to perforation of a sigmoid diverticulum.

The following deaths were related to obstruction. 2. A.P. No. 61350, female aged 69. This patient had acute crampy colicky abdominal pain of 36 hours duration. Examination upon admission revealed abdominal rigidity with marked lower abdominal tenderness. A diagnosis of intra abdominal strangulation was made and

the patient was operated upon immediately. Spinal anesthesia was used. The patient was somewhat cyanotic at the time of operation and the systolic blood pressure was 80 millimeters of mercury. About 3 feet of strangulated small bowel were exteriorized and resected. Strangulation was caused by an adhesive band secondary to an old hernioplasty. The patient stopped breathing and became comatose during the operation. Resuscitation measures and acacia and blood were given and the patient left the operating room in fair condition. The patient did not respond following surgery and never regained consciousness. Blood pressure and pulse however were satisfactory. She died the second postoperative day. Autopsy revealed pulmonary atelectasis and congestion and some injection of the peritoneal surfaces. Cultures of the abdominal fluid taken at the time of operation were positive for *Bacillus coli*. The immediate cause of death obviously was the reaction attending employment of spinal anesthesia similar to case No. 64306.

outlet as has introduction of the tube by fluoroscopic visualization. In the presence of great distention it may be difficult or impossible to get beyond the pyloric sphincter by any method.

THE DEMANDS OF SUCTION TREATMENT

The observations which it is necessary to make during the course of conservative decompression of instances of mechanical obstruction of the small bowel have been repeated so often that they will merely be enumerated here. The importance of roentgenographic, check up, scout films of the abdomen cannot be overestimated. If the increments of swallowed air and fluid dumped in at the upper reaches of the gut are being withdrawn through the agency of an intubating duodenal tube even if there be no satisfactory reduction of the existing distention, the patient often will cease to complain of pain because there is no accretion of distention

It is decidedly unsafe, therefore, to employ suction without periodic check up films. Usually a film every 12 hours will suffice but in an occasional case a film may have to be taken every 4 to 6 hours while it is being decided whether operative interference will be necessary. Patients treated for mechanical obstruction are given no narcotics. Hot moist packs, however are applied over the abdomen.

It would appear needless to remark that a liberal para-oral administration of saline solution is in order in all patients with acute bowel obstruction in which the fluid loss item has been great. That it is even more important when suction is employed as a therapeutic agent is self evident. Yet the experience of seeing patients inadequately hydrated in consultation suggests that this consideration is not given the attention which it merits. Careful daily determination of the fluid loss (gastric aspirations) and urinary output are more

TABLE VII—GROUP 3—MISCELLANEOUS GROUP—NO THERAPY DIRECTED AT RELIEF OF OBSTRUCTION

Patients moribund or dead on arrival at the ward, the obstruction had righted itself spontaneously, or presence of obstruction was not recognized

	Patients	Cases	Deaths	Per cent mortality		Unrelated deaths	Corrected mortality per cent

Hernias		7	3		42.8			42.8
Carcinoma*		1	0		0			0
Mesenteric embolism		1	1		100			100

*The patient who had probable carcinoma refused surgery and was discharged against advice

Deaths in Group 3

Death No. 1 is considered as unrelated to the obstruction. 1 M C, No 650106, male, aged 47. This patient died 6 days after pneumonectomy for carcinoma of the lung. Small bowel obstruction (not strangulated) was found at autopsy.

The following deaths were related to the obstruction. 2 J R, No 64679, male, aged 56. The patient had a 36 hour history of prostration and emesis of fecal character. He expired while being transported to the ward. Autopsy revealed complete obstruction of the ileum by adhesions and acute dilatation of the stomach. The cause of death was hypochloremia.

3 E L, No 648123, female, aged 52. This patient was admitted after 3 days of vomiting, and diagnosis of strangulated inguinal hernia was made. The patient was in a state of profound shock at the time of admission. The shock was combatted unsuccessfully and the patient died 24 hours after admission. At autopsy strangulation was revealed.

4 H N, No 660199, female, aged 56. This woman had a 10 months' history of ascites, paracentesis had been done 4 times. Four months before admission the patient noted a persistent abdominal mass. She experienced sudden pain

in the abdomen and was brought to the hospital in an apathetic, comatose state, suggesting cerebral accident, an incarcerated ventral hernia was present. The patient's condition was considered too poor for surgery. She expired the third hospital day. Autopsy showed cirrhosis of the liver and strangulated incisional hernia.

5 J P, No 668085, male, aged 69. The patient had an incisional hernia and within the year prior to admission had 2 bouts of vomiting and abdominal pain. A third attack appeared and the patient was sent to the University Hospitals. While on the way he vomited and expired immediately. He was dead upon arrival. Autopsy revealed aspiration asphyxia and a strangulated incisional hernia.

6 E W, No 669216, female, aged 58. This patient had known rheumatic valvular heart disease. She had had intermittent attacks of abdominal pain questionably related to intake of foods. Two weeks before admission she vomited several times. Three days prior to admission she became comatose. A diagnosis of mesenteric embolism was made upon admission. She expired the day after admission and an auricular mural thrombus with embolism of the superior mesenteric artery and infarction of the small intestine and right half of the colon were found at autopsy. Peritonitis was generalized.

daily in which the presence of sodium chloride can be demonstrated.

The treatment of intestinal distention no matter what the cause should be passive as far as the patient is concerned. The administration of drugs which enhance peristaltic activity is out of place in the management of mechanical obstructions, so also in physiological types of ileus due to intestinal paresis. The latter type of case without exception has been treated solely by suction in this clinic for over 7 years, and the number of instances in which suction has been unsuccessful has been very small.

It was for the relief of this type of distention that Ward (26, 27) suggested and em-

ployed suction in 1925. It seems now not a little unusual that it required the demonstration of the efficacy of suction in the management of mechanical obstruction to lend the propelling impetus to the general adoption of this mode of management for physiological distentions. The story of the use of the duodenal tube in the relief of intestinal distention has been told very interestingly by Paine (16).

The advent of the double lumen tube (1, 9) with the balloon at the tip to facilitate migration down the gut, once the duodenum has been entered, will pyramid undoubtedly the usefulness of suction in such cases. Another increasingly important use of the Miller-

TABLE VI—GROUP 2—PATIENTS TREATED BY IMMEDIATE OPERATION

C. Intussusception

	Patients	Cases	Deaths	Per cent mortality		Unrelated deaths	Corrected mortality per cent	
				Patient	Case		Patient	Case
Procedure	15	15	8	40	40	0	40	40
Reduction		12	5		41.7			41.7
Ileocolostomy		1	1		100			100
Found reduced by barium enema		1	0		0			0
Ligation over hard rubber tube*		1	0		0			0

* (Case of rectosigmoid intussusception)

Reduced on by barium enema was attempted in 10 cases. The intussusception was partially reduced in 8 cases. In one of these reductions was found to be complete at the time of operation. In another case reduction was complete several times but the intussusception recurred each time and reduction was done surgically.

Meckel's diverticulum was present in 2 cases.

One case (death No. 4) is also classified as Group C.

Deaths in Group 2C

All deaths are considered as related to the obstruction.
 1. B. B. M. No. 63576 male, aged 4 months. This child had a typical history and findings of intussusception with a mass palpable both abdominally and rectally. He was operated upon immediately after admission within 24 hours of onset. A colicocolic and an ileocecal intussusception were both readily reduced. The patient had a rather stormy course the basis for which did not appear to be in the abdomen or chest. He died the seventeenth postoperative day of bronchopneumonia and mastoiditis. There was no peritonitis.

2. R. R. No. 60661 female aged 4 months. The patient was breast fed for 2½ months and was then given feedings of boiled whole cow's milk half and half with a 100 per cent carbohydrate syrup. About a week later the child developed diarrhea, vomiting and fever and had lost 6 pounds at the time of admission. 5 weeks after onset of symptoms. The baby showed marked signs of recent weight loss and was febrile. She was treated on the pediatric service as a case of nutritional disturbance and otitis media. Five days after admission bloody stools were noted. The next day they were again noted the abdomen was distended but the child showed no sign of pain. Tenderness was not elicited. A mass was felt per rectum and the patient was operated upon. Death occurred as the peritoneum was opened. An ileocecal intussusception was found. Had the child lived enterocolic anastomosis would have been necessary because of gangrene. The intussusception seemed to have been present about 3 to 4 days.

3. M. T. No. 60613 female aged 6 months. This patient had a 40 hour history of intussusception which was reduced by surgery shortly after admission. About 2 inches

of terminal ileum and cecum were blue after reduction but resection was deemed inadvisable. The child died 16 days after operation of perforation of the cecum with localized peritonitis, bilateral otitis media, wound infection and bronchopneumonia.

4. M. T. No. 637430 female aged 2 years. A rather typical history of intussusception had been present for 36 hours before the patient was admitted. Physical findings were typical. Surgery was done immediately. An ileocecal intussusception was found this could not be reduced so an ileocolostomy was done. The postoperative course was very stormy for 7 days at which time the patient's temperature fell to 100 degrees F. The ninth postoperative day the patient eviscerated the two eviscerated loops of bowel were replaced and the wound was taped. The patient died of peritonitis the twelfth postoperative day. At autopsy the non reducible ileum was gangrenous.

5. C. M. No. 651505 male aged 12 years. This boy had an 18 hour history of cramp like colicky abdominal pain and vomiting. Upon admission a mass was palpable in the right lower quadrant of the abdomen. This was palpable rectally. The mass was quite tender but there was no tenderness elsewhere. The abdomen was silent. The patient was operated upon without delay. The pre-operative diagnosis was intussusception, volvulus or intra abdominal hernia. A compound enteric intussusception was found this was partially reduced when the patient's blood pressure suddenly became unstable. The patient had been receiving intravenous fluid during the entire procedure. Blood was given and the involved bowel was quickly exteriorized but resuscitation measures failed.

6. L. C. No. 610990 female aged 27 (See death No. 10 (Group 1C)).

significant than the tallying of the pulse rate and the recording of the temperature. When will these items be recorded on the face sheet of all hospital records for the orientation of the surgeon? Orr has lent particular consideration to the fluid requirements of patients with bowel obstruction. Collet and his associates have defined the fluid requirements of

surgical patients of all types. An excellent review of this aspect of the problem incorporating the practice of the Ann Arbor group has been made by Bartlett, Bingham and Pedersen which is deserving of careful study. In our clinic enough fluid has been given parenterally to patients with obstruction to provide 800 to 1000 cubic centimeters of urine

tunately, decline to operate on many of these patients with formidable, incisional hernias when they are unobstructed. Grave as the situation appears, this study would indicate that all patients with strangulated, incisional hernias should be operated on at once, the discouraging magnitude of the undertaking in a seriously ill patient to the contrary notwithstanding.¹

In this series there is one strangulated internal hernia (diaphragmatic—pleuroperitoneal hiatus) treated conservatively for a period somewhat longer than 12 hours, during which time suction improved the respiratory embarrassment considerably. It is our opinion that suction is of more value than preliminary phrenicectomy as suggested by Harrington (6, 7) in preparing the patient for operation and in minimizing compromise of the blood supply of the strangulated gut. Placement of the patient in various positions to prevent aspiration of the gas and fluid trapped in the stomach above the diaphragm is usually important. In the instance of a complete diaphragmatic rupture observed and successfully treated since June 1 of this year, preliminary suction was a helpful agent in diminishing dyspnea and cyanosis as well as distention before operation. There probably is more justification for treating an internal obstructed hernia conservatively for a few hours before operation than an external hernia in which the strangulating agent is less yielding.

Another feature brought out by this study, to which allusion has been made on previous occasions, is the infrequency with which early postoperative obstructions occur after abdominal operation when suction is used prophylactically to obviate intestinal distention, a practice of this clinic, the continuance of which this review justifies.

In patients with simple obstruction due to adhesions not decompressed satisfactorily by suction, enterostomy is still the operation of choice. The findings of our study support this contention. In a group of 20 such patients—and these represent the worst types of simple obstruction caused by adhesions—suction failed and enterostomy was done

TABLE VIII—SUMMARY OF MORTALITY OF ACUTE MECHANICAL OBSTRUCTION OF SMALL INTESTINE.

	No of deaths		No of deaths related to obstruction		Mortality per cent	
	Pa-tients	Cases	Pa-tients	Cases	Pa-tients	Cases
All treated cases	156	190	28	28	17.9	14.7
All cases treated by suction	96	126	15	15	15.6	11.9
Cases decompressed by suction (Group 1, A and B)	64	83	5	5	7.8	6.0

There were 2 deaths, both due to the limitations of "blind enterostomy." In one (Table III, death No. 2) a complicated, strangulating type of mechanism was uncovered at autopsy; in the other (Table III, death No. 5) a single adhesive band had brought about compression necrosis of the gut. Simple division of it undoubtedly would have obviated this occurrence. Yet, it would not have been found without eviscerating the strangulated gut, a procedure which is not justified as a frequent operative measure in the light of the recorded observations of Morton (12) and of Ochsner and Storck. Holden, however, endorses it enthusiastically. There is, to be sure, no fool-proof procedure which may be applied to all types of cases. Our own experience indicates that enterostomy is a good operation for non-strangulated obstruction. Had the gut been eviscerated and stripped in this group of 20 cases in which suction failed, the mortality no doubt would have been much higher.

Division of single adhesions is a commendable procedure, but division of complicated multiple adhesions is dangerous and unwarranted as is well shown in Table III. The performance of entero-anastomosis, in the main, has little place in the treatment of acute intestinal obstruction, though it appears occasionally to be the wisest choice of procedure. The thoughtful paper of Morton (13) concerning the surgical management of acute bowel obstruction merits attentive perusal by every surgeon interested in the subject.

THE MORTALITY OF TREATMENT

There is to be reckoned with in the obstruction problem a sizeable mortality in the very

¹Division of the constricting bands without repair of the hernia would appear to be the procedure of choice.

Abbott type of tube will be found to be in the identification of unobstructive lesions of the small bowel. The experience of this clinic with a tube of double lumen extends back to 1932, but the excellent suggestion of Miller, Abbott, and Johnston to employ an inflatable balloon in conjunction therewith has been tried only during the last 6 months covered by this period of study. One of us (Dr. Baxter A. Smith) has during this period of time been trying to evaluate the comparative merits of the usual duodenal tube with the balloon type of double lumen tube. In Table IX the experiences with mechanical obstructions and a few other types of cases are summarized briefly. Although our experience in the main, with the double lumen tube has been reassuring, it has not yet been extensive enough to establish valid comparisons. It would appear unsettled and somewhat doubtful if the indications for conservative decompression in mechanical obstruction were to be extended materially by use of the tube of the Miller-Abbott type beyond those outlined by the senior author in 1931 (18).

Instances of colonic obstruction in which distention of the large bowel is not great may probably be decompressed more often by the entry of such a tube into the cecum. Yet, during the time of this study (not included in this series, for suction in the management of mechanical obstruction concerns essentially the small bowel) 6 patients with acute colonic obstruction with lesser grades of distention were treated successfully by suction alone, a direct surgical attack being made later on the obstructing mechanism. Einhorn, McClendon (10, 11), van der Reis, and Schembera have succeeded in passing the ordinary duodenal tube down into the lower reaches of the bowel. Though we have frequently been successful in pushing the usual duodenal tube well into the obstructed small intestine, its progression beyond the pyloric sphincter is slow, as contrasted with the balloon type of tube.

OTHER AUXILIARY CONSERVATIVE TREATMENT

The work of Fine and his associates has established the value of oxygen in the treatment of intestinal distention. Unless used in

combination with suction, however, the method probably has little worth. Suction is so much more a direct approach to the problem of relieving the distention of mechanical intestinal obstruction that the administration of oxygen in high concentration is probably only of secondary import. In inhibition (paralytic) types of ileus, it has a much more proper indication.

The administration of blood to patients with strangulating types of obstruction in whom the blood loss factor may be great is mandatory and has not been used enough even in this series as is indicated by this critical review of our own experience. Death No. 5 in Table VI (intussusception) was due undoubtedly to failure to replace blood by transfusion and in death No. 2 it was an important though somewhat less significant item in the light of the antecedent history. It is also likely that transfusion of blood would be a helpful therapeutic measure in all simple obstructions accompanied by transudation of fluid into the peritoneal cavity, even though the protein content of such fluid is low.¹

SPECIAL LESSONS TAUGHT BY THIS METHOD

Apart from failure to recognize strangulating obstructions, which have been described above as a pitfall of the conservative management of acute obstruction of the small intestine and failure to transfuse patients adequately with strangulating types of obstruction, the most startling observation revealed by this study is the great risk run by patients with strangulated incisional hernias. The necessity for operating on such patients needs no emphasis. In this series one feeble obese patient was treated unsuccessfully by suction alone (Table I, death No. 10). Another was temporized with for 24 hours and then an enterostomy was made on a loop of gut in one of the sacs in the abdominal wall which was also a futile gesture (Table III, death No. 9). Many of these patients are marked for death on entry to the hospital. Most of us, unfor-

¹ If not mix with high grad. intestine I dist. from a increase of venous pressure, the on 1th low, a tendency to be demonstrated ally. The circulatory system is lowered so in permanent established distensions in the dog it was observed that the venous pressure in the abdomen was increased, a tendency more than in the cavity. The peritoneal pressure was decreased. A comparison rate from 1th (relaxation) the low is (tremity was observed also. (C. J. Bellis, 10, 11, H. M. Mattern, L. Paul, bed dates)

nature of the disease, but the mortality of treatment must be evaluated critically, too. It exists in every clinic and anyone having to do with the care of patients may contribute to it. It relates to the improper identification of disorders, unwise choice of therapeutic agent, and poorly selected as well as badly executed operative procedures. Enterostomy, in the presence of obstruction must be done carefully and aseptically. There would, as a matter of fact, be no mortality in simple obstructions, if adequate relief of distention could be obtained without peritoneal soiling. Witness the low mortality attending conservative decompression of acute simple obstruction (Table I). If those patients in satisfactory physical condition needing operation could be relieved of their distention, maintaining at the same time, the sterility of the peritoneal cavity, the mortality would be minimal. The experience of this clinic with aseptic surgical decompression of the colon acutely obstructed by malignancy substantiates this opinion (21). In strangulating obstructions not submitted to early operation, the mortality will continue to be high because of the hazard of transperitoneal migration of noxious substances, particularly bacteria, from the obstructed gut lumen.

SUMMARY

The experience of this clinic with all types of mechanical obstruction of the small bowel over the 7 year interval between June 1, 1931, and June 1, 1938, has been reviewed. This experience is related in detail in the tables and is summarized briefly in Table VIII. The indications and contra-indications for the suction management of mechanical obstructions described in 1931 have been reiterated and the lessons learned in the intervening years have been reviewed.

Among 156 patients treated for acute mechanical obstruction of the small intestine, there were because of repetition of obstruction in some patients, 190 cases. There were 28 deaths in the entire group, a patient mortality of 17.9 per cent and a case mortality of 14.7 per cent.

In Group 1, the assembly of cases in which suction was the primary treatment (though in

a portion of these, Group 1C, operation became necessary to effect a satisfactory decompression), there were 96 patients and 126 cases of obstruction. There were 15 deaths, a patient mortality of 15.6 per cent and a case mortality of 11.9 per cent. In those instances in which suction alone accomplished a satisfactory decompression (Group 1, A and B) and relief of the acute obstruction, there were 64 patients and 83 cases. Five deaths occurred, giving a patient mortality of 7.8 per cent and a case mortality of 6 per cent.

The suction group constitutes 61.5 per cent by patient and 66.3 per cent by case of all patients treated for acute mechanical obstruction of the small intestine during the period under study. The number in which suction alone was the only direct attack employed for the relief of acute obstruction (Group 1, A and B) was 41 per cent by patient and 43.6 per cent by case of the entire group.

CONCLUSIONS

Suction applied to an inlying duodenal tube has a definite rôle in the treatment of acute mechanical obstruction of the intestine. In suitable cases, complete relief of obstruction may be obtained through this agent alone. In a far larger group, suction is to be employed solely as an ancillary procedure, subordinate in importance to operative decompression or direct attack on the obstructive mechanism.

The intelligent use of suction in the relief of acute intestinal obstruction rests upon the following.

1. Ability to differentiate simple and strangulating types of obstruction.
2. Ability to distinguish between acute obstruction of the large and small bowel.
3. Appreciation of the importance of scout x-ray films for indicating the location of the obstruction and whether it is complete or incomplete, and for determining whether a satisfactory decompression is being obtained.
4. Appreciation of the shortcomings of suction applied to an inlying duodenal tube in the management of acute intestinal obstruction.

The experience of this clinic with the use of suction in the management of obstruction

THE PREVENTION OF MATERNAL AND INFANT ANEMIA

R. GOTTLIEB, M.Sc., M.D., and G. J. STREAN, B.A., M.D., F.R.C.S (C.), M.C.O.G.,
Montreal, Canada

THE association of pregnancy and anemia is so common that one may almost feel inclined to consider a moderate degree of anemia during pregnancy as a physiologic condition. Goodall and Gottlieb in an analysis of two hundred consecutive, non-selected cases of pregnancy were able to show that during pregnancy there is a definite tendency toward the development of a progressive hypochromic anemia; that this anemia becomes most pronounced in the third trimester, and is most severe in cases in which pregnancies succeed one another in rapid order. They also found a diminution or even complete disappearance of free hydrochloric acid in the later months of gestation and a strong tendency to a return to the normal postpartum.

In a previous publication (6) we were able to show the close relationship of maternal and fetal erythropoiesis. Paradoxically enough, it was found that the greater the anemia of the mother, the greater fetal polycythemia. This was explained by the fact that the anemia of the mother intensifies the existing anoxemia of the fetus (5) which is compensated for by an increase in the number of erythrocytes. Strauss (2) was able to show that infants born of anemic mothers, although normal at birth, develop anemia during the first year of life and that this anemia could be prevented by the oral administration of iron.

Realizing the importance of preventing the development of anemia with all its complications during pregnancy, we proceeded to study the effect of preventative therapy on the mother, and later, the infant. We were soon, however, faced with another problem. The easily upset gastro-intestinal tract of pregnant women was greatly upset with different preparations of iron in general use.

This paper deals with a hematological study of 525 consecutive, non-selected cases of pregnancy. Of these 275 cases received no therapy, while 250 were treated with different iron preparations. In 100 cases the infants were also studied. Fifty of these infants were born of mothers who had no therapy, while in the other 50 cases the mother had received iron.

METHOD

In all patients examined complete hematological examinations were made on the mothers when first seen, usually during the second or third month of pregnancy, and the examinations repeated at intervals until delivery. In the patients who received treatment, re-examinations were made for some time postpartum. In the 100 cases in which the infants were studied, the blood was examined at birth (cord blood) and at intervals for 8 months after birth. Only average figures of the findings are given to save space.

RESULTS

Group 1. This group comprised the 275 untreated cases. The average amount of hemoglobin was 75 per cent—10.50 grams. The reduction was most marked in the third trimester. The averages were first trimester, 80 per cent—11.20 grams, second trimester, 75 per cent—10.50 grams; third trimester, 65 per cent—9.10 grams. The hemoglobin reductions are most marked in multiparous women who had had pregnancies in rapid succession.

The red blood cells were also reduced in all cases, but not as markedly as the hemoglobin. Microcytes were usually present and the number of reticulocytes increased, depending upon the degree of the anemia.

Group 2. In this group 250 cases were treated with different iron preparations. The hemoglobin values in this group ranged from

From the Departments of Medicine and Obstetrics, Jewish General Hospital, Montreal

suggests that when employed on suitable indications and with full realization of its weaknesses and defects, it is a worth while addition to the available therapeutic agents, and that its rational use should lead to a definite, general lowering of the mortality of acute intestinal obstruction.

The conservative decompression mode of management is a painstaking procedure which demands meticulous attention to detail. The limitations of the method demand also that patients accepted for treatment be passed upon by trained observers. Frequent periodic resurvey of the status of a patient being treated conservatively is mandatory. The consistently best results in the treatment of acute intestinal obstruction will be obtained in hospital practice when the management of all such cases is concentrated in the hands of a few individuals who are interested in and willing to devote time and energy which such cases should rightfully command.

DISCUSSION

The development of an iron deficiency during pregnancy is easy to understand if one considers that the fetus not only develops its own blood supply during the intra-uterine life, but actually develops a polycythemia during its prenatal stage, to overcome the normal degree of anoxemia in which it has to live before birth. The iron for the production of hemoglobin (3) must be supplied from the iron storage of the mother. These iron requirements are rather large. Bunge has shown that the livers of young animals contain weight for weight about five times the quantity of iron that is found in adult livers. The greater polycythemia in the fetuses of anemic, untreated mothers is essential for the maintenance of the oxygenation of the fetal tissues, but the iron storage of these fetuses is apparently deficient and the infant obviously cannot maintain its normal erythrocyte and hemoglobin level during the first year of its most rapid growth and development.

Our study shows that the anemia of the mothers as well as of the infants can be easily prevented. We feel that this fact is of great clinical importance. Many maternal complications could be prevented and the infant mortality reduced.

CONCLUSIONS

- 1 Maternal anemia is associated with a greater fetal polycythemia
2. Infants of anemic mothers develop anemia during the first year of life
- 3 Both the maternal anemia and the anemia of infants can be prevented by prophylactic iron therapy
4. Many iron preparations are effective but produce considerable gastro-intestinal upset
- 5 Ferrous sulphate in combination with vitamin B complex was found to be very effective without greatly upsetting the gastro-intestinal tract

Chart 1 Straight line represents red blood cells and hemoglobin of infants whose mothers did not receive iron. Interrupted lines red blood cells and hemoglobin of infants whose mothers received iron.

58 per cent—8 12 grams to 80 per cent—11 20 grams. The erythrocytes ranged from 3,600,000 to 4,300,000. In dividing the therapy among 250 cases, special care was taken to select the patients in such a way that each group would show about the same average findings.

1 Fifty patients were treated with ferri et ammonium citrate, of which 30 grains were given three times daily. Elixir lactopepsin was used as a vehicle. The results in this group were excellent and normal values were reached in 4 weeks. These values were maintained throughout the pregnancy with very little variation. There was a slight drop in the hemoglobin after delivery, but this was rapidly restored. However 38 of the 50 cases 76 per cent showed a good deal of gastro intestinal upset.

2 Fifty patients were treated with ferrous carbonate and copper in the combination of 6 grains of ferrous carbonate and 1/48 grains of copper. This amount was given three times daily. The results in this group were fairly good. However, the response was not as rapid as in the previous group. Approximately normal values were reached in 6 weeks. A slight drop in the hemoglobin after delivery

was rapidly restored. The gastro intestinal upsets, on the other hand, were less marked and only 24 cases in 50, 48 per cent, showed upset. In 25 cases 1/12 grains of phenol phthalein was added but there was no appreciable difference in the number of gastro intestinal upsets, 11 patients showed reaction in the group without phenolphthalein and 13 patients in the group with phenolphthalein.

3 Fifty patients were treated with reduced iron of which 5 grains were given three times daily. The results were about equal to those obtained with ferrous carbonate. Normal hemoglobin values were reached in 5 weeks and a slight drop in hemoglobin after delivery was restored in a short time. There were less cases with gastro intestinal upset, 18 of the 50 cases, 36 per cent, showed upsets.

4 One hundred patients were treated with ferrous sulphate, grains 3, combined with vitamin B derived from yeast concentrate.¹ A total of 15 grains were given daily. Preference was given to this preparation because there were very few gastric upsets. Only 5 of the 100 patients, 5 per cent, showed some disturbances. The results obtained were equal to those with ferri et ammonium citrate. Normal values were reached in 4 weeks and a slight drop after delivery was rapidly restored.

Group 3 This group comprises 50 infants, whose mothers had not received any iron therapy, and 50 infants whose mothers had received iron. A striking difference in the blood of these infants was found.

In the treated group the average number of erythrocytes at birth was 7,450,000 and the average amount of hemoglobin 120 per cent—16.80 grams. While in the treated group the average number of erythrocytes was only 5,290,000 and the average amount of hemoglobin 111 per cent—15.44 grams. At the end of 32 weeks however the picture was just reversed. In the untreated group the average number of erythrocytes was 860,000 and the average amount of hemoglobin 51 per cent—7.14 grams. The treatment group had an average erythrocyte count of 4,300,000 and an average amount of hemoglobin of 82 per cent—11.48 grams. Chart 1 shows the relation of these two groups of infants.

¹Supplied in the form of hematolaks.

TABLE I—FIVE YEAR SURVIVALS BY AGE

Age in years	Total number	Survivals number	per cent
30-39	5	4	80.0

one passes to the higher grades of malignancy. They found, too, that the prognostic influence of nodal involvement operates quite as well in any one grade as in the entire group. The present figures are in agreement with all of these observations (Tables II, III, and IV).

The prognostic importance of lymph node involvement considered alone is illustrated in Table V. Whereas in this series 44.7 per cent of the patients with lymph node involvement were alive 5 years or more after operation, it is interesting to note that in 1923 Miller stated that there is no reason to believe that any patient with lymph node metastasis can survive and that, therefore, excision of the growth itself is all that ever need be done.

Karsner and Clark, in a series of 104 cases, noted a decreasing frequency of lymph node metastases as one progressed from left to right in the colon. In the present series, on the contrary, the frequency increases from left to right (Table VI).

Ochsenhirt, in a study of 188 cases, found that secretion of mucus by the carcinoma cell is a function indicating differentiation and

that the percentage of mucus-secreting cells is inversely proportional to the malignancy. Rankin and Olson in their series found essentially no prognostic difference between the mucous adenocarcinomas and the adenocarcinomas in general. Therefore, no separate classification was made for this group in the present study.

In regard to the mechanism of penetration of the cancer cell, Ewing stated, "The disease arises usually in a circumscribed area of mucosa in which the glands become enlarged, the lining cells hypertrophied and multiplied, the production of mucous cells increased, and the lumina elongated and bifurcated. The neoplastic alveoli soon break through the muscularis mucosa and extend along the submucosa, often reaching the surface at lateral points, thus extending the lesion or penetrating the muscularis along lymph or blood channels" (Fig 1).

Cole, studying rectal carcinoma, stated that the initial carcinomatous focus is covered by unbroken epithelium and surface ulceration may thereafter take place (1) by the under-

THE MURAL PENETRATION OF THE CARCINOMA CELL IN THE COLON ANATOMIC AND CLINICAL STUDY

WYATT C SIMPSON, M D, and CHARLES W MAYO M D, F A C S

THE importance of carcinoma of the colon is attested by the frequency of its occurrence. At least 10 individuals out of each 100,000 population die of carcinoma of the colon every year. This study is concerned not primarily with those 10 individuals who die, but with that group of patients who undergo a resection of their carcinoma bearing bowel and survive. Analyses of the factors concerned in their survival will be presented and an approach in the classification of these carcinomas which appears to throw some light on the prognosis will be proposed.

The cases on which this study is based comprise 120 patients selected from those treated at The Mayo Clinic in the years 1928, 1929 and 1930. All of them were patients from whom single carcinomas of the colon were removed, in whom no evidence of distant metastasis was present at the time of operation, and who survived the operation and were dismissed from the clinic with apparently good chances of cure. In all of these cases follow up information is available covering a period of 5 years or more.

In all but 30 of these cases the histological grade of malignancy by Broders' method had been recorded already. These remaining specimens were therefore graded and the grading was checked by Dr Broders (1, 2). Information regarding the presence or absence of lymph node involvement was available from the pathological reports on the fresh specimens. This information was accepted without further study of the specimens.

Of these 120 patients from whom carcinomas of the colon had been removed, 67, or 55.8 per cent, lived at least 5 years after oper-

ation. What factors then determine which cases are to fall in this fortunate group?

MacCarty, studying carcinomas of the stomach, breast, and rectum, observed a uniform prolongation of postoperative life in the presence of lymphocytic infiltration, fibrosis, hyalinization, and cellular differentiation, and suggested that the first 3 factors play a significant role as part of the natural defense mechanism against carcinoma after it has once developed.

Rankin and Olson pointed out that such local conditions as fixation, perforation, and abscess formation affect operability, but are merely local influencing factors which are usually the result of prolonged neglect in the absence of symptoms or of intense activity of the carcinomatous cell. In a group of 453 cases they noted a better prognosis for growths of the right side of the colon than of the left. This observation does not correspond to the figures in the present smaller series, where 5 year survivals are noted in 53.6 per cent of carcinomas of the right half of the colon, 46.7 per cent of the transverse part of the colon, 62.3 per cent of the descending part of the colon, and 51.1 per cent of the sigmoid.

They also noted a better prognosis in the older age groups and suggested that age is a factor by virtue of a decreased activity of the tissue cells of the host, not of the cancer. In the present series (Table I) the greatest number of patients was between 40 and 69 years of age. Among these the prognosis was somewhat better between 50 and 59 years than between 40 and 49 years and considerably better between 60 and 69 years.

Rankin and Olson also noted a direct relationship between the grade of malignancy and the survival period, the outlook being progressively worse as the grade of malignancy increased. They also noted a progressive increase in the involvement of lymph nodes as

Abrelement of these submitted by Dr Simpson to the Faculty of the Graduate School of the University of Minnesota in partial fulfillment of requirements for degree of M.S. in Surgery.
Dr Simpson now residing in Gadsden, Alabama.

21, or 17.5 per cent, belong to class B, and 89, or 74.2 per cent, belong to class C.

The prognosis is observed to be best in class A, with all 10 patients reported alive 5 years after the operation. The worst prognosis is observed in class C, in which a 49.4 per cent 5 year survival is found, and the intermediate prognosis is observed in class B, with a 5 year survival rate of 61.9 per cent.

In Dukes' (4) study of rectal carcinoma, his class C includes those growths that have penetrated the perirectal tissues and involved the regional lymph nodes.

Table VIII suggests a definite relation between the degree of mural penetration and the

Fig 3 Class B, grade 2, nodes positive. A female aged 53 years had symptoms of 36 months' duration, 5 year survival. Cancer cells in but not through muscularis $\times 35$

Fig 2 Class A, grade 2, nodes positive. A male aged 42 years, had symptoms of 6 months' duration, 5 year survival. Cancer has not spread beyond the muscularis mucosa, but there is a focus of polymorphonuclear leucocytes in the serosa $\times 34$

presence of lymph node involvement in carcinoma of the colon above the rectosigmoid.

When the average duration of symptoms is compared in the 3 classes (Table IX), it is seen that the symptoms have been present for the shortest time in class B, longer in class C, and longest in class A. This apparent paradox is explained by the fact that class A includes those polypoid growths of low invasive qualities that have given the symptom of bleeding periodically, often for many years.

Except for the preponderance of grade 1 cases in class A, the majority of all classes of cases is found to be in grade 2, the majority of all grades is in class C (Table X). These 2

mining of successive portions of the mucous membrane, or (2) by the direct involvement of overlying mucous membrane by upgrowths of carcinoma into and replacing the membrane (Fig 1) Welch expressed the opinion that the cancer spreads, so far as the mucosa is concerned, by the progressive transformation of normal into neoplastic cells as if some malign influence were passing by direct contagion to the normal cells.

Rankin and Olson found a significantly larger proportion of 5 year survivals among those cases in which the dominant direction of the growth was toward the lumen rather than among those in which the dominant direction was toward the serosa. Gray in studying cases of carcinoma of the stomach found serosal involvement to be a finding of grave prognostic import. Cuthbert Dukes (4, 5) studying carcinoma of the rectum observed that the degree of penetration of the carcinoma cell into and beyond the rectal wall was of prognostic importance comparable to that attributable to the grade of malignancy (12). It seemed, therefore, that a similar situation might exist with regard to carcinoma of the colon above the rectosigmoid, and it was to clarify this point that the present study was undertaken.

METHOD OF STUDY

The specimens of the 120 carcinomas of the colon included in this study had been preserved in a 10 per cent solution of formalin

TABLE IX—AVERAGE DURATION OF SYMPTOMS ACCORDING TO DEGREE OF MURAL PENETRATION

Total	16		50		23		6		95

A series of thin slices was made through the tumor from within outward. A thin block of tissue was removed from the region of deepest penetration. This was embedded, sectioned and stained with hematoxylin and eosin. These sections were studied and the degree to which the carcinoma cells had penetrated the intestinal wall was determined. Employing a system of classification somewhat similar to that which Dukes (4) found to be of significance in carcinoma of the rectum, but of necessity modified to conform to different anatomical circumstances, the specimens were divided into classes A, B, and C, depending on the degree of mural penetration of the cancer cells. In class A were placed those cases in which the cancer cells had not penetrated beyond the submucosa (Fig 2). In class B were placed those cases in which the cancer cells had penetrated into but not beyond the muscularis (Fig 3). In class C were placed those cases in which the cancer cells had penetrated through the muscularis and into the subperitoneal fatty and fibrous tissue of the serosa (Fig 4).

Table VII indicates that of 120 resected carcinomas 10, or 8.3 per cent, belong to class A,

Fig 1 Lateral mucosal spread of carcinoma cells by multiple foci. Carcinoma cells have also penetrated through the muscularis and are invading the serosal fat $\times 73$

Fig 2 Class A, grade 2, nodes positive. A male aged 42 years, had symptoms of 6 months' duration, 5 year survival. Cancer has not spread beyond the muscularis mucosa, but there is a focus of polymorphonuclear leucocytes in the serosa $\times 34$

21, or 17.5 per cent, belong to class B, and 89, or 74.2 per cent, belong to class C.

The prognosis is observed to be best in class A, with all 10 patients reported alive 5 years after the operation. The worst prognosis is observed in class C, in which a 49.4 per cent 5 year survival is found, and the intermediate prognosis is observed in class B, with a 5 year survival rate of 61.9 per cent.

In Dukes' (4) study of rectal carcinoma, his class C includes those growths that have penetrated the perirectal tissues and involved the regional lymph nodes.

Table VIII suggests a definite relation between the degree of mural penetration and the

presence of lymph node involvement in carcinoma of the colon above the rectosigmoid.

When the average duration of symptoms is compared in the 3 classes (Table IX), it is seen that the symptoms have been present for the shortest time in class B, longer in class C, and longest in class A. This apparent paradox is explained by the fact that class A includes those polypoid growths of low invasive qualities that have given the symptom of bleeding periodically, often for many years.

Except for the preponderance of grade 1 cases in class A, the majority of all classes of cases is found to be in grade 2, the majority of all grades is in class C (Table X). These 2

TABLE VI—FIVE YEAR SURVIVALS BY GRADE OF MALIGNANCY—CASES SHOWING DEGREE C OF MURAL PENETRATION

Grade of malignancy	Total number	Survivals number	Survivals per cent
1	9	6	66.7
2	55	29	52.7
3 and 4	25	0	36.0
Total	89	44	49.4

TABLE VII—FIVE YEAR SURVIVALS BY DEGREE OF MURAL PENETRATION—CASES SHOWING GRADE 2 OF MALIGNANCY

Degree of mural penetration	Total number	Survivals number	Survivals per cent
A	2	2	100.0
B	15	10	66.7
C	55	29	52.7
Total	72	41	56.9

groups were therefore analyzed separately as to the survival period (Tables VI and VII).

These comparisons demonstrate that in the large series of grade 2 growths, where most of the cases are to be found the percentage of 5 year survivals is directly dependent on the degree of mural penetration, being greatest in class A and least in class C. This fact offers a means of further individualizing the prognosis in this large group.

Similarly in the large group of class C cases the outlook follows the line that is predictable by the grade of malignancy, being poorest in grades 3 and 4 and best in grades 1 and 2. Thus by classifying these growths as to both grade of malignancy and degree of mural penetration a more accurate prognosis can be achieved than by employing either method of classification alone.

In the effort to further individualize the prognosis these same groups, that is, those falling in grade 2 and those in class C, were compared for the percentage of 5 year survivals depending on the presence or absence of lymph node involvement (Tables IV and VIII). Involvement of lymph nodes by carcinoma is a factor of definite prognostic importance in both of these groups. Thus, when these 3 factors are considered together in a given group of cases of carcinoma of the colon, a fairly accurate prognosis can be made. However, lest one be led into too gloomy an

TABLE VIII—INVOLVEMENT OF LYMPH NODES AND FIVE YEAR SURVIVALS—CASES SHOWING DEGREE C OF MURAL PENETRATION

Lymph nodes	Total number	Survivals number	Survivals per cent
Not involved	51	30	58.8
Involved	38	14	36.8
Total	89	44	49.4

outlook from such calculations, it is well to mention that of 5 cases of grade 4 malignancy, class C mural penetration and with positive involvement of lymph nodes by carcinoma, 2 are to be found in the group surviving resection for 5 or more years.

CONCLUSIONS

1. Prognosis is observed to be unfavorably influenced especially by higher degrees of mural penetration of carcinoma cells by higher histological grade of malignancy and by carcinomatous involvement of regional lymph nodes.

2. The 3 aforementioned factors are mutually dependent to a considerable degree in that the deeper the carcinomatous penetration, the greater the probability of lymph node involvement, and the greater the probability that the growth is of a higher histological grade of malignancy. Likewise, the higher the histological grade of malignancy, the deeper is mural penetration likely to be found and the more likely it is that lymph nodes are involved. Nevertheless, these factors operate independently to a certain degree in that for any class of penetration the prognosis is poorer the higher the histological grade of malignancy, similarly for any histological grade of malignancy, the deeper the penetration the worse the prognosis.

3. A more accurate estimation of prognosis in cases of carcinoma of the colon can be achieved by employing the method of classification proposed here together with Broders' histological grading of malignancy than is possible by the use of either method alone.

THE INFLUENCE OF VITAMIN D UPON BONE REPAIR

The Healing of Fractures of Rachitic Bones

EDWARD L. COMPERE, M.D., BENGT HAMILTON, M.D. and MARGARET DEWAR
Chicago, Illinois

THE importance of vitamin D supplements in the repair of bone has been a subject of much controversy during the past 10 years. Opinions expressed by clinicians and results reported from the research laboratories have differed widely. The statement, found in most of the textbooks, that "fractures of rachitic bones heal promptly and with abundant callus" was not supported by our clinical experience except in those instances in which vitamin D was added to the diet of the patient.

Royster states, "Fractures of long bones (in rickets) are common. These are usually of the greenstick variety." Cotton believed that in rickets the common injury is an "infracture." He states, "An infracture is a fracture that differs from a greenstick in that the convex side is bent, the concave side crushed. They occur typically in the fractures of rickets." Foote, in discussing traumatic injuries in rickets, stated, "fractures of the long bones such as the clavicle, radius, ulna, humerus, femur, ribs, and fibula are quite common. These fractures are very frequently of the impacted greenstick type, with little or no displacement and with abundant callus." In a second reference from the same book (8) this author says, "The bones readily unite and form abundant callus and the injury seems less painful than fractures in normal bones."

Our clinical observations indicated that fractures of rachitic bones were not infrequently complete, with displacement and angulation. Union occurred slowly and little callus was formed, although in contrast with the extremely atrophic bone the amount or density of callus might appear to be adequate. The following reports demonstrate the healing of fractures in 2 patients with active rickets.

CASE 1: J. T., female, aged 15 months, was admitted to the University of Chicago Clinics on January 5, 1934 for the treatment of rickets and deformity of the left femur. Five months before admission she fell out of bed sustaining a fracture of the femur. A cast was worn for only 2 weeks. After removal of the cast an anterolateral angulation developed. She had not walked since the date of the fracture. No vitamin D supplement was administered during this 5 month interval. Physical examination revealed a marked anterolateral bowing of the left leg. The epiphyses of the wrists and ankles were palpably enlarged and roentgenograms showed a fracture of the middle third of the left femur with angulation and minimal callus. The lower end of the femur showed cupping, flaring and irregular ossification indicative of an extremely active rickets (Fig. 1). Calcium of the blood serum was found to be 9.9 milligrams per cent and the inorganic phosphate was 2.1 milligram per cent. This patient was given 10.5 grams of cod liver oil daily in addition to a balanced diet and there was rapid healing of the rickets and of the fracture and the patient became normally active. After 3 months the serum calcium was 10.3 milligrams per cent and the inorganic phosphate was 5.6 milligrams per cent.

CASE 2: C. P., male, aged 16 months, was admitted to the University of Chicago Clinics on July 10, 1931 for treatment of active rickets and a 2 day old fracture of the femur. Antirachitic therapy consisted of viosterol and cod liver oil and both the fracture and the rickets healed rapidly (Fig. 2).

These cases are typical of those which we have observed in treating fractures of rachitic bones. They indicate that bone repair in the presence of an acute deficiency of vitamin D may be greatly retarded.

Fischer and Key, Hellner, Lewis, Moritsch and Krammer, Pincussen and Neumann, Swart and Vara Lopez have individually studied the effect of vitamin D supplements in the treatment of fractures of supposedly normal bones and have reported no change in the rate or quality of healing. Collazo reported that the addition of vitamin D produced better callus and stronger union than was present in the control animals but that it delayed absorp-

Fig 1 Case 1, J T, female, age 15 months Five months before admission to the University of Chicago Clinics, at the age of 10 months the patient fell out of bed, sustaining a fracture of the left femur A cast was applied and worn for 2 weeks Upon removal of the cast, marked anterior angulation of the femur developed During the 5 months she had not been willing to try to walk and showed evidence of pain when attempts were made to persuade her to stand A, Roentgenogram of the left femur, 5 months after fracture, shows changes typical of moderately active rickets The femur is atrophic with paper-thin cortices and a wide medullary canal The fracture has united in marked malposition with a minimal amount of callus From the date of this roentgenogram she was given 10.5 grams of cod liver oil daily, in addition to a well balanced diet B, Roentgenogram 49 days after beginning cod liver oil therapy Evidence of better ossification especially in the metaphyseal region indicates the quality of healing of the rickets There is better healing of the fractured femur C, This roentgenogram shows complete healing of the rickets and extensive new bone formation on the concave side of the fracture angulation 89 days after beginning the vitamin D supplement The medullary canal has been restored The portions of cortex of the femur which are incorporated within the new bone formed at the fracture site are undergoing absorption It is of interest to note that as more tensile strength develops in the bone which is filling out the angle formed by the malunion of the fragments and there is accordingly less stress on the cortex of the femur on the convex side of the angle, a tendency toward remodeling is under way, as evidenced by the absorption of this lateral cortex Such a process may be expected to lead to gradual straightening

Fig 2 Case 2, C P, male, age 16 months A, Roentgenogram of complete transverse fracture of the midshaft of the femur of an infant with active rickets The distal end of the femur and the proximal end of the tibia show marked fraying and slight cupping There is some increase in density in the metaphyseal region of the femur suggesting

beginning healing Beginning on the third day after the fracture, viosterol (15 drops) was administered twice each day Three days later, 5 grams of cod liver oil daily were added B, Four weeks after fracture A moderate amount of callus has formed and there is further evidence of healing of the rickets C, After 7 weeks The rickets has healed and there is complete union of the fracture but the cortices of the fragment ends contained within the callus have not undergone absorption and the medullary canal has not been restored The apparent defect, a, on the lateral side of the distal end of the femur probably represents a cartilage inclusion Note the densely ossified, but smooth serrations of the distal end of the femur

tion of the old fragment cortices Collazo's reports are confusing in view of the fact that his studies included fractures in both rachitic and normal animals Tammann was unable

to determine any difference in the rate or quality of fracture healing in animals receiving therapeutic doses of vitamin D, but after 60 days he found that the callus at the site of

Fig. 3. Experiment 1. Group 1. Compound fractures of the tibia and of the radius of rats Nos. 5, 6, and 7 showing active rickets at the time of fracture, November 6, 1934. The deficiency diet was continued throughout the experiment. As illustrated in roentgenograms taken at intervals

of approximately 2 weeks, the rickets remained active and there was little evidence of healing of any of the fractures. The bones of both extremities shown in the roentgenograms show little growth or development and are as atrophic 38 days after fracture as on the day of operation.

the fracture of the animals receiving massive doses of the vitamin supplement began to undergo absorption. He was able to demonstrate in the histological sections median necrosis in the callus. Bors concluded that the callus of the animals treated was the same after 15 days following fracture but was denser 22 days after than that of the controls.

Pappenheimer found that in fractures of rachitic bones the callus remained calcium free unless the animals were given treatment with cod liver oil. Somewhat similar results were also obtained by Urst.

Grauer reported bone absorption when massive doses of vitamin D were given to experimental animals, and Jones and Robson were

also able to demonstrate that irradiated ergosterol in toxic doses produced marked degenerative changes in the growing bones of rats. Their microscopic studies showed that the atrophy resulted from the removal of organic as well as inorganic matrix. The bones were soft and fragile.

One of the authors (Compere) together with Goisman in a recently published report in which the healing of fractures of atrophic bones was the subject of an experimental study, suggested that there is a threshold of mineral and vitamin normalcy below which bones become atrophic or rachitic, but that addition of minerals or vitamins to the well balanced diet was not therapeutically sound.

Fig 4 Experiment 1, Group 2 Compound fracture of the radius and tibia of 3 of the rats in this group Active rickets at the time of operation November 6, 1934 Cod liver oil was added to the diet on the day following operation and 43 days later, December 19, 1934, the roentgenograms show marked improvement in quality of the bone,

in healing of the rickets, and union of the fractures of rats Nos 5 and 8 Callus has formed about the fracture of rat No 7 but refracture occurred A line of decreased density across the site of the fracture shown in the roentgenogram which was taken December 19, 1934 suggests pseudarthrosis

With the exception of the report of Pappenheimer and the unpublished work of Urist, the importance of vitamin D in the repair of bones of animals kept for long periods of time on a vitamin D deficiency diet has not been made the subject of an experimental study

Because of the apparent confusion with regard to the importance of vitamin D supplements in bone repair, the experiments reviewed in this report were undertaken. In the furtherance of this study the department of pediatrics and the division of orthopedic surgery collaborated

The rat was selected as the experimental animal, both because of the ease with which

rickets can be produced and because of the relatively short time required for growth to skeletal maturity Each of 3 experiments was carried out with groups of 21 day old rats, of standard stock The rickets-producing McCollum Diet, No 3143, was used This diet is high in calcium, low in phosphorus and quite deficient in vitamin D Its components are: 33 parts ground whole yellow corn, 33 parts ground wheat, 15 parts gluten, 15 parts gelatin; 3 parts calcium carbonate, and 1 part sodium chloride.

The normal stock diet used had the following composition 150 parts ground whole yellow corn, 67 parts whole milk powder, 32

TABLE 1—EXPERIMENT I COMPOUND FRACTURES OF TIBIA AND RADIUS ANALYSES OF POOLED BLOOD OF EACH GROUP OF RATS SURVIVING 44 DAYS AFTER FRACTURE*

Group	No. of rats	Mgm phosphorus per 100 ccm serum	Results
1 Rickets producing diet + vitamin D	8	2.3	No osseous union, faint callus, atrophic bone alight beneath of rickets
2 Cod liver oil added to rickets diet + vitamin D after fracture	8	5.1	Moderate callus union in 7 rats pseudarthrosis in 1 rickets healed
3 Rachitic diet + cod liver oil from start of the experiment	8	5.1	Moderate callus no rickets
4 Stock diet	7	7.8	Satisfactory large bones all at medullary canal rest of

The results shown in Table I are demonstrated more graphically in Chart 1. They indicate a correlation between the inorganic phosphorus content of the blood serum and the rate and degree of healing of the fractures.

In each of the 3 experiments the blood was drawn by heart puncture under light ether anesthesia.

parts linseed oil meal, 10 parts casein, 4 parts alfalfa meal, 4 parts yeast, 1 part calcium carbonate, and 1 part sodium chloride. Vitamin D supplements of 2.5 per cent of cod liver oil were added to the rachitic diet of Group 2 immediately after fracture and to that of Group 3 at the beginning of the experiment 3 weeks before fracture.

EXPERIMENT I COMPOUND FRACTURE OF TIBIA AND RADIUS

Thirty-one rats 21 days of age were used in this experiment. They were placed on special diets for 21 days before fracture, as follows:

Group 1 Eight rats were fed rachitic diet No 3143.

Group 2 Eight rats were fed the same diet as Group 1 (Cod liver oil added after fracture).

Group 3 Eight rats were fed rachitic diet with cod liver oil supplement.

Group 4 Seven rats placed on normal stock diet.

At the end of 21 days on these various diets one tibia and one radius were exposed under ether anesthesia. The bones were divided with heavy scissors and the wound was closed. No splint was used. To the rachitic diet of Group 2 cod liver oil was added from the day of this operation. Roentgenograms were made at intervals of 1 week. One half of the animals used in this experiment were killed at the end

PROTOCOL OF EXPERIMENT I RESULTS OF X RAY EXAMINATIONS*

Date	Group 1**	Group 2	Group 3	Group 4
11-6-34	Active rickets	Cod liver oil added to diet all showed active rickets	No rickets 1 rat died	Long rat a large bones than in any of other 3 groups
11-14-35	No callus	Faint callus brown rickets healing	No union no definite callus	All showed callus a beginning union
11-17-34	No callus	Union complete in 4 with good callus adequate in 3 but had re-fractured in 1 No 6 there was pseudarthrosis in 1 well healed in all	Beginning union in all moderate callus	Fracture of tibia showed bone union in 2 showed good callus but had refractured
11-28-34	No bone union	Seven showed union 1 rat No 7 had pseudarthrosis	All good osseous union except No 1	All showed satisfactory union
12-6-34	No bone union at all	Rat No 7 showed poor union No 6 was doubtful	Only Nos 5 & 6 a definite union but they were well unioned	All showed satisfactory union
1-14-35	Fibro union but very little callus	Nos 5 and 6 excellent union with re-opening of medullary canal	Solid bony union of both tibia and radius	All showed satisfactory union
12-19-34	43 days after fracture slight spontaneous healing of rickets in osseous union Surviving rats sacrificed	All unioned except No 7	Excellent bony union in all 3	Excellent regeneration of bone medullary canal reformed

*Diets used all groups were begun on October 1, 1934 date of performance for all 4 groups was 11-5-34.

**Eight rats were used in each group except Group 4 in which there were 7.

†Rats Nos 1, 2, 3 and 4 of all groups were sacrificed November 25, 1934.

of 3 weeks. The remaining animals were bled under light ether anesthesia and sacrificed 6 weeks following the fracture, when they were 63 days old.

Because of the small number of rats in each group insufficient serum was obtained to determine both phosphorus and calcium so that only inorganic phosphate determinations were made. The results of this study are shown briefly in Table I and more graphically in Chart 1.

Most of the rats that were fed the stock diet were able to use the fractured extremities

Chart 1 Experiment 1, rate of union of compound fractures of tibia (rats) For the preparation of this chart an attempt was made to compare the degree of fracture healing shown in roentgenograms, taken at approximately weekly intervals, from the time of fracture. The healing of the fracture occurred most rapidly and the fractured bone was restored to a more nearly normal roentgenographic appearance in the rats of the group receiving the normal stock diet. From a roentgenographic standpoint there was very little evidence of healing of the fractures in the group of rats with active rickets. Addition of cod liver oil to the rickets-producing diet, either at the time of fracture (Group 2) or at the beginning of the dietary portion of the experiment (Group 3) resulted in very definite improvement in the rate and degree of fracture healing, but none of the rats in these 2 groups developed as large bones and the fractures did not heal as rapidly nor as completely as did those receiving the stock diet without any vitamin supplement (Group 4). A direct correlation is shown between the inorganic phosphate content of the blood serum of the rats sacrificed 44 days after fracture and the extent of healing as shown in the roentgenograms.

within 2 weeks after fracture, and by the time the experiment ended it was not possible to tell that they had ever been fractured in so far as function was concerned. The rats in all of the 3 other groups were slower to recover use of the fractured extremities. In the group that was constantly fed the rickets-producing diet, some of the rats were never able to use the injured limb. The rats fed the normal diet were more than twice as large and were much more active than were those in the 3 other groups. In this experiment, as well as those to follow, the inorganic phosphorus was determined by the method of Fiske and Subbarow and the calcium was determined by the method of Fiske and Logan, with a slight modification.

Acute vitamin D deficiency, which produced rickets in rats, appeared to be a definite factor in causing delayed union and non-union of compound fractures of both the radius and tibia. The compound fractures were not in-

fectured and the wounds through which the bones were exposed, healed by primary intention. Additions of vitamin D to the deficiency diet either prevented or cured rickets. The addition of this supplement, however, did not raise the quality of the diet to that of the stock diet, as evidenced by the fact that the rats in Group 4 developed more rapidly and their fractures healed more promptly than did those of any other group.

EXPERIMENT 2: SIMPLE FRACTURES OF THE TIBIA

The rats were divided into 3 groups. Group 3, which in Experiment 1 had received cod liver oil in addition to the rickets-producing diet from the time of beginning the experiment, was omitted.

Three weeks after beginning the special diets, one tibia of each rat was fractured at about the level of the middle and upper thirds. No splints were used. With the exception of

Fig 5 Experiment 1 Group 3 The rats in this group were given the rickets producing diet with cod liver oil added from the beginning of the experiment. They did not develop rickets. Compound fractures were created in one

radius and one tibia of each rat on November 6 1934. The röntgenograms show healing of the fractures of rats Nos 6 7 and 8 in from 22 to 41 days after the operation.

TABLE II — EXPERIMENT 2 SIMPLE FRACTURES OF ONE TIBIA ANALYSES OF POOLED BLOOD OF THE RATS OF EACH GROUP SACRIFICED 6 WEEKS AFTER FRACTURE

Group	No of rats	Mgm phos ph tu per 100 ccm serum	Mgm albumen per 100 ccm serum	Results
1 Rickets produced diet	7	4.7	4.0	No new rickets
2 Control diet led to achillectic fracture	8	4.4	1.2	All died
3 Tibia group not included in the experiment	—	—	—	—
4 Normal diet	8	7	9.3	Healthy bones well healed

*Diet in all groups was deficient in Dec 1934 and 1935. The results were as follows: 1. 8 rats were perished. 2. 8 rats were perished. 3. 8 rats were perished. 4. 8 rats were perished.

†All rats in Groups 1, 2 and 4 were sacrificed on February 20 1935.

PROTOCOL OF EXPERIMENT 2 RESULTS OF X RAY EXAMINATIONS*

Date	Group 1	Group 2	Group 3
11-35	All rickets in bones with rickets	All rickets in bones with rickets	All rickets in bones with rickets
12-35	No new rickets	No new rickets	Calculus in bones
1-35	—	Fat in bones	Abnormalities
1-35-35	No new rickets	Calculus in bones	Unhealthy bones
2-35	No new rickets	Calculus in bones	Unhealthy bones
3-35	No new rickets	Calculus in bones	Unhealthy bones
4-35	No new rickets	Calculus in bones	Unhealthy bones
5-35	No new rickets	Calculus in bones	Unhealthy bones
6-35	No new rickets	Calculus in bones	Unhealthy bones

Fig 6

Fig 6 Experiment 1, Group 4 Stock diet The rats in this group were larger and the bones were better developed than were those of any of the preceding groups The compound fracture of the radius and tibia of each rat was made November 6, 1934 Within 22 days, functional union had occurred at the site of each fracture At the end of 34 days the medullary canals at the fracture levels had been re-established The rate and quality of healing of fractures in this group on the normal stock diet, without the addition of a vitamin D supplement, was definitely better than in any of the groups in which a mineral-vitamin D deficiency diet had been maintained, either separately or in combination with cod liver oil

Fig 7 Experiment 2, Group 4, Rat No 1 Normal stock diet Photomicrograph of tibia of rat in the control group of the second experiment This shows strong bone union with the abundant callus completely ossified

Fig 7

those in Group 1, these rats were using the fractured leg within 2 to 3 weeks after fracture Within 4 to 6 weeks, function of this extremity appeared to be entirely normal Some of the rachitic rats did not recover use of the fractured extremity Toward the end

Fig 8 Experiment 3. Roentgenograms made 43 days after fracture of the tibia of all of the surviving rats in Groups 4, 2, and 3. These roentgenograms show that the development of the bones and the rate and degree of healing of the fractured tibiae of the rats of Group 4 which were fed

a normal stock diet and the rats of Group 2 which received the rachitic diet with the cod liver oil supplement are more advanced than are those of the rats which were kept constantly on the deficiency diet (Group 3).

of the experiment the rats fed the normal stock diet were nearly twice as large as were those of any other group. All of the rats were sacrificed 6 weeks after fracture. The pooled blood from each group was analyzed for inorganic phosphorus and calcium. The fractured bones were removed, roentgenographed, fixed in celluloid, and microscopic sections were prepared. The results were quite similar to those obtained with the compound fractures. No

definite bone union occurred in the rats with active rickets. The rickets in the rats of Group 2 continued active throughout the experiment. At the termination of the experiment inorganic phosphorus of the rachitic group was not as low as it had been in the same group in Experiment 1.

In Group 2, in which cod liver oil was added to the rickets producing diet at the time of fracture and continued until the end of the

Fig 9

Fig 9 Experiment 3, Group 1, Rat No 3 Active rickets 43 days after fracture Photomicrographs (low and high power) showing active rickets There is angulation at the site of fracture Note the feeble attempt toward osteoplastic union between the ends of the fracture fragments, the poorly calcified, but moderately abundant subperiosteal fibrous, *a*, and cartilaginous, *b*, callus, and the partial absorption of the thin cortices of the fracture fragments contained within the callus

Fig 10 Experiment 3, Group 2, Rat No 1 Active rickets when fractured, then cod liver oil added Photomicrograph 43 days after fracture The rickets is healed The fracture has united and the callus is moderately well ossified A small area of fibrous tissue, *a*, is still contained within the fracture site

Fig 11 Experiment 3, Group 3, Rat No 1 The cod liver oil supplement was added to the rickets producing

diet 3 weeks before fracture and continued throughout the experiment Rickets did not develop The tibia of this animal is smaller and the cortices are thinner than those of the rats on the control stock diet The fracture has healed, but in the line of fracture there is a transverse zone of decreased density representing an incomplete pseudarthrosis partially filled by fibrous tissue Cortices of the fracture fragments have been extensively absorbed but the medullary canals of the 2 fragments are still separated by a thin zone of cortical bone

Fig 12 Experiment 3, Group 4, Rat No 3 Normal stock diet No rickets Photomicrograph 43 days after fracture The tibia is larger and the cortices are thicker than are those of other groups There has been complete osseous union at the site of fracture with re-establishment of most of the medullary canal Absorption of the cortices of the fracture fragments is still incomplete

Chart 2 Experiment 3 rate of union of simple fractures of tibia (rats). This chart, prepared from study of the roentgenograms and the blood chemistry determinations of the rats used in Experiment 3, duplicates the findings charted for Experiment 1 in which the fractures were of 2 bones and were compounded. The inorganic phosphate factor is seen to be of greater significance than the percentage of calcium as far as the rate or degree of fracture healing is concerned.

experiment all of the fractures united and the animals were using the extremities normally at the time they were sacrificed. The bones of the rats in Group 2 were larger and better formed than those of Group 1. The fractures

in the group fed the normal stock diet united within 2 to 3 weeks; the bones were large and the medullary canals had been restored.

We were reasonably convinced from Experiment 2 that a well balanced stock diet led to

TABLE III—EXPERIMENT 3 SIMPLE FRACTURES OF ONE TIBIA. ANALYSES OF POOLED BLOOD OF THE RATS OF EACH GROUP 43 DAYS AFTER FRACTURE

Group	% fat	Mgms phosphorus per 100 cc serum	Mgms calcium per 100 cc serum	Result
1 Rickets producing diet throughout the experiment	9	2.9		Active rickets, none united but faint callus
2 Cod liver oil added to rickets producing diet after fracture	9	4.6	12.1	Large bone, all united
3 Cod liver oil plus rickets producing diet throughout the experiment	9	3.3	5.5	Quiescent, no bone, no callus, no union
4 No malnutrition	1	6.6	14.1	Excellent union, small bone, no callus, no union

*Some of the rats in this group had died. The few seen through serum for calcium determinations.

PROTOCOL OF EXPERIMENT 3 RESULTS OF VITAL EXAMINATIONS*

Date	Group 1**	Group 2	Group 3	Group 4
4-6-35	Active rickets	Active rickets	No rickets but bones were smaller than those of Group 4	No rickets well developed bones
4-17-35	No union, no callus	Faint callus, rickets healing	Small amount of callus	All showed abundant callus
4-4-35	No union	Rickts healed, all showed good callus	Medial callus but not united	All union, callus solid
5-3-35†	No union	All p. acts showed bone union	All united	Excellent union with no union
5-8-35	Faint callus, slow in union	Excellent union	Excellent union	All well union
5-17-35	Faint callus, no union	Bones larger than those in Group 1	Medial callus, slow in union	Medial callus, slow in union

*Diets in all 4 groups were begun on March 12, 1935 at 10:15 a.m. and continued until 3:35 p.m.

**The diet in Group 1 was not changed until May 3, 1935 and May 8, 1935.

†Three rats in Group 3 died between May 3, 1935 and May 8, 1935.

the development of healthier, stronger bones which healed more rapidly following fracture, and the quality of union was much better than in the bones that were atrophic because of subacute vitamin D deficiency as noted in Group 3 of Experiment 1, or in the case of active rickets. We decided to attempt to confirm or to correct this impression by repeating Experiment 2 and including Group 3.

EXPERIMENT 3. SIMPLE FRACTURES OF TIBIA

The plan of Experiment 3 was identical with that of Experiment 2, with the exception that Group 3, which included the rats fed the rachitic diet plus cod liver oil for 3 weeks before fracture and continued after fracture until they were sacrificed, was included. These rats were sacrificed 43 days after fracture and the pooled blood from each group was analyzed for its calcium and phosphorus content. The results of this experiment are shown in Table III and more graphically in Chart 2.

The results of the analyses of the blood serum pooled from the rats of each of the 4 groups in Experiment 3 show findings quite similar to those of Experiments 1 and 2.

The photomicrographic sections show better development of the bones and better healing of the fractures of the rats fed a normal stock diet than could be demonstrated in any other group (Fig 7). There was no osseous union of the fractures in the group that still had active rickets. Healing of the fractures, the quality of bone, and the restoration of function seemed to be in direct proportion to the maintenance or re-establishment of the normal content of inorganic phosphorus in the blood serum.

DISCUSSION

The histology of healing fractures in rats fed diets low in total salt, calcium, and phosphorus, and in rats fed normal diets, has been described in detail by Downs and McKeown. Using a similar technique, Goisman and Compere were able to demonstrate that the healing of fractures of atrophic bones produced by a diet low in calcium progressed to a stage of complete bony union at a rate comparable to that observed in animals fed a normal stock diet. The total amount of bone laid down in

repair was less and the new trabeculae and cortices of the bone were definitely thinner in those animals fed the deficient diet than in those constantly receiving a diet adequate in calcium. In some instances union of the atrophic bones occurred more quickly although the quality of the union was never better than the quality of the bone which had been fractured.

In the study which is presented here, it would seem quite definite that fractures of bone affected by active rickets heal poorly. Fibrous union occurred, but calcification was delayed in each instance by active rickets. Non-osseous union and pseudarthrosis were found in the majority of the fractures of rachitic bones after the rats were sacrificed. As demonstrated from observation of rats, from the roentgenograms, the blood chemistry determinations, and photomicrographic sections, *the animals which were kept on a normal stock diet throughout, without additional supplement of vitamin D, developed more rapidly, were definitely larger, had longer and larger bones, and the fractures healed more promptly than did the treated or untreated rachitic rats.* Normal function was restored in from 2 to 3 weeks with complete bony union of the fractures and restoration of the medullary canals both in the compound and in the simple fractures. The rats which were fed the rickets-producing diet until the time of fracture and then were treated by adding cod liver oil as a supplement until they were sacrificed, showed healing of the rickets and of the fractures.

The results obtained in the rats of Group 3 which were fed the vitamin D supplement in addition to the rickets-producing diet from the time of the beginning of the experiment were similar to those of Group 2, which had the vitamin D supplement added at the time of the fracture. In neither of the 2 groups did the rats grow as large, the bones as long, the cortices as thick, nor the diameter of the shafts as wide as did the rats fed the unre-enforced stock diet, and fractures were definitely slower in healing.

In the previously reported study of Goisman and Compere, it was shown that the administration of an excess of vitamin D or calcium carbonate or both of these elements to the diet of rats previously fed a diet low in calcium or a

normal stock diet, did not hasten the rate or the quality of the healing of fractures. Grauer, and Jones and Robson have demonstrated degenerative changes in the bones and retardation healing of fractures as a result of the feeding of excessive or toxic doses of vitamin D.

Our studies indicate the importance of including in the diet sufficient vitamin D to supply the basal requirement for the growth or repair of bones of growing animals. We may postulate a need of vitamin D supplement for adults whose diet may have been deficient in mineral or vitamin content producing osteoporosis or osteomalacia. Where either type of skeletal change is demonstrated we may be justified in prescribing vitamin D in therapeutic amounts. It would seem reasonable to assume that such therapy would be of value in the treatment of fractures in these types of cases. Knoflach has reported that vitamin D added to the diet of patients over 55 years of age aided greatly in fracture healing but he was not able to see any benefit from the vitamin D supplement in younger patients. If true, these observations would seem to indicate that chronic vitamin D deficiency (subclinical) is common among elderly patients.

Within the past few years many clinicians have been prescribing enormous doses of vitamin D in the form of purified concentrates. Some of them have advocated both the addition of vitamin D and calcium to the diet of patients who had sustained fractures. Unless these patients are suffering from chronic or acute vitamin D deficiency it is possible that such excessive amounts of vitamin D concentrates may cause non union or delayed union since prolonged use of such large doses of vitamin D may not only delay healing of fractures but produce degenerative changes in the bones of experimental animals.

CONCLUSIONS

1. Acute vitamin D deficiency in growing rats if continued long enough to produce active rickets, may cause delayed or non union of fractures.

2. The addition of vitamin D in therapeutic doses to the rickets producing diet was found to prevent or to heal the rickets and to bring

about more rapid and a better quality of healing of fractures of the bones of rats.

3. Bone growth and development was definitely retarded in the rats kept constantly on the vitamin D and phosphorus deficiency diet. In each of the experiments the rats in this group were smaller, the bones shorter and more fragile than were those of the other 3 groups.

4. Rats receiving no vitamin D supplement but kept consistently on the well balanced stock diet developed more rapidly, and at the termination of the experiment were twice as large as those in the other 3 groups. The bones were proportionately larger and stronger and fractures in the bones of the rats in this group healed more rapidly, function was restored more promptly, and at the end of the experiment it was difficult to observe any defect in the appearance or the function of the extremity in which the fracture had occurred.

STUDIES OF THE ANALEPTICS I CORAMINE

R W WHITEHEAD M A, M D, and W B DRAPER, M S M D,
Denver, Colorado

IN a previous paper (4) dealing with the acute safety of ether, divinyl ether, and chloroform, we emphasized the fact that *an anesthetic death should be regarded as a failure of resuscitation*. The studies of resuscitation from respiratory arrest produced by these drugs showed that *prompt artificial respiration combined with the administration of oxygen is highly efficient*. In practice, these measures are usually supplemented by one of the analeptics. We are attempting in this series of studies to determine the value of certain of these drugs for this purpose.

Among the analeptics, one of the most commonly employed is pyridine beta carboxylic acid diethylamide, studied extensively by Uhlmann in 1924 and popularly known as "coramine". This substance is reputed to have an "awakening action" in various types of narcosis and to stimulate the severely depressed respiratory center. Although numerous experiments have been conducted to determine its value in barbiturate and avertin narcosis, there have been few controlled studies dealing with its antidotal action against the inhalation anesthetics.

The experiments reported in this paper deal with the effect of coramine upon the minimal dose of ether and of chloroform required to produce respiratory arrest in dogs and with its influence upon the probability of resuscitation from a rapidly administered overdose of these agents.

THE EVALUATION OF AN ANALEPTIC

The satisfactory clinical determination of the value of an analeptic presents two serious difficulties which arise from the necessary absence of control experiments. In the first place, the physician can never be quite sure that the dose of the depressant acting would be certainly fatal in the absence of treatment. Secondly, he is not free to use his patient

condition as an opportunity for an experimental study of a drug but must do everything in his power to aid recovery. Acceptable evidence of the value of an analeptic is almost impossible to obtain under these handicaps.

The laboratory worker has the great advantage of being able to administer deliberately a measured fatal dose of a depressant to his experimental animal under a standardized set of conditions. He is thus enabled to assay the antidotal efficiency of an analeptic agent against doses of the depressant known to be fatal. This type of data can be obtained only in the experimental laboratory.

As the following brief analysis shows the antidotal action of coramine varies with (1) the physiological conditions existing at the moment, (2) the depth of the narcosis, (3) the particular depressant against which it is employed, and (4) the dose of the drug.

1 Physiological conditions at the moment
The response of the cells of the respiratory center to a stimulant is an expression of their specialized function. Here, as elsewhere in the body, anoxemia injures the specialized function first. Consequently, as asphyxia becomes more acute the vigor of the center's response to stimulation progressively diminishes with the result that the best of the analeptics become unreliable just when their action is needed most.

Not only do the respiratory stimulants lose most of their potency in the extremity of asphyxia but, occasionally, after producing a brief and ineffectual action they actually appear to hasten cessation of breathing. Not infrequently, we have seen this "therapeutic paradox" develop during the course of our experiments, and it is our observation that such animals are usually difficult to resuscitate.

The explanation for this phenomenon is probably as follows. Intensification of the activity of the respiratory neurons necessarily increases their rate of oxygen consumption

If this increased activity fails to improve their oxygen supply immediately, acute anoxemia and death of the center will quickly follow. Whether or not, therefore, the injection of an analeptic will precipitate failure of breathing by this mechanism depends upon the ability of the stimulated respiratory and circulatory functions to increase the oxygen supply to the medulla without delay. For this reason, when an analeptic is injected in the treatment of asphyxia, particular care should be taken to maintain a free airway and to enrich the oxygen content of the inspired air.

If our understanding of the physiology of this condition is correct, oxygen is the best and probably the only safe respiratory stimulant for use when asphyxial death is imminent.

2 *Depth of narcosis* The first comprehensive investigation dealing with the antagonism of coramine to the narcotics was carried out by Kohlhoff (1928). He found that coramine (50 milligrams per kilogram intravenously) interrupted a moderate paraldehyde narcosis in rabbits for a period of about 10 minutes. An increase of this dose, or, the administration of a series of injections within a short time, did not strengthen this effect. In deep narcosis the response to even large doses of coramine was very slight. Killian reported that coramine overcame the light narcosis produced in rabbits by a dose of 150 to 200 milligrams per kilogram of avertin. Barlow, on the basis of a very large series of experiments, concluded that coramine will not overcome the deep narcosis produced in rabbits by 300 milligrams per kilogram of avertin. A similar difference between the antidotal action of coramine against light and deep narcosis was observed by Guns. This worker obtained stimulation of respiration during very light chloroform narcosis only. In the presence of deep chloroform narcosis it produced either no effect or was actually a depressant to the respiration. In rats Wagner found that coramine had an awakening effect in light chloral hydrate narcosis but when used against a deep narcosis the duration of sleep was prolonged. Similar results are reported by Zipf, Windschus and Kokoschka.

We may conclude, therefore, that the antidotal action of coramine is experimentally

demonstrable against only the lighter levels of narcosis. An antagonism against the deeper levels of narcosis has not been satisfactorily shown. There is even considerable evidence that under these circumstances coramine may act as a synergist to the depressant.

3 *Nature of the depressant* Kohlhoff found coramine somewhat more antidotal to paraldehyde than to chloral hydrate. According to Maloney and Tatum, coramine is more or less capable of stimulating the respiratory center depressed by urethane, chloral hydrate, avertin, and ether but is ineffective against barbiturate depression. Completely negative results were obtained by Axmacher against barbital narcosis in rabbits. Moritsch found that 40 milligrams per kilogram of coramine intravenously definitely deepened barbital narcosis in rabbits. On the other hand, Lendle obtained marked stimulation of the respiration depressed by morphine. When pernocton or avertin was used he found that coramine prolonged the narcosis.

It is evident from the experiments cited that the antidotal efficiency of coramine probably varies with the depressant.

4 *Dose of coramine* Eichler and Klein found that 100 milligrams per kilogram of coramine intravenously improved the depressed respiration produced in rabbits by 200 milligrams per kilogram of avertin but when a higher dose of coramine was used (above 120 milligrams per kilogram) the respiratory depression was intensified. Maloney employed coramine against the depression produced in rats by 200 milligrams per kilogram of barbital. This dose of barbital is only two-thirds the minimum lethal dose for rats and of itself produced no fatalities in the untreated controls. Doses up to 150 milligrams per kilogram of coramine had no demonstrable antidotal action. When the depression was treated by 200 milligrams per kilogram, the animals were aroused for an average of 1 hour but subsequently became renarcotized and, as compared with the controls, recovery from the poisoning was delayed. After a dose of 300 milligrams per kilogram of coramine the narcosis was lightened for a time but soon a convulsive state developed which later passed into a deep de-

pression during which over 60 per cent of the animals died as compared with none of the untreated controls. When the dose of coramine was increased to 400 milligrams per kilogram the depression was deepened without evidence of a preliminary awakening action and all the animals died. From Maloney's extensive experiments therefore it appears that the smaller doses of coramine have no antidotal action against barbital in rats and that the larger doses are so consistently synergistic to its toxic effects that a combination of the 2 drugs results in a high mortality.

Hildebrandt concludes in his recent review of the available data that although a degree of antagonism to depressants may be elicited with the lower doses of coramine, the use of higher doses is apt to intensify the depression. This is in sharp contrast to the view frequently expressed in the clinical literature (Wood) to the effect that coramine possesses a wide margin of safety. This assertion is probably true when restricted to the margin between the doses causing respiratory stimulation and death of unanesthetized animals. It is apparently quite incorrect when applied to the margin between the doses causing respiratory stimulation and respiratory depression of deeply narcotized animals.

TECHNIQUE EMPLOYED

Measured per kilogram doses of ether and chloroform were administered to healthy mongrel dogs by the method described in a previous paper (4). In brief the apparatus is essentially a closed soda lime absorption system having approximately 5.5 liters capacity, within which the anesthetic is volatilized in an atmosphere of pure oxygen. The mask contains a rubber diaphragm through which by means of a syringe and needle, the dose of the anesthetic is injected on to a wire screen for volatilization. The mask is fitted tightly to the dog's muzzle by means of a rubber face piece. Every effort was made to prevent gas leakage at this point and the entire system was checked frequently for leaks. Volatilization of the anesthetic is rapidly completed and the drug develops its maximum effects within an average period of 2 minutes. Experiments were performed at intervals of 4 days.

The minimal dose of each of the two anesthetics required to produce an apparently permanent respiratory arrest was established for each animal by repeated experiments. For this purpose the initial dose employed was below the average of the series. It was then increased or decreased as required until we had determined the amount of the drug which produces an apparently permanent respiratory arrest in not less than 2 of 3 consecutive experiments and which, when reduced by 10 per cent, produces arrest in not more than 1 of 3 consecutive experiments. When the respiratory paralysis had lasted 15 seconds the mask was removed and the animal was resuscitated by artificial respiration and the administration of oxygen. After the minimal dose for respiratory arrest, as defined above, had been determined for each individual dog a second series of 3 anesthetics each consisting of the minimal dose for respiratory arrest was administered. As soon as the animal passed into surgical anesthesia a dose of 37.5 milligrams per kilogram of coramine was injected intravenously. (This dose of coramine is equivalent for the average adult human to 10 cubic centimeters of the commercial 25 per cent solution.) In the event of respiratory arrest the animal was resuscitated by the same method used for the controls.

The use of this technique has enabled us to study the influence of coramine upon the individually determined minimal dose for respiratory arrest of ether and of chloroform for dogs and to assay its efficiency as an aid to resuscitation following the minimum certainly fatal dose of these agents.

EXPERIMENTAL RESULTS

In the 19 animals given chloroform the minimal dose for respiratory arrest ranged from 0.145 cubic centimeters to 0.257 cubic centimeters per kilogram with a median of 0.185 cubic centimeters per kilogram. It is of interest to note that by analogy this would place the fatal dose of chloroform administered by the closed technique at less than 13 cubic centimeters for an average adult human. Undoubtedly many would die following a much smaller dose. The potency of the volatile anesthetics rapidly administered in a

closed system is thus much greater than is generally realized. The probable explanation for this phenomenon lies in the fact that, following a very rapid absorption the vital centers of the medulla receive an unduly large proportion of the drug as compared with the rest of the body. The danger associated with very rapid induction of anesthesia is obvious.

In the 10 animals given ether the minimal dose for respiratory arrest ranged from 1.1 cubic centimeters to 2.8 cubic centimeters per kilogram with a median of 1.75 cubic centimeters per kilogram.

The individual variation in susceptibility shown in our control experiments may appear unduly large to those unfamiliar with biological assay, but is probably no greater than has often been encountered in similar studies both in animals and in man. This question of individual variation in susceptibility was discussed in some detail in our previous paper (4).

Although the various individuals of a population undoubtedly differ greatly in susceptibility, it has been our experience that the susceptibility of any one dog tends to remain constant during a considerable series of anesthetics. That our dogs responded consistently is clearly shown by the great reduction in the percentage of respiratory arrests obtained when the minimal dose for respiratory arrest was reduced by 10 per cent. The accuracy of our method for determining the minimal dose for respiratory arrest of inhalation anesthetics is also illustrated by the fact that both the median minimal doses for respiratory arrest of ether and chloroform in this series of animals are within 6 per cent of those found in our previous group (4). In both series of dogs the ratio of the chloroform-ether minimal dose for respiratory arrest was found to be 1.94. We recognize, of course, that such exact correspondence of results must be accidental but we feel that our method provides controls of sufficient accuracy to permit bioassay of the analeptic action of drugs. Our results are briefly summarized in Table I.

It is apparent from Table I that, although the percentage of respiratory arrests can be diminished by reducing the minimal dose for respiratory arrest of the anesthetic by 10 per cent, the use of coramine is without effect.

TABLE I.—INFLUENCE OF CORAMINE ON THE MINIMAL DOSE REQUIRED TO PRODUCE RESPIRATORY ARREST

	Respiratory arrests	Non-arrests	Total administrations of M D R A	Per cent of arrests to total of administrations
Ether				
*M D R A alone	28	8	36	78

M D R A reduced by 10 per cent	6	29	35	17

*The M D R A is the (M)inimal (D)ose required to produce (R)espiratory (A)rrrest.

CORAMINE AS AN AID TO RESUSCITATION

Every scientist recognizes the truth of the ancient maxim, "The proof of the pudding is seen in the eating." Similarly, claims for analeptic action are best tested during resuscitation. Unfortunately, this fact has not always received the consideration it deserves.

During the course of the experiments described we have carried out 161 resuscitations from the measured minimal dose of ether and chloroform for respiratory arrest. This has given us the opportunity to determine the influence of coramine upon the probability of resuscitation. In 95 control experiments, resuscitation was carried out by means of artificial respiration and the administration of oxygen alone. In the remaining 66 experiments, 37.5 milligrams per kilogram of coramine were injected intravenously with the onset of surgical anesthesia. Fifteen seconds after respiratory arrest the animal was resuscitated by the same means employed for the controls. Our experience is summarized in Table II.

As Table II shows, there were no failures to resuscitate from the minimal dose of ether required for respiratory arrest in 53 attempts either with or without coramine. We have been unable, therefore, to obtain any information concerning the value of coramine in the treatment of ether overdose. There was no indication that coramine increased the ease or speed of resuscitation. Occasionally, a tempo-

TABLE II—INFLUENCE OF CORAMINE ON THE PROBABILITY OF RESUSCITATION

Ether	Respiratory Arrests	Failures to resuscitate	Per cent of failures to resuscitate
M D R A. without coramine	33	0	00

*M D R A is the (M) normal (D)ose redu ced to p roduce (R)espi atory (A)rrrest

rary stimulation of the respiration occurred, especially when the injection happened to be made relatively early in the surgical stage of anesthesia, but usually this did not persist into the late toxic stage.

The higher mortality from chloroform overdose provides a much better opportunity of studying the influence of coramine upon the ease and certainty of resuscitation. As indicated in the table, the use of coramine almost doubled the mortality from an overdose of chloroform.

IMPORTANCE OF THE CIRCULATORY EFFECTS OF AN ANALEPTIC

Although the respiratory and circulatory functions are equally necessary for life yet from the viewpoint of resuscitation, there is an essential difference. By means of artificial respiration etc. it is possible to efficiently substitute for failure of breathing but for cessation of circulation little or nothing can be done. The end result, therefore, of any attempt at resuscitation depends ultimately upon the behavior of the circulation. For this reason the action of an analeptic upon the circulation must be of much greater importance than its respiratory effects. Notwithstanding this, certain substances considered by pharmacologists to be potential cardiac poisons (3, 25) have been used as analeptics.

Experimental investigations of the circulatory action of coramine have yielded some what equivocal results. It seems well established that coramine, under favorable circumstances is capable of raising the blood

pressure. Stros and Van Esveld believe that the pressor effect is due entirely to a central action. This stimulation of the vasomotor center appears to be part of a generalized medullary excitation which involves, in addition, the respiratory, cardioinhibitory, and vomiting centers. The results obtained by several investigators indicate that the pressor action is often absent when the blood pressure has been lowered by circulatory poisons. Thus Issekutz found that severe circulatory collapse induced by chloroform was not improved by coramine. On the contrary, it caused a prolonged fall in blood pressure and dilatation of the heart. Somewhat more favorable results were obtained by Russu and Spärchez who report a few experiments in which coramine apparently prevented adrenalin chloroform collapse. Trendelenburg found coramine inactive against cardiac and vasomotor insufficiency whether produced by novocain, histamine, or chloral hydrate.

A favorable action on the contractions of the isolated heart following perfusion by a 1:50,000 solution of coramine was described in 1924 by Uhlmann but a number of subsequent workers (Trendelenburg, Gremels, Leyko, Gollwitzer, Meier, and Peters and Visscher) have failed to confirm his results.

The results of Peters and Visscher are worthy of comment. Using the Starling heart lung preparation these workers found that coramine dilates the heart and diminishes its output and metabolic efficiency.

Thus a review of the available data seems to indicate that the central vasopressor action of coramine is frequently absent in severe poisoning and that the drug exerts no significant favorable action upon the insufficient heart. Certain investigators have found it even definitely injurious.

The injurious effects upon the chloroform poisoned heart observed by Issekutz and others are an adequate explanation for the fact that, in our hands, the use of coramine almost doubled the mortality from an overdose of chloroform.

SUMMARY AND CONCLUSIONS

1. A new method for the determination of the analeptic value of drugs is proposed.

2 Coramine does not increase the dose of ether or chloroform required to produce respiratory arrest in dogs

3 Resuscitation by means of artificial respiration and the administration of oxygen from respiratory arrest produced by measured doses of ether was uniformly successful in 53 attempts with or without the use of coramine. There was no evidence that coramine increased the ease or speed of resuscitation

4 In 63 experiments, during which respiratory arrest was produced by measured doses of chloroform, there were 4 or 6 per cent failures to resuscitate by means of artificial respiration and oxygen. In 45 similar experiments in which, in addition to this procedure, coramine was injected just before respiratory arrest, there were 5 or 11 per cent failures to resuscitate. Thus, the use of coramine, in our hands, almost doubled the mortality from an overdose of chloroform

CERVICAL STUMP CARCINOMA

MARION E. BLACK, M.D., Cleveland, Ohio

A CLINICAL study of a series of our cases of carcinoma of the cervix was prompted by the increasing number of cancers of the cervix we have seen following supracervical hysterectomy. Over a 5 year period, from July 1932, to July, 1937, 234 consecutive cases of carcinoma of the cervix were admitted to the University Hospitals of Western Reserve University. The diagnosis in each case was substantiated by a histological study of tissue removed by biopsy.

AGE INCIDENCE, RACE, AND PARITY

On admission, 157 patients (67 per cent) were between the ages of 40 and 60, 39 (16 per cent) were over 60 years of age. There were 38 patients under 40 years of age, 7 patients were between 25 and 29 years. There were 9 patients between 70 and 79 years. The youngest patient was 25 years of age, the oldest 73 years. The average age for the entire group was 49 years (Table I).

There were 190 (81.2 per cent) white patients, and 44 (18.8 per cent) colored. The multiparæ numbered 211 (90.5 per cent), there were 23 (9.5 per cent) nulliparæ.

MENOPAUSE, MENARCHE, RELATIONSHIP AND REGULARITY OF THE MENSTRUAL CYCLE

In this group data were complete in 215 cases. Sixty-two patients (28.8 per cent) in the premenopausal group had not exhibited any of the nervous manifestations of the menopause and their periods had been regular

from the Department of Obstetric and Gynecology, Western Reserve University School of Medicine and the University Hospital.

TABLE I — AGE INCIDENCE

Decade*	Patients	Percent
20-29	7	2.9
30-39	31	13.2
40-49	84	35.9
50-59	73	31.1
60-69	30	12.8
70-79	9	3.8

*The youngest patient was 25 years, the oldest 73 years. Average age 49.

prior to the onset of symptoms. One hundred five patients (48.8 per cent) were definitely in the menopause when their symptoms began. In 48 patients (22.3 per cent) no definite symptoms of the menopause existed except irregular bleeding which may have been due to the existing carcinoma.

This group includes the 10 patients who had had a supracervical hysterectomy.

The pre- and postmenopausal groups were checked for the age at menarche, and the records were complete in 104 cases. In the postmenopausal group 108 had an average menarche age of 13.5 years. The premenopausal group of 56 cases had an average menarche age of 13.5 years.

From the records 182 cases were obtained with accurate menstrual history. In the postmenopausal group 117 (64.2 per cent) had a regular cycle up to the menopause, 4 (2.2 per cent) had an irregular cycle. In the premenopausal group 60 (37.9 per cent) had a regular cycle, 1 (0.5 per cent) had an irregular cycle.

The occurrence of carcinoma as to premenopausal and postmenopausal grouping conforms to the age incidence of the entire group studied. The menarche relationship and the regularity of the menstrual flow were similar to that found in a group of non-cancerous patients (Table II).

Pyometra	4	1.7
Ectopic pregnancy	5	2.1
Pelvic abscess	3	1.3
Carcinoma elsewhere	3	1.3
Procidencia uteri	1	0.5

ASSOCIATED LESIONS AND PREVIOUS PELVIC LESIONS (TABLE III)

The occurrence of fibromyoma in this group was the most frequently associated lesion, occurring in 16 patients (6.8 per cent). There was a surprisingly low number of patients with secondary anemia, 14 (5.9 per cent), in view of the fact that the most common complaint was vaginal bleeding.

Diabetes occurred in 9 (3.8 per cent), and syphilis in 13 (5.5 per cent). The degenerative diseases, generalized arteriosclerosis and hypertensive cardiovascular disease, were the most commonly found, which would be expected in a group of patients in which the average age is 49 years. Ten patients had gall-bladder disease or their condition had been previously diagnosed as such.

The most common associated pathological lesion of the pelvis, excepting fibromyoma, was chronic salpingitis in 6 (2.5 per cent) patients. Five patients (2.1 per cent) had atypical hyperplasia of the endometrium. Five (2.1 per cent) had had previous salpingectomies for ectopic pregnancy. Four (1.7 per cent) had an existing pyometra at the time of radiation. Pelvic abscess occurred in 3 (1.3 per cent) cases. One patient had a complete procidentia uteri.

Concomitantly with malignancy of the cervix, cancer occurred elsewhere in 3 patients (1.3 per cent), 1 had an epithelioma of the face, 1, malignancy of the left breast, and 1, scirrhous carcinoma of the stomach.

PREVIOUS PELVIC OPERATIONS (TABLE IV)

A previous pelvic operation had been performed in 49 patients (20.9 per cent). 19 of

TABLE IV

Previous pelvic operations	Patients	
	Number	Per cent
Unilateral salpingectomy	7	14.2
Unilateral oophorectomy	3	6.1

whom had supracervical hysterectomies. Seven patients (14.2 per cent) had unilateral salpingectomies. Three patients (6.1 per cent) had unilateral oophorectomies, three (6.1 per cent) had unilateral salpingo-oophorectomies, three (6.1 per cent) had suspensions of the uterus. Two patients (4.1 per cent) had bilateral salpingectomies, 2 (4.1 per cent) had bilateral salpingo-oophorectomies, 2 (4.1 per cent) trachelorrhaphies, 2 (4.1 per cent) bilateral oophorectomies, and 2 (4.1 per cent) drainage of the pelvis for a pelvic abscess. One patient each had the following: interposition operation, amputation of the cervix, and myomectomy.

PRECEDING SYMPTOMS AND THEIR DURATION (TABLES V AND VI)

The predominating symptom was vaginal bleeding, occurring in 187 patients (79.9 per cent). This varied from intermenstrual spotting to menorrhagia and metrorrhagia. Vaginal discharge occurred in 94 patients (40.1 per cent), in the form of a foul, watery, white, or brown discharge. A watery discharge was the most common type found. Backache occurred in 28 (11.9 per cent). Loss of weight was noted in 26 (11.1 per cent). Bleeding, in the form of spotting only after intercourse or douching was present in 24 (10.2 per cent), not associated with any other type of bleeding and apparently entirely due to trauma. There was frequency of urination, dysuria, or nocturia in 46 (19.6 per cent), and constipation in 12 patients (5.1 per cent). The majority of the patients had 2 or more of the above symptoms. There were 25 patients who had no

whom had supracervical hysterectomies. Seven patients (14.2 per cent) had unilateral salpingectomies. Three patients (6.1 per cent) had unilateral oophorectomies, three (6.1 per cent) had unilateral salpingo-oophorectomies, three (6.1 per cent) had suspensions of the uterus. Two patients (4.1 per cent) had bilateral salpingectomies, 2 (4.1 per cent) had bilateral salpingo-oophorectomies, 2 (4.1 per cent) trachelorrhaphies, 2 (4.1 per cent) bilateral oophorectomies, and 2 (4.1 per cent) drainage of the pelvis for a pelvic abscess. One patient each had the following interposition operation, amputation of the cervix, and myomectomy.

PRECEDING SYMPTOMS AND THEIR DURATION (TABLES V AND VI)

The predominating symptom was vaginal bleeding, occurring in 187 patients (79.9 per cent). This varied from intermenstrual spotting to menorrhagia and metrorrhagia. Vaginal discharge occurred in 94 patients (40.1 per cent), in the form of a foul, watery, white, or brown discharge. A watery discharge was the most common type found. Backache occurred in 28 (11.9 per cent). Loss of weight was noted in 26 (11.1 per cent). Bleeding, in the form of spotting only after intercourse or douching was present in 24 (10.2 per cent), not associated with any other type of bleeding and apparently entirely due to trauma. There was frequency of urination, dysuria, or nocturia in 46 (19.6 per cent), and constipation in 12 patients (5.1 per cent). The majority of the patients had 2 or more of the above symptoms. There were 25 patients who had no

TABLE V —PRECEDING SYMPTOMS

Patients	Number	Per cent
Vaginal bleeding	187	79.9
Vaginal discharge	94	40.1

Frequency of urination, dysuria		
nocturia	46	19.6
Constipation	12	5.1
No history of bleeding	35	10.7

TABLE VI —DURATION OF SYMPTOMS BEFORE DIAGNOSIS

Patients	Number	Per cent
Time		
1 week to 1 year	185	79.0
1 year to 10 years	49	20.9

history of bleeding and whose only complaint was a vaginal discharge usually associated with backache or lower abdominal pain.

The duration of symptoms varied from 1 week to 10 years before the diagnosis was made. There were 185 patients (79 per cent) whose duration of symptoms before diagnosis was 1 week to 1 year, 49 patients (20.9 per cent) whose duration of symptoms was over 1 year, and 1 patient who had shown marked irregular bleeding for the past 10 years. Most of this patient's symptoms could be accounted for by causes other than the existing carcinoma. A fair estimate of the average duration of symptoms due alone to carcinoma is difficult to evaluate. Taking the first group as a fair estimate the average duration of symptoms would be 4 3/4 months. The relatively short duration of symptoms and the usual finding that the growth has spread beyond the cervix as shown in this series and as has been stated in the literature, demonstrate the importance of a careful cervical examination as part of any adequate physical check up in women. Pomeroy estimates 8 months as the average interval between the onset of symptoms and the time the patient first sees the doctor.

TYPE OF CARCINOMA AND CLINICAL CLASSIFICATION OF EXTENT OF GROWTH

There were 215 patients (91.9 per cent) who had squamous cell carcinoma, 19 (8.1 per cent) had adenocarcinoma of the cervix.

TABLE VII

Patients	Number	Per cent
Type of Carcinoma		
Squamous-cell	215	91.9
Adenocarcinoma	19	8.1
Clinical classification		
Group A	21	8.9
Groups B and C	154	65.8
Group D	33	14.1
*Out of the 234 patients only 8.9 per cent were limited to the cervix.		

The clinical classification used is that of the American College of Surgeons. Twenty-one patients (8.9 per cent) were classified in Group A (limited to the cervix). There were 154 patients (65.8 per cent) in Groups B and C (broad ligament and vaginal involvement). Thirty-three patients (14.1 per cent) were classified in Group D (wide fixation). There were 26 patients not clinically classified.

TREATMENT

Only the initial treatment during the patients' hospitalization is reported. Of the total number 190 patients were given radium in the form of radium tube in the cervical canal or implantation of radium seeds in the cervix. The usual treatment was a combination of the tube and radium seeds. The average dosage of radium was 4,742 millicurie hours.

Fourteen patients (5.9 per cent) were considered too far advanced for any treatment. Eleven patients were treated by panhysterectomy and 3 patients by vaginal hysterectomy. These cases with operation include 8 patients on whom vaginal or abdominal panhysterectomy was done and carcinoma of the cervix was found incidentally. Four patients received deep x-ray therapy only. Five patients were given deep x-ray therapy to be followed by radium. In 7 patients previous diagnosis had been made and treatment carried out elsewhere for carcinoma of the cervix.

Complications following treatment. This includes only the initial complications during the patients' hospital stay. The average length of the hospital course was 5 days. Complications occurred in 10 patients (4.2 per cent). Two patients developed pelvic peritonitis. Two patients had a phlebitis of the sphenous vein. The following complications were each noted once, stricture of the urethra, recto

TABLE VIII —AGE—STUMP CARCINOMA

Years	Patients	
	Number	Per cent
2-4	10	52.6
5-17	5	26.3
20-36	4	21.1

vaginal fistula, pyometrium, necrosis of the uterine artery with a fatal hemorrhage, peritonitis from an instrumental wound of the uterus, and an instrumental wound of the uterus with no complication. There has been no follow-up on any of the patients studied because diagnosis was made in all and treatment was carried out in the last 5 years.

INCIDENCE OF CARCINOMA OF THE CERVIX FOLLOWING SUPRACERVICAL HYSTERECTOMY

Of the 234 carcinoma patients coming to the hospital during the past 5 years, 19 or 8.1 per cent had had a supracervical hysterectomy previously. Diagnosis of the carcinoma of the cervix in all cases was made 2 or more years after the operation, so that it is reasonable to believe that at the time of the subtotal hysterectomy, the carcinoma was not present.

Ten of the patients or 52.6 per cent developed cancer from 2 to 4 years following the operation. In 5 patients or 26.3 per cent the cancer occurred 8 to 10 years following the operation, and in 4 patients or 21.1 per cent it occurred 20 to 36 years after the operation. The shortest interval was 19 months (this occurred in only one patient) and the longest interval was 36 years.

AGE, PARITY, AND RACE IN STUMP CARCINOMA

The average age for the group of 19 patients was 49 years; the same average age as found for the entire group of 234. Sixteen patients (84.2 per cent) were multiparæ, three (15.7 per cent) were nulliparæ, which shows a higher percentage of nulliparæ than that found in the entire group. This is in accord with the figures published by Meigs who found 25 per cent of stump cancer occurred in nulliparæ. Von Graff found 22 per cent of 300 stump cancers had never been pregnant.

Fifteen patients were white (78.9 per cent) and 4 were colored (21.1 per cent).

CLINICAL CLASSIFICATION OF EXTENT OF GROWTH IN STUMP CARCINOMA

The grouping of the estimated involvement present was that suggested by the American College of Surgeons. Upon this basis 2 patients (10.5 per cent) were class 4 A (limited to the cervix). Ten patients (52.6 per cent) were classes 4 B and 4 C (extension to the vaginal wall and involving the broad ligaments). Four patients (21.1 per cent) were class 4 D (wide fixation). Three patients (15.8 per cent) were not classified as to extent of growth.

Type of carcinoma. Seventeen patients (89.4 per cent) had squamous-cell carcinoma. Two patients (10.5 per cent) had adenocarcinoma.

REMARKS

In this clinical review the data collected conforms with that which has been reported in the literature. The balancing together of the relatively short duration of symptoms, likely to be confused with menopausal changes, and the far advanced stage of the carcinoma when found, leads inevitably to the poor results in treatment universally reported in the literature.

Particularly interesting is the 8.1 per cent of stump cancer found in this review. Ward and Sackett report in their clinic 56 cases in 752 patients, a percentage of 7.4. The interval in 25 cases was less than 3 years, and more than 3 years in 31 cases. Farrar, at Women's Hospital in New York, found stump cancer which had developed one or more years after hysterectomy in 7 per cent of the cervical cancers. Meigs in 1218 cervical cancers found 26 or 2.1 per cent. This he presented as the corrected figure from 80 stump cancers found, eliminating 22 which were recurrences in the vault following panhysterectomy and 23 found within 1 year after operation, probably present at the time of operation, and 9 cases following subtotal hysterectomy for adenocarcinoma of the fundus. Healy and Arenson found 67 stump cancers (2.6 per cent) among 2600 cancers of the cervix at the Memorial Hospital, New York.

Nuttall and Todd divide their cases of carcinoma of the cervical stump into 2 groups as to prognosis. Group A, carcinoma present at

the time of operation, and Group B, carcinoma discovered 2 or more years after hysterectomy. The prognosis in Group A is bad, analogous to results obtained in carcinoma elsewhere in the body, because of the presence of a malignant process an incomplete operation is done. In our findings all stump cancers occurred 2 years or more following supracervical hysterectomy, but 52.6 per cent were discovered in the 2 to 4 year period following the operation.

Schiller emphasizes the prodromal stage of carcinoma of the cervix, i.e., months to several years may elapse before the surface cancer becomes active and begins to penetrate the deeper tissues. This Schiller designates as the primary stage of carcinoma of the cervix. The activation of a precancerous lesion of the cervix by a subtotal hysterectomy in the 52.6 per cent of the cases seems to be a definite possibility. This, in our opinion, is a potent argument in favor of the total operation.

The importance of pre-operative examination of the cervix, when a hysterectomy is contemplated, and especially the subtotal opera-

tion, must be stressed. When the subtotal operation has been performed, the patient's cervix should be observed at regular intervals after operation making use of all modern methods of examination: the colposcope, the iodine test as advocated by Schiller followed by a study of tissue removed at biopsy from any suspicious lesion thus demonstrated.

UNUSUAL LESIONS OF MUSCLES AND TENDONS OF THE SHOULDER GIRDLE AND UPPER ARM

EDGAR LORRINGTON GILCREEST, M D, F A C S, and PIERO ALBI, M.D.,
San Francisco, California

NO surgeon ever sees many ruptures of muscles of the shoulder girdle and upper arm and, therefore, even a report of a few cases and a review of the literature should be enlightening. We shall confine our remarks to lesions of the deltoid, supraspinatus, serratus magnus, pectoralis major, subscapularis, coracobrachialis, triceps, and biceps muscles.

LESIONS OF THE DELTOID MUSCLE

The deltoid muscle is an abductor of the arm, and its 3 portions, anterior or clavicular, acromial or intermediate, and scapular or posterior take part in this motion of elevation (41). According to Duchenne (41), the posterior fibers alone cannot abduct the arm more than to 45 degrees, while the anterior ones are the most powerful and are capable of abducting the arm to 90 degrees.

Lesions of the deltoid may involve the muscle itself or its nerve, or both. These lesions may or may not be associated with injuries to other muscles or nerves, they may follow direct or indirect trauma, or an inflammatory process of the muscle, nerve, or surrounding structures (5). Lesions of the axillary nerve, formerly called circumflex, are usually the most common cause of paralysis, and often are associated with paralysis of other muscles of the shoulder girdle (43).

In a review of the literature, we found that Bunts reported and tabulated 19 cases of isolated injury to the circumflex nerve, of these, 8 were the result of dislocation and 7 of a contusion of the shoulder. He also reviewed the history of nerve injuries about the shoulder joint and said that paralysis of the arm as a complication of luxation of the shoulder had been mentioned by Erasistratus in

300 B C, and reported by Galen in his *Officina Medici*. According to Bunts, however, it was not until Desault mentioned an injury to the deltoid muscle itself following luxation of the shoulder, that this lesion received recognition which has increased since then. In our review of the literature, we have been unable to find any case reported of injury to the deltoid muscle itself with the exception of the one by Clemens in 1913. This was a case of traumatic hernia of the deltoid muscle in a man whose arm was suddenly jerked when his co-worker by mistake dropped one end of a track they were moving. The patient felt intense pain in his arm, and later in the middle of the right deltoid noticed a tumor which caused him pain when moving the arm. This tumor became bigger and harder on contraction of the deltoid; and while the patient complained of it a great deal, he was not incapacitated. He declined operation. Clemens at that time commented on the rarity of a hernia of the deltoid muscle and stated that he had been unable to find a single case reported in the literature. Davis, in 1919, reported a case of detachment of the deltoid muscle from its bony origin following suppuration due to osteomyelitis of the right clavicle. He described how he had bridged the gap between the retracted deltoid and its normal origin by implantation with fascia from the thigh.

Smith and Christensen, in 1925, said that the mechanism of production of paralysis of the deltoid muscle is not explained in the repeated references found in the literature. They reported 2 cases of paralysis with definite solution of continuity of the circumflex nerve one inch from the origin, which followed blows on the shoulder and which was verified at operation. They emphasized that even common shoulder injuries, without penetration or lacerations, may result in a complete and permanent paralysis of the deltoid muscle.

Read before the Western Surgical Association, Indianapolis, December 3, 1937.
From the Department of Surgery, University of California Medical School.

Symptoms of traumatic lesions of the deltoid muscle vary according to type and extension of the injury and the time elapsed after the injury. Those involving the muscle itself are easily recognized by the alteration in contour of the shoulder which is increased on active movements of the deltoid muscle and more so on movements performed against resistance. The alteration of contour will depend also on the site and extent of the lesion. Usually, it is in the body of the muscle, more so toward the lower attachment (Figs. 1 and 2). At this point one may see and feel a groove or hiatus, the depth of which varies according to the extent of the lesion, and proximal to the hiatus is a tumor which hardens and increases in size and may move proximally on active abduction of the arm. This tumor, like all subcutaneous muscular ruptures, is not attached to the skin and is movable under it when the muscle is relaxed and becomes more fixed when it is contracted. There may or may not be an extensive ecchymosis, according to the time when the rupture is seen. Usually it is more evident a few days after the injury and may extend down to the hand. When the lesion involves the axillary nerve itself (Sherren believes this not as common as textbooks infer) or the fibers of other brachial plexus nerves, the symptomatology is different and the extent of paralysis depends on where the lesion is produced, i.e. the cervical, axillary, or humeral portion of nerve (5).

Usually there is a paralysis of the deltoid muscle which atrophies. The contour of the shoulder is flattened. This wasting away of the muscle makes the acromion process more prominent. The head of the humerus, however, does not tend to fall away from the glenoid cavity as it does when the spinatous muscles also are affected (43). As Bunts has remarked, 'the appearance is not at first glance unlike that of dislocation of the shoulder joint. In extreme cases the great relaxation and thinning of the deltoid make it possible to feel the groove between the neck of the scapula and the head of the humerus and it has very frequently occurred that this deformity has been incorrectly diagnosed or interpreted as an unreduced dislocation of the head of the humerus (5).'

Sensory changes always accompany injuries to the axillary nerve, these changes involving loss of epicritic and protopathic sensibility over an area corresponding to the deltoid muscle (43).

Diagnosis at times is made easily by inspection in cases of rupture of the muscle. The tumor at this site, which changes its size and consistency on active movements, the hiatus, etc., are all sufficient signs to make a diagnosis of rupture. When atrophy and paralysis are present instead, the diagnosis is more difficult, as the problems then to be solved are recognition of a nerve injury, its type, its location, and its extension. The reactions of degeneration of various nerves and muscles of the shoulder girdle and sensory changes have to be investigated. Sherren has laid down the rule that "paralysis of the deltoid without sensory changes is due to interference with the function of the fifth cervical nerve and not with the circumflex."

The functional disability, prognosis, and treatment also depend on the extent of the lesion and whether it involves the muscle, the nerve, or both. Injuries to the axillary nerve alone, or to other nerves, are always followed by a severe degree of paralysis which may involve the other muscles besides the deltoid, thus increasing the functional disability and making the prognosis practically hopeless. This is true especially if ankylosis follows the paralysis as a result of a failure of development of synergistic muscles. If the deltoid alone is involved other muscles in the shoulder which normally have a synergistic action, may develop and assume a compensatory action (5). Such function, however, by careful and intelligent development may be assumed by other muscles, the action of which normally is not synergistic to that of the deltoid, such as the serratus magnus, middle part of the trapezius and pectoralis major (50). The supraspinatous muscle alone or with these other muscles, has been reported to have assumed the function of the deltoid.

Bunts has stressed the necessity of examining for injury to the axillary nerve after a dislocation of the shoulder with consecutive compression of the nerves and vessels in the axilla, or following blows or falls on the shoulder.

der in which instance the mass of the deltoid may not act as a sufficient protective layer. Thus we would often make a more serious prognosis in injuries which at first may appear to be insignificant.

Treatment Injuries to the deltoid muscle are to be repaired as soon as possible, and the after-treatment consists of an abduction splint at 90 degrees in a slightly forward position from 3 to 4 weeks, supplemented by gentle massage and heat starting about 1 week after the repair. This is to be followed by passive abduction of the shoulder by stooping-over exercises as outlined by E. A. Codman. The treatment of injuries to the nerves depends on the extent of damage produced, and ranges from the usual treatment of a neuritis to neurolysis or neurorrhaphy for the restoration of the continuity of the injured nerve or nerves. This is done by suturing the torn ends and by freeing the adhesions and cicatricial tissue which follow the trauma and which, especially in "aged individuals in whom a tendency to neurofibrosis exists" (5), is also apt to lead to actual complete paralysis of the nerves from the pressure exerted upon the circumflex nerve or its branches by the surrounding fibrous tissue (5).

While on the subject of injuries to the deltoid muscle and the axillary nerve, let us remember the damage that may be done by the surgeon who operates on the shoulder, especially for bursitis, and carries his incision on the lateral aspect of the shoulder for a distance greater than 6 centimeters from the tip of the acromion. If this is done, severing the axillary nerve is unavoidable with resulting paralysis of the fibers of the deltoid muscle anterior to the incision. Mayer, in 1937, reported 3 such instances following an operation for the repair of ruptured supraspinatous tendons.

In cases of severe atrophy of the deltoid, many plastic operations have been devised to substitute for the lack of power of abduction of this muscle, such as transplanting of the pectoralis, etc. Lemperg reported a case in which he shortened the clavicle, and succeeded in pulling the deltoid over the acromion to about the middle of where it inserts. He obtained a good functional result (abduction to 90 degrees), and a fairly good cosmetic one

with the exception of a slight winging of the scapula.

RUPTURE OF THE SUPRASPINATOUS TENDON

Codman, of Boston, has been a pioneer in lesions of the supraspinatus and the subacromial bursæ. His remarkable book, *The Shoulder* as well as his various articles, chiefly considers lesions of that muscle and its tendon, and is a masterpiece of surgical literature, worthy of careful study by all desiring to become familiar with a much neglected subject. Never before have the anatomy, physiology, and pathology of the shoulder been so thoroughly reviewed and discussed.

Patients with lesions of the supraspinatous muscle are disabled from carrying on any laborious occupation because of the important rôle played by this muscle and tendon in the function of the shoulder. When one familiarizes himself with the subject, he cannot but agree with Codman that all of these patients, even those in which we are in doubt, should be given the benefit of an exploratory incision which, in many cases, can be carried out under local anesthesia. If a lesion of this important structure is found, it can be remedied, thus returning the patient to work weeks if not months sooner than if a conservative line of treatment had been carried out.

We shall not go into detail about the diagnosis of this lesion other than to emphasize that any time a patient has pain or weakness in the shoulder on abduction of the humerus and a tender point just below the tip of the acromion, one must consider the probability of a lesion of the supraspinatous muscle. One may also palpate, if the patient is not too fat or too muscular, a small sulcus. If, with the pain and weakness, there is an alteration of the scapulohumeral rhythm on movements of abduction or adduction, and if these movements can be performed more easily when the patient is examined in the stooping position with the arm hanging down, the diagnosis offers little difficulty.

LESIONS OF THE SERRATUS MAGNUS (ANTERIOR) MUSCLE

Judging by the paucity of the literature on the subject, it would be logical to assume that

injury to the serratus magnus is rare. Fitchet, however, wrote in 1930 that he believed "the scarcity of information about this injury is due not so much to its rarity as to its being overlooked by the examiner."

From the literature we have found only 8 cases of rupture reported: 1 by Morf, in 1874, 1 by Skillern, in 1913, 1 by Lockhart, and 5 by Fitchet, in 1930. Skillern mentioned a contribution by Gower and monograph by Berger, in 1875, which covered many aspects of the subject. He also noted that Hecker, Jobert, and Fuehrer reported patients in whom paralysis followed heavy work that required frequent energetic lifting of the arm. He also added that Weisner attributed the injury in these cases to violent alteration of the entire supraclavicular fossa in shape and position.

The chief function of this muscle is to maintain the scapula against the thorax and to assist in rotating it when the arm is elevated. It is also a powerful aid to inspiration (4). Its antagonists are the rhomboids, the trapezius and the levator scapula muscles. It is innervated by the long thoracic nerve (the posterior thoracic nerve, the long external respiratory nerve of Bell). The different muscles have a complicated action and any "loss of function of any one or more in a large measure might be compensated for by the others" (12).

Rupture of this muscle or paralysis of its nerve prevents the patient from elevating the arm more than 90 degrees. When the arm is held horizontally in front, the scapula, especially its inferior angle and vertebral edge separates from the chest like a door on hinges producing the winged scapula (Fig. 3).

A motor or a muscular lesion may result following a direct or indirect trauma such as a fall, a blow, a compression of the nerve as it traverses the scalenus medius after emerging from its superficial position or unloading of heavy objects by a short quick shrug of the shoulder. Skillern reported a case of paralysis which occurred in a laborer working at a machine. He was required to reach forward with his arms 800 times during the night. Berkheiser and Shapiro also mentioned inflammation of the nerve as a complication to febrile diseases such as typhoid, influenza, diphtheria or puerperal sepsis. They reported 4 cases of

concussion of the long thoracic nerve, 3 of which followed injury to the shoulder, and 1 of which was associated with the effort of bearing down maneuvers during childbirth.

The patient's complaints are usually weakness, pain, stiffness, lameness, inability to raise his arm higher than the level of his shoulder, and inability to work.

A diagnosis of winged or alar scapula is made easily by inspection. Berkheiser and Shapiro wrote, however, that the difficulty of differentiating between a traumatic rupture of the serratus magnus at its insertion to the scapula and an injury to the long thoracic nerve of Bell is very great because of the inaccessibility of the motor points of the serratus magnus muscle. Many times only the result, that is the amount of return of function, obtained by "immobilization in the position of election for relaxation of the involved muscles," will permit a differentiation between a motor or a muscular lesion. They believe that nerve concussion rather than muscular rupture is the factor directly responsible in these cases which respond to conservative treatment.

The treatment at first should consist in putting the arm at rest in an abducted position, preferably in a cast, with the arm slightly forward. This should be followed later by heat, gentle massage, stimulation by the faradic current, and muscle training exercises.

Berkheiser and Shapiro believe that alar scapula following trauma is more often the result of an injury to the nerve of Bell than to laceration of the serratus magnus. They have obtained complete recovery in 4 cases as late as 18 months after the onset of the paralysis by constant immobilization in a plaster shoulder-pica cast in a position which held the scapula close to the thoracic wall and the serratus magnus muscle relaxed.

Operative procedures should be postponed as a last resort. Skillern has proposed a suture between the proximal end of the short subscapular nerve to the distal end of the long thoracic nerve. Fitchet has suggested that as "the short subscapular nerve is about equal size, of the same origin, and is in close proximity to the long thoracic," the short subscapular might be used.

Fig 1 Case 1 Partial rupture of right deltoid muscle

Others (51) have considered transplantation of muscles, such as the latissimus dorsi over the inferior angle of the scapula, to decrease the deformity, and transplantation of the clavicular origin of the pectoralis major to the serratus magnus or the axillary border of the scapula. The vertebral border of the scapula may be fixed by fascial transplants through drill holes drilled through its border at different points corresponding to transverse processes of the thoracic vertebræ. This would help to stabilize the scapula and somewhat improve the function of the shoulder.

The prognosis should be guarded in such a lesion. If only the muscle is involved and the patient is seen early and proper treatment is instituted, the outlook is favorable for a complete recovery. After that the amount of recovery, as in all shoulder and muscular lesions, is commensurate with the delay in beginning treatment. If the injury involves the nerve primarily, the degree of recovery will depend on several factors, namely, "the early recognition, the extent of the anatomical lesion, the nutritional state of the paralyzed muscle and the extent of the secondary changes in the antagonists." The nerve may be only compressed or contused or the muscle may be severely damaged by lacerations. If this muscle cannot be stimulated to react to the faradic or galvanic currents, no time should be lost in considering surgical intervention, or, in lieu of that, the other muscles of the shoulder girdle should be re-educated to take on some of the function of the disabled serratus magnus.

Fig 2 Case 2 Partial rupture of right deltoid

LESIONS OF PECTORALIS MAJOR MUSCLE

As this muscle is an important one in adduction and in internal rotation of the arm, a tear of any size proves very disabling. Such a lesion occurs much more often than one realizes, especially in athletes. Letenneur, in 1861, reported one case, that of a truckman injured when one of the wheels of his truck ran over his shoulder. Letenneur wrote at the time on the facility of healing of subcutaneous ruptures of muscles and tendons and the rapidity of restoration to health, which in certain cases had "made doubtful the existence of the lesion." At that time he stated he did not know of any case of rupture of the pectoralis major having been reported.

This case had unquestionable signs of a direct rupture of the muscle, i.e., swelling of the mammary region, a sulcus between it and the shoulder, inability to adduct the arm, induration and enlargement of the tumor on adduction, and at the point of rupture the anterior wall of the axilla was formed only by skin with no trace of the great pectoral. Leten-

injury to the serratus magnus is rare. Fitchet, however, wrote in 1930 that he believed "the scarcity of information about this injury is due not so much to its rarity as to its being overlooked by the examiner."

From the literature we have found only 8 cases of rupture reported: 1 by Morf, in 1874, 1 by Skillern, in 1913, 1 by Lockhart, and 5 by Fitchet, in 1930. Skillern mentioned a contribution by Gower and monograph by Berger, in 1875 which covered many aspects of the subject. He also noted that Hecker, Jobert, and Guehrer reported patients in whom paralysis followed heavy work that required frequent energetic lifting of the arm. He also added that Weisner attributed the injury in these cases to violent alteration of the entire supraclavicular fossa in shape and position.

The chief function of this muscle is to maintain the scapula against the thorax and to assist in rotating it when the arm is elevated. It is also a powerful aid to inspiration (41). Its antagonists are the rhomboids, the trapezius, and the levator scapulae muscles. It is innervated by the long thoracic nerve (the posterior thoracic nerve, the long external respiratory nerve of Bell). The different muscles have a complicated action and any "loss of function of any one or more in a large measure might be compensated for by the others (12)."

Rupture of this muscle or paralysis of its nerve prevents the patient from elevating the arm more than 90 degrees. When the arm is held horizontally in front, the scapula, especially its inferior angle and vertebral edge, separates from the chest like a door on hinges producing the winged scapula (Fig. 3).

A motor or a muscular lesion may result following a direct or indirect trauma such as a fall, a blow, a compression of the nerve as it traverses the scalenus medius after emerging from its superficial position or unloading of heavy objects by a short quick shrug of the shoulder. Skillern reported a case of paralysis which occurred in a laborer working at a machine. He was required to reach forward with his arms 800 times during the night. Berkheiser and Shapiro also mentioned inflammation of the nerve as a complication to febrile diseases such as typhoid, influenza, diphtheria or puerperal sepsis. They reported 4 cases of

concussion of the long thoracic nerve, 3 of which followed injury to the shoulder, and 1 of which was associated with the effort of bearing down maneuvers during childbirth.

The patient's complaints are usually weakness, pain, stiffness, lameness, inability to raise his arm higher than the level of his shoulder, and inability to work.

A diagnosis of winged or alar scapula is made easily by inspection. Berkheiser and Shapiro wrote, however, that the difficulty of differentiating between a traumatic rupture of the serratus magnus at its insertion to the scapula and an injury to the long thoracic nerve of Bell is very great because of the inaccessibility of the motor points of the serratus magnus muscle. Many times only the result that is the amount of return of function, obtained by "immobilization in the position of election for relaxation of the involved muscles," will permit a differentiation between a motor or a muscular lesion. They believe that nerve concussion rather than muscular rupture is the factor directly responsible in these cases which respond to conservative treatment.

The treatment at first should consist in putting the arm at rest in an abducted position, preferably in a cast, with the arm slightly forward. This should be followed later by heat, gentle massage, stimulation by the faradic current and muscle training exercises.

Berkheiser and Shapiro believe that alar scapula following trauma is more often the result of an injury to the nerve of Bell than to laceration of the serratus magnus. They have obtained complete recovery in 4 cases as late as 18 months after the onset of the paralysis by constant immobilization in a plaster shoulder spica cast in a position which held the scapula close to the thoracic wall and the serratus magnus muscle relaxed.

Operative procedures should be postponed as a last resort. Skillern has proposed a suture between the proximal end of the short subscapular nerve to the distal end of the long thoracic nerve. Fitchet has suggested that as "the short subscapular nerve is about equal size of the same origin and is in close proximity to the long thoracic," the short subscapular might be used.

Fig 1 Case 1 Partial rupture of right deltoid muscle

Others (51) have considered transplantation of muscles, such as the latissimus dorsi over the inferior angle of the scapula, to decrease the deformity, and transplantation of the clavicular origin of the pectoralis major to the serratus magnus or the axillary border of the scapula. The vertebral border of the scapula may be fixed by fascial transplants through drill holes drilled through its border at different points corresponding to transverse processes of the thoracic vertebrae. This would help to stabilize the scapula and somewhat improve the function of the shoulder.

The prognosis should be guarded in such a lesion. If only the muscle is involved and the patient is seen early and proper treatment is instituted, the outlook is favorable for a complete recovery. After that the amount of recovery, as in all shoulder and muscular lesions, is commensurate with the delay in beginning treatment. If the injury involves the nerve primarily, the degree of recovery will depend on several factors, namely, "the early recognition, the extent of the anatomical lesion, the nutritional state of the paralyzed muscle and the extent of the secondary changes in the antagonists." The nerve may be only compressed or contused or the muscle may be severely damaged by lacerations. If this muscle cannot be stimulated to react to the faradic or galvanic currents, no time should be lost in considering surgical intervention, or, in lieu of that, the other muscles of the shoulder girdle should be re-educated to take on some of the function of the disabled serratus magnus.

Fig 2 Case 2 Partial rupture of right deltoid

LESIONS OF PECTORALIS MAJOR MUSCLE

As this muscle is an important one in adduction and in internal rotation of the arm, a tear of any size proves very disabling. Such a lesion occurs much more often than one realizes, especially in athletes. Letenneur, in 1861, reported one case, that of a truckman injured when one of the wheels of his truck ran over his shoulder. Letenneur wrote at the time on the facility of healing of subcutaneous ruptures of muscles and tendons and the rapidity of restoration to health, which in certain cases had "made doubtful the existence of the lesion." At that time he stated he did not know of any case of rupture of the pectoralis major having been reported.

This case had unquestionable signs of a direct rupture of the muscle, i.e., swelling of the mammary region, a sulcus between it and the shoulder, inability to adduct the arm, induration and enlargement of the tumor on adduction, and at the point of rupture the anterior wall of the axilla was formed only by skin with no trace of the great pectoral. Leten-

Fig. 3 Case 3 Lesion of right serratus magnus

neur wrote that with conservative treatment this case recovered completely in 15 days with formation of cicatricial tissue at the level of the ruptured muscle.

In 1873, Smart reported one case. In 1885, Malinowski reported one case. This case was one of rupture at its distal attachment to the humerus. Mandl in 1925 reported a case which occurred in a gymnast while he was swinging on rings and attempting to rotate his body in its long axis through 360 degrees.¹ Mandl found 3 cases reported in the current literature all of which occurred in well developed muscular subjects during the performance of gymnastic exercises.

McKelvey in 1928, reported a partial rupture which occurred in a boxer and wrote that to produce such a lesion the muscle must have been contracted violently while on the stretch.² He was able to find only 5 cases in the literature.

Von Eiselberg mentioned having seen in the Billroth Clinic a case with a suppurating

hematoma following a partial rupture of the pectoralis major.

In 1932, Borchers reported 1 case and found reports of 10 others in the literature. He came to the conclusion that tears are not uncommon but that they are often not diagnosed.

Pirker, in 1934, also remarked that cases of tears of the pectoralis muscle are seldom found in the literature although this injury occurs occasionally in gymnasts. In commenting on a case of rupture reported by Borchers and Tontscheff, which was the result of a direct trauma on a contracted pectoral muscle, Pirker said that the site of rupture is either in the abdominal or in the sternocostal portion, one third of a hand's breadth from the insertion of the humerus, and that seldom does such a tear occur in the muscle attached to the sternum. A complete rupture of the origin of this muscle has never been reported.

A diagnosis is possible only when in the pectoral region one can elicit a swelling and an indentation which become more pronounced on adduction of the arm against resistance. The impairment of function is directly in relation to the extension of the tear. Treatment depends on the disturbance of function and may require suture or even a plastic operation.

In sharp contrast with these tears and complete ruptures occurring in athletes, Dr. C. B. Horton, of Toronto, Canada, wrote to us of a lesion occurring in a chronic invalid. He said, "an aged imbecile at the Ontario Hospital for the Insane had been completely helpless for years and had to be fed and cared for. One morning on going the rounds the attendant reported that this man had a large swelling with an ecchymotic appearance in the region of the left pectoralis major muscle. I was not aware of the cause until a day or two afterward when I explored the hematoma with the intention of evacuating the clot and of hastening recovery. I found a complete rupture of the pectoralis major with the upper portion drawn into a tense mass at the anterior border of the axilla and the lower portion forming a raised edge along the costal origin of the muscle. It is my present recollection that the clavicular portion of the muscle was unaffected. There was no history of injury, and

Fig 4 Case 4 Complete rupture of the mid-portion of the right coracobrachialis muscle. The rupture is made conspicuous by the extreme internal rotation of the arm

the rupture evidently occurred while the patient was in bed."

Moulonguet, in 1924, also reported a case of spontaneous rupture of the great pectoralis muscle in a man 72 years old. He interpreted the rupture as due to senility, probably produced by a sudden change of temperature from an overheated place to cold and humid air. An autopsy performed 3 weeks after the rupture revealed a large hematoma in the pectoral region containing one quart of blood. The ends of the great pectoral were torn, shredded, and free in the cavity occupied by the hematoma. Microscopic examination revealed granular disintegration. He concluded that in a review of the literature an infectious myositis or a dystrophic one (such as in scurvy) was mentioned as the cause of pathological muscular rupture. This observation proved that senile alterations of muscle are susceptible of being complicated by a spontaneous rupture with abundant hemorrhage.

RUPTURE OF SUBSCAPULARIS MUSCLE

This muscle is an important one of the shoulder girdle and acts especially as an internal rotator and adductor of the humerus, and as a forward flexor at the shoulder joint. It forms the greater part of the posterior wall of the axilla and at its attachment to the lesser tuberosity of the humerus its tendon blends into the musculotendinous cuff where it fuses with the short rotators of the humerus and the capsule of the joint.

In a review of the literature we have been unable to find any case of rupture of this mus-

Fig 5 Case 4 Schematic drawing of condition found at operation of rupture of coracobrachialis

cle. In a personal communication, Dr Kellogg Speed has informed us of 2 patients in whom he made diagnoses of ruptures of the subscapularis tendon but they did not come to operation. Dr Bull and Dr Gilbert have had 1 patient in whom the rupture was found at operation. This was a very interesting case because of the length and degree of disability, the localized symptoms, the objective, and the operative findings.

RUPTURE OF CORACOBRACHIALIS MUSCLE

We have been unable to find any cases reported in the literature. We can report one case which was due to direct violence. Early operation resulted in a complete recovery which would not have occurred otherwise as there was a large rupture in the belly of the muscle (Figs 4 and 5). The patient did not have much pain but complained of consider-

Fig 6 Case 5 Rupture of left triceps before operation
Fig 7 Case 5 Postoperative result showing line and extent of incision and absence of former bulging of triceps.

able impairment of the function of his arm. Although some may consider this muscle as an unimportant or even a rudimentary one, the action of which is to assist the biceps as an adductor and flexor of the humerus the muscle in this patient was large and well developed.

RUPTURE OF THE TRICEPS MUSCLE

Rupture of the triceps muscle is an uncommon injury. We have been able to collect only 10 cases in the literature. Cases have been reported as follows: Partridge, 1 in 1868; Gueterbock, 1 in 1881; Bilhaut, 1 in 1903 (he considered it a case of muscular hernia with rupture of the aponeurosis, but from his description of the case it must have been one of extensive partial muscular rupture); Schiack, Cottbus, 1 in 1908 and also 6 collected from the literature; Penhallow, 1 in 1910; Stromeyer, 1 in 1917; Montgomery, 1 in 1920; Cassirer, 1 in 1922, and Hackenbrock, 1 in

Fig 8 Rupture of right triceps¹

Kindness of Dr R L Waugh of the U S Marine Hospital in New Orleans

1912. Fasiani, in 1923 reported 1 case which was treated conservatively. All but 1 of the cases were the result of direct violence. We have 3 additional cases to report. We operated upon one of these patients (Figs 9 and 10). For 2 of these cases we are indebted to Dr L L Stanley, of San Quentin Prison, and for the third to Dr R L Waugh of the United States Marine Hospital in New Orleans.

A tear of any size in the triceps muscle considerably impairs the power of extension of the elbow. There is usually moderate swelling and the interruption of the tendon will permit palpation of the margins of the olecranon and of the humerus. Early exploration and repair usually achieves a complete restoration.

RUPTURE OF THE BICEPS MUSCLE

Lesions of this muscle and tendon have interested one of us (15) for the past 14 years and its various manifestations have been discussed by him in 4 previous articles, in one of which 100 cases were analyzed (17). For a complete clinical account therefore the reader is referred to them. For a graphic account of anatomical observations the reader is referred to the various articles by Meyer (32, 33). He has had well over 1,000 shoulders dissected in his laboratory and it has been our great privilege on numerous occasions to examine these interesting specimens with him.

When these shoulders are opened one observes that there has been a destruction from within, that is extra articular rather than intra articular. One sees a fraying of the under surface of the deltoid muscle, considerable wear in the superior part of the floor of the subdeltoid bursa, a circular defect in the ten-

Fig 9 Rupture of triceps brachii in an elderly man¹

¹Courtesy of Dr L L Stanley (San Quentin)

don of the supraspinatus, erosion and sometimes complete destruction of the tendon of the biceps, large defects in the humeroscapular articulation, etc. None of the changes noted was, in any sense, inflammatory in nature. When the capsule was opened, there was no collection of fluid or pus nor the slightest evidence of arthritis.

Reviewing his specimens, Meyer was impressed further by finding early defects in the capsule near its attachment to the greater tuberosity. He reasoned that these capsular defects resulted "from repeated and long continued use of the arm in a position of marked abduction and external rotation." These observations naturally led him "to consider the possibility of an occupational cause." He concluded that the incidence of spontaneous destruction and dislocation of this tendon must be exceedingly common in laborers working in lumber and construction camps and in mines. A sudden trauma in such cases, therefore, would be only the immediate cause. Physicians and surgeons in general have been slow in appreciating the wide clinical significance of Meyer's epoch-making discoveries which were first brought to our attention in 1915.

While attrition due to occupation will, undoubtedly, explain many lesions of the tendon, one must bear in mind other causes such as the degenerative changes due to senility, arthritis, myositis, arteriosclerosis, acute and chronic infectious diseases, fatigue, and trauma. We have seen however, a number of lesions which occurred in young, healthy, and robust

men while they were engaged in games to which they were accustomed, such as handball, football, and bowling. In these patients it is very important to make an early diagnosis and to repair the lesion to obtain a complete restoration of function (Figs 10 and 11).

The surgical approach for the repair of disinsertion of the proximal end of the tendon of the long biceps, which we have used recently, consists in extending the incision up over the anterior portion of the shoulder and, instead of retracting and cutting the lower portion of the great pectoral muscle, the fibers over the coracoid process are separated. In this manner the upper and detached end of the long biceps can easily be brought up and sutured to the coracoid process and to the tendon of the short head.

Elongation of the tendon of the long biceps
This lesion may arise from many causes, which have been discussed by one of the authors in a previous article (18). He has used various methods for shortening the tendon, and thereby brought up the belly of the muscle to its proper place. Not only is a gratifying cosmetic result obtained but the function of the arm is much improved (Figs 12, 13, and 14).

Dislocation of the tendon of the long biceps
This condition has proved, heretofore, to be very baffling. Although 71 cases have been recorded as having been seen clinically since the first article by Cowper in 1724, and many cases found at autopsy have been recorded, and even though Meyer has observed over 50 cases of marked dislocation and many others

Fig 10 Case 7 Before operation. Disinsertion of tendon of right long biceps from lip of glenoid in a ten-pin bowler. Note lowering and bulging of the belly of long biceps.

Fig 11 Case 7 After operation. Note that the contour of the region of the biceps has been restored.

Fig 12 Case 8 Before operation. Elongation of tendon. Note besides the characteristic bulging of belly the widening and deepening of hollow between deltoid and belly of long head of right biceps.

Fig 14 Case 8 A few weeks after operation. Note the perfect re establishment of muscle balance and the restoration of contour.

of lesser degree in the dissection of 1000 shoulders no patient had been operated upon for the relief of this condition until in recent years (Figs 15 and 16). One of the authors operated upon such a patient in 1926 and analyzed 6 cases (18), 2 of these patients having been operated on by Dr Edward C Bull. Dr Abbott and Dr Saunders presented a paper on this subject before the California Medical Association in 1934 and recorded, I believe, 3 operative cases.

The symptoms of this condition depend on the degree of dislocation. The onset is usually acute. The symptoms may not be very pronounced at first and many of the objective signs may be obscured by the tenosynovitis and generalized soreness which result from the production of such a lesion. We have worked out a simple and useful diagnostic test which is fully described elsewhere (17). Surgical repair will give an excellent result.

Fig 13 Case 8 Author's method of shortening tendon and thereby securing a muscle balance with short head.

REPORT OF CASES

CASE 1st A B a man aged 27 years was injured while lifting a heavy box from the ground to a place above his head. He felt a sudden snap in the upper right arm and noticed a large lump which gradually increased.

Examination. Eight months after the accident there was a large and indurated mass in the region of the deltoid muscle. Movements of the arm were painless and complete but the power of abduction in the affected arm was impaired. There was a definite hiatus just above the insertion of the deltoid where the fibers evidently had been avulsed upward. Past history was essentially negative. Patient declined to have an operation.

CASE 2nd A H a man aged 21 years, was injured August 14, 1934 while driving an automobile. Another car drove into him and as a result of the collision he received an injury to the right shoulder. Following the accident he was taken to the Berkeley General Hospital where he remained 3½ days. He stayed at home then in bed for 6 days. He had pain in his right shoulder when he attempted to use it strenuously and the power of abduction was considerably reduced in his right shoulder.

Examination. He was able to put his right arm through a normal range of motion. The power in the right arm was reduced in performing the motion of abduction to about one half of that in the left arm. Examination of the right deltoid muscle showed a marked irregularity in this muscle. The posterior half of the muscle apparently had been torn loose from its insertion and was retracted upwards a distance of about 2 inches. This caused the posterior half of the muscle to bulge unduly when it was contracted. The patient declined an operation.

CASE 3rd W L G a man aged 63 was injured March 14, 1934 when after lifting a heavy stone

Fig 15 Left, A dissection made in the anatomical laboratory of Dr A W Meyer of Stanford University "The left shoulder showing the long tendon practically unaffected and displaced anteriorly or ventrally, in order to reveal the position in which it lay The arrow points to the supratubercular ridge This tendon is never dislocated distal to the ridge A little proximal from the supratubercular ridge can be seen the capsular sling on which this tendon played and which protected it from wear underneath, a small portion of the cartilage of the head of the humerus is revealed immediately proximal to it "

Fig 16 Same as Figure 15 "The left humerus showing the distal portion of the long tendon *in situ*, and with a bifurcated attachment extending toward both the tuberosities However, the tendon is also attached in the floor of the sulcus, and the great widening of the proximal portion of the sulcus shows that this tendon was maximally dislocated before it was divided Some osteophytic reaction is evident in the intertubercular region of the sulcus and proximal to this region "

he tried to throw it forward into a truck Instantly he felt a sudden twinge of pain in the region of his right scapula From that time he had an ache and a feeling of lameness in his shoulder and a few days later his wife called his attention to "a winging out of his shoulder blade "

Examination On inspection April 21, 1934, one could see a moderate drooping of the right shoulder, the acromion being conspicuously lower on the right than on the left side When viewed from the side, with his arm hanging at rest, his right scapula projected from the chest When viewed from the rear with the arms raised his scapula assumed the classical angel-winged position On palpation there was moderate tenderness on pressure over the vertebral border of the right scapula Electrical reactions were normal to galvanism in so far as reversal of the poles was concerned, but faradic irritability was reduced over the right serratus muscle

Diagnosis This evidently was a traumatic paralysis of the right serratus muscle due to injury of the long thoracic nerve

Result The patient was unable to remain for treatment He declined operation

CASE 4 E R B, a man, aged 33, was injured on June 30, 1934, while helping to operate a charging machine He had his right arm extended forward and downward and was holding on to the shoe of the machine so that his arm was tense When the machine went backward his arm followed outward until it became caught against a stanchion Instantly he felt a heavy pressure on the internal aspect of the right arm, near the axilla He shouted, and the machine was immediately reversed, thereby freeing his arm He swung his arm around to ascertain if it was hurt and then he noticed a depression in it although he felt little pain The next day his arm was sore and felt weak when he attempted to pull anything toward him or to pull his arm towards his body (adduct to median line) He said that on flexing his arm, it felt weak at the beginning of flexion until one-third of the way In adduction to mid-line the arm was weak all the way Since the day following the accident he had had only a slight soreness and a

sort of catch in the region where the indentation was whenever he used his arm. This region had also been tender to touch.

Examination. On July 2, 1934, there was a slight erythema over the upper third of the right arm but no abrasion of skin and very little if any swelling. With his right arm abducted an indentation or hiatus was clearly visible in the lower portion of the upper third between the short head of the biceps and the triceps. When the arm was rotated as far internally as possible and the patient was told to make a strong grip the depression became more pronounced and on palpation one felt a distinct diastasis and this area was tender. There was no evidence of injury to either the long head or short head of the biceps or to the triceps.

Operation and result. On July 15, 1934, under local anesthesia of one half per cent novocain an incision of 15 centimeters in length was made over the border of the right pectoral muscle extending down the inner aspect of the right arm and exposing the muscles in this region. The edge of the pectoralis major short head of the biceps coracobrachialis and the triceps muscles were exposed and brought into view. When the patient was requested to contract his arm nothing abnormal was seen but when he flexed and adducted his arm a hiatus was seen in the mid portion of the coracobrachialis muscle. This muscle was covered by a sheath and no rupture was visible although a definite depression could be seen and felt with the finger. The muscle sheath then was opened and a complete rupture of the mid portion of this muscle was found.

Each half of the muscle belly which was about the size of a lemon cut transversely had separated for about an inch. There was no hematoma present and only 1 or 2 minute blood clots. The forearm was flexed and the arm lifted and adducted in the position of putting the right hand over the left shoulder. This brought the 2 halves of the ruptured muscle without tension into complete apposition. They were approximated by 3 interrupted sutures of No. 2 chromic catgut reinforced by 4 fascial strips secured from the right thigh.

The wound of the arm was closed in layers without drainage. The operation was performed mostly under local anesthesia to achieve a complete reparation under voluntary control of his muscles and was finished under gas. The arm was immobilized in a Velpeau bandage to the chest leaving the coracobrachialis muscle in complete relaxation that is having the right arm forward over the chest with the right hand near the left shoulder. After operation the patient obtained a good functional result.

CASE 5. J. J. aged 23 was injured in 1931 when he was in an automobile accident. While under the influence of liquor he was driving with his left arm resting on the window sill. He failed to negotiate a turn and collided with an iron post hitting the left forearm and elbow. He was removed to a hospital

and treated for a fractured left elbow for 2 days. His whole left arm from the wrist to the shoulder was badly swollen. He could not get his arm in the sleeve of his shirt, bend the arm or move his fingers.

The swelling subsided in 2 weeks when he noticed a big lump on the undersurface of the upper left arm which had persisted without apparent diminution in size. He had fairly good function in the left arm but stated that he had not so much strength in that arm as in the right one. This was especially noticeable when he attempted lifting.

Examination. There was a bulging tumor mass in the upper third of the posterior or extensor surface of the left arm. On palpation it was readily discernible that the tumor consisted of a contraction of the muscular belly of the triceps muscle.

Operation and result. On May 20, 1936, under general anesthesia a linear incision 12 centimeters in length was made over the mid portion and lower end of the left triceps and carried up exposing the belly of the triceps muscle which was found to be contracted and bulging. The muscular portion of the long head of the triceps had torn loose from the tendinous portion of the lower end. The muscular portion of course was found to be adherent to all the surrounding tissues. These adhesions were liberated with the finger and by sharp dissection with the scalpel. Then by slow traction on the muscle it was possible to lengthen it gradually without tearing until its normal length was practically reestablished.

The repair was carried out in this manner. By 6 mattress sutures the lower end of the muscle was sutured to the tendinous portion. It was also found that a portion of the lower end of the external head of the triceps was torn and after liberating this, the muscular end was brought through the lower end of the tendon by incising the tendon and pulling through the lower end of the muscle. By interrupted sutures as a further method of fortification the fascia over the belly of the muscle was sutured over the musculotendinous portion giving a firm fixation. With this accomplished it appeared as if a complete reestablishment of the large rupture of the triceps had been accomplished. The wound was sutured in layers and the arm immobilized in extension. The patient received a good functional result.

CASE 6. D. L. G. a man aged 30 was injured in September, 1935. He was carrying a steel cable choker weighing 70 pounds and threw it over some brush with his right hand. A hook caught on the glove of his left hand and the spring of the coiled cable jerked and twisted the relaxed arm which was extended by the jerk. There was immediate pain and disability in the left shoulder and arm. The pain radiated to the left side of the neck and chest. He then consulted a physician who immobilized the arm and prescribed heat and massage. After several weeks treatment he began to try using the arm but felt a catching grating and clicking sensation especially when arm was in a position of abduction

Examination On April 23, 1936, there was only moderate atrophy of the muscles of the left shoulder. The movements were restricted, especially abduction (70/180) and forward rotation (80/180) with pain at the limit of the range of motion. External rotation of the humerus caused loud, multiple, snapping sounds, associated with pain, which felt as if it were produced by a tendon or a thickened mass of soft tissue passing over the tip of the greater tuberosity under some tension or compression. About 1 out of 3 times when he carried out this movement a loud sharp snap was heard as if a definite structure, like the biceps tendon, might be slipping over a bony prominence while under some tension. It was this repetition of movements which produced those snapping sensations which caused his shoulder to become sore in a short time. As this developed the disability in his shoulder became very marked. The supraspinatus muscle was not tender, apparently was not atrophied, and appeared to be used very much like its mate in the uninjured shoulder. Tension on the biceps muscle seemed to make no difference in the manner in which he performed his movements or in the degree of discomfort felt. This suggested that the snapping sound was produced by some other mechanism than an abnormally movable biceps tendon. The patient moved his shoulder quite willingly but guarded the movements carefully as the painful point was approached, seeming to have actual pain and wincing with each of the multiple snaps produced by movement. Roentgen examination revealed an irregular area of bone absorption just below the level of the greater tuberosity.

Diagnosis Probable partial tear of one of the muscular insertions about the greater tuberosity of the humerus.

Operation and result On April 27, 1936, under general anesthesia an incision was made along the anterior margin of the deltoid muscle and carried down exposing the joint structures. It was readily seen that there had been an extensive tear of the tendon of the subscapularis muscle near its insertion on the humerus. The muscle appeared to have been torn transversely a distance of about an inch, the tear extending backward from the anterior margin of the tendon parallel to the joint margin and about one-half or three-fourths of an inch from the insertion on the humerus. The tear had extended also proximally between the supraspinatus and subscapularis for a distance of probably $1\frac{1}{2}$ to 2 inches. This had created a defect in the fibrous capsule of the shoulder joint which had filled in with very inadequate and thin scar tissue, and at this point the capsule was very loose and would probably have permitted dislocation of the shoulder on slight provocation if the patient's discomfort had allowed him to abduct the arm freely. There was also a loose flap of fibrous and synovial tissue hanging free from the joint lining for a distance of an inch or more. This flap was one-half or three-fourths of an inch from the articular margin and about five-eighths of an inch wide. Its structure was rather dense and it seemed likely

that the clicking and snapping sensation observed on examination of the patient was due to movements of this loose flap. The torn subscapularis tendon had retracted considerably, but the margin of the tendon was freed along the general line of the original tear and it was drawn as near as possible to its original position and sutured in place with interrupted chromic catgut sutures. The loose fibrous capsule of the shoulder joint was partially excised and the freshened margins of the subscapularis and supraspinatus tendons were sutured together as closely as possible in an attempt to restore normal strength in this part of the shoulder joint capsule. The patient's arm was bandaged to his side in a position of internal rotation with the elbow forward on the chest to relax the sutured muscle.

Result. He secured a satisfactory result and returned to his regular work.

CASE 7 J. O., a man, aged 52, was injured on May 5, 1935, while playing in a bowling tournament. He raised his right arm above his head in the usual manner and had gripped in his hand a bowling ball, weighing 15 pounds 13 ounces. The regulation weight of a bowling ball is 16 pounds. This was 3 ounces less, and was the weight of the ball he used all the time. He said he made no more strenuous effort than he had made thousands of times. Just as he threw the ball he heard and felt something tear in his right arm in the region of the biceps muscle. Then he picked up a second ball and threw that. As he did this he had the sensation of someone putting a knife in his elbow and ripping it up to his shoulder. Then he took a third ball and as he started to throw it he gripped it and it fell right out of his hand. After this he became sick to his stomach and his arm felt weak. He lay down for 15 or 20 minutes in a cold perspiration. A doctor was called, who came to the bowling alley to see him, and wrapped his arm and told him he had torn a muscle. His arm caused him no pain when it was at rest, but when he tried to lift anything he found it difficult to raise it more than a few inches, and he had a feeling of soreness and a sharp pain, cutting in character, in the biceps muscle.

Examination May 8, 1935, there was an area of ecchymosis over the proximal end of the right biceps. The belly of the biceps had dropped down so that when the arms were held in extension the hiatus between the deltoid and the biceps was very conspicuous, measuring in the left arm 1 finger's breadth, and in the right arm 3 fingers' breadth. With arms hung to the sides in a natural position with the palm forward one could see that the belly of the biceps had dropped down and there was a hollow above the biceps.

Operation and result On May 10, 1935, under local anesthesia an incision was made over the tendon of the long head of the biceps and carried down exposing the tendon which was found ruptured near its upper end. The tendon had gone down toward the muscle but had not turned over. It was freed and brought out and seen to be long enough to put up to the coracoid process. As the pectoral muscle was so

well developed it was impossible to retract it sufficiently to get a good fixation of the tendon of the long head of the biceps on the coracoid process. Therefore the fibers of this muscle were split with the fingers and separated so that the coracoid process was visualized easily which gave adequate space for the tendon to be brought up underneath this muscle and the fixation could be performed readily. The fibers of the tendon of the short head of the biceps were then separated at the level of the coracoid process and the tendon of the long head of the biceps was pushed through the opening. Then the proximal end of the long head of the tendon was sutured to the coracoid process and reinforced by suturing to each side of the tendon of the short head of the biceps through which it had been inserted. Silk sutures were used throughout. The muscles were then approximated loosely with No. 1 catgut and the wound closed in layers. The operation was done under local anesthesia and the patient stood it well. The arm was put up in a Velpeau bandage.

Result. On June 8, 1935, result was most satisfactory. On July 15 he returned to his regular work.

CASE 6. C. H., a man aged 35 years, was injured June, 1925, when he was thrown from a truck which turned over pinning him underneath. While making an effort to free himself he felt a slight snap in the right shoulder. After hearing the snap in his shoulder he felt a very severe pain there and then became unconscious. In this accident he suffered a fracture of the occiput and a dislocated vertebra.

Examination. On April 17, 1928 (Fig. 12) it was revealed that the belly of the long head of the right biceps was definitely smaller than the left and on flexion the belly bulged and this bulging was about 2 fingers breadth lower down the arm than the muscle of the long head of the other arm. This arm was seen readily to be weaker than the other.

Operation and results. On April 17, 1928, under general anesthesia an incision was made from the shoulder extending from along the insertion of the pectoralis major over the biceps. The 2 muscles of the biceps were then exposed and separated from each other. The muscle and tendon of the short head were normal. The muscle of the long head had retracted and the tendon had become attenuated but was not seen to be ruptured. The tendon was pulled up and shortened about 2 centimeters and then the loop of the tendon was pulled through an opening in the muscle at the beginning of the tendon (13). This shortened the tendon about 2 centimeters and brought the bellies of the long head and the short head side by side. This man secured a very satisfactory and useful arm. The contour of the muscles became practically normal (Fig. 14).

SUMMARY

No surgeon ever sees many ruptures of the various muscles of the shoulder.

The authors are indebted to Dr. L. L. Stanley of the California State Prison at San Quentin for permission to examine and operate upon the patient.

A review of the literature revealed that with the exception of many cases of supraspinatus and biceps, a surprisingly few cases of the other muscles and tendons of the shoulder girdle and upper arm have been reported. We have found only 1 uncomplicated rupture of the deltoid, 8 of the serratus magnus (anterior), 8 of the pectoralis major, none of the subscapularis, none of the coracobrachialis and 10 of the triceps.

The rôle of acute trauma, direct or indirect, is greater than all other causes of shoulder disability, including senility, disease, fatigue and attrition.

The most frequent mechanism producing a partial or complete rupture of a muscle or a tendon is the sudden application of a stretching force to a muscle which is in the process of vigorous contraction.

A tear in a muscle or tendon about shoulder joint or upper arm will produce pain in the joint and often cause an incorrect diagnosis.

A careful history and examination usually will lead to an early diagnosis.

Treatment should be directed to prevent contracture and atrophy of the muscles of the shoulder girdle.

Prompt surgical intervention and repair of the tears in the muscles and tendons about the shoulder in the majority of the patients will give satisfactory results.

CLINICAL SURGERY

FROM THE GLASGOW ROYAL INFIRMARY

SUPRAPUBIC PROSTATECTOMY

ARTHUR JACOBS FR FRS (Glas.), Glasgow, Scotland

REMOVAL of the prostate by the suprapubic route is the procedure preferred by the writer on all patients whose obstructive symptoms are due to prostates of the large adenomatous type. Transurethral resection is the method favored for the smaller types of glandular obstructions and for carcinoma. Suprapubic cystotomy is reserved for those who are unfit for either procedure. Out of a total of 106 patients operated upon for prostatic obstruction in 1937 a suprapubic prostatectomy was carried out on 50 or 47 per cent. A two stage operation was performed on 12 of these patients.

The technique of suprapubic prostatectomy now used by me has been arrived at after extensive experience with the operative methods used by Freyer, Thomson, Walker, Bentley, Squier and Harris. The various steps are based on the work of these great pioneers in this branch of surgery.

POSSIBLE DANGERS AND COMPLICATIONS

Failure of the cardiovascular system to stand up under the strain of the operation, postoperative pulmonary complications including embolus, renal failure and urinary sepsis are the dangers and complications to be feared and guarded against. Methods to avoid the two latter conditions will be dealt with in subsequent paragraphs. With regard to the cardiovascular system I think it is correct to say that the majority of prostatic patients exhibit degenerative vascular changes and varying degrees of weakness of the cardiac musculature. A thorough medical overhauling should therefore be a routine practice. It is difficult however even for an expert physician to determine the exact degree of cardiac reserve in any given case. In patients with a recognizable impairment test in bed with appropriate treatment of the heart, combined with drainage of the

bladder may result in such a degree of improvement that operation can be carried out. If sufficient improvement does not occur, one can not proceed with major operative intervention. To lessen the risk of postanesthetic pulmonary complications, cyclopropane or gas and oxygen with a minimum of ether are the anesthetics usually preferred. At the termination of the operation respiratory activity is stimulated by carbon dioxide inhalation. The patient is slightly elevated on pillows as soon as he is out of the anesthetic. The degree of elevation is gradually increased and within 24 hours he is usually well enough to be in a sitting position. He is encouraged to move his lower limbs about in bed at frequent intervals and is allowed out of bed at the earliest possible date.

PRE-OPERATIVE INVESTIGATION AND PREPARATION OF THE URINARY TRACT

A satisfactory renal function is a *sine qua non* before operation is decided on. The existence of marked impairment is usually recognizable by obvious clinical manifestations such as a dry skin, loss of appetite, indigestion, and constipation. Persistent thirst, a dry mouth and a furred tongue are ominous signs. As an aid to the recognition of the lesser degrees of renal impairment the routine biochemical tests which are relied on are an estimation of the blood urea and the urea concentration test. If the blood urea is higher than 50 milligrams per cent the renal condition is regarded as unsatisfactory. A reading below this figure is not however considered by itself to indicate a good renal function. Chief reliance for this information is placed on the urine urea concentration test. The patient is given 15 grams of urea dissolved in 100 cubic centimeters of water and the percentage of the urea found in the urine during the first, second and third hours is estimated. If the patient is not on bladder drainage by an indwelling urethral catheter one is usually inserted for the period of the test. The quantity

The illustrations for this article were all drawn by Miss C. Brown Kelly. Figures 6 and 7 are based on illustrations in the paper by the late Mr. Harry Harris published in the *British Journal of Surgery* in January 1931 and as acknowledged in the text. Figure 3 is a replica of a drawing in the same paper.

of urine passed in each hour is noted and the percentage of urea excreted in each specimen is estimated. The total amount of urea eliminated in each hour is thus calculated and should in the second hour be not less than 15 grams, i.e., one tenth of the amount swallowed.

As a check-up on the above tests, the indigo-carmin test is frequently used. An intravenous injection of 8 cubic centimeters of a 0.4 per cent solution is given. A good blue coloration should appear in the urine within 10 minutes.

If these tests indicate a renal insufficiency, treatment must be carried out with a view to its correction before operation. Forced diuresis and continuous bladder drainage are the methods used to achieve this objective. The patient is encouraged to drink as much fluid as possible, aiming at a minimum of 5 pints per day. A soft rubber catheter is retained in the urethra and connected by a glass connection to a length of rubber tubing, which drains into a bottle containing a measured quantity of antiseptic at the side of the bed. The bladder is washed out once or twice a day depending on the degree of urinary infection present. Two to 3 pints of 1:10,000 silver nitrate solution are used for each wash out. For very dirty bladders the routine recommended by Harris has been found useful. It is as follows: A solution of potassium permanganate of a light pink color is washed backward and forward through the catheter until the return fluid is clear. The remainder is then washed out with plain sterile water. Four ounces of 1:3,000 solution of nitrate of silver are then injected into the bladder and the catheter is clamped for half an hour if the patient will tolerate it for that time. Then it is connected to bottle at the bedside.

Throughout the period of preparation the urine is kept acid by acid sodium phosphate, 10 grains three times daily. If a stronger acidifier is required, ammonium chloride, 15 grains in capsules, 3 to 4 times daily, is substituted. As long as the urine is acid, hexamine in doses of 10 grains thrice daily is also given.

For a patient whose renal impairment is not marked, catheter drainage for a week or 10 days will usually suffice. For a patient with a good renal function, I see no advantage in draining the bladder for more than 4 or 5 days even if he has had a residual urine of several ounces. This applies particularly to that type of patient who has suffered from repeated attacks of retention but who in the intervals between the attacks is able to empty the bladder quite satisfactorily. I consider about 3 weeks the maximum period that urethral catheter drainage can be continued to

advantage. If by that time the renal function is not sufficiently good to warrant a prostatectomy, a suprapubic cystostomy should be carried out and the prostate removed at a later stage.

LIGATURE OF THE VAS

This is a routine procedure done in order to prevent a postoperative epididymitis. If the initial renal functional tests indicate that more than one week of catheter drainage is likely to be necessary, the vas ligation is done as a separate procedure under local anesthesia. If there is to be only a few days of catheter drainage, the ligation is made at the time of the prostatectomy.

The vas is grasped a little below the root of the scrotum and held firmly between the left thumb and index finger. About 20 cubic centimeters of 1 per cent novocain injected subcutaneously and into the cord in an upward direction for about an inch, starting at the level where the vas is held, will usually suffice. Keeping a firm grasp on the vas, a half inch incision is made over the anesthetized area of the cord, the coverings incised, and the vas rolled into the field, where it is grasped with dissecting forceps. It is now separated from the other structures of the cord by blunt dissection and clamped by 2 pressure forceps placed about 1 inch apart. The intervening segment of the vas between the 2 forceps is cut away and a catgut ligature is placed on each end. The skin incision is closed by 2 silkworm sutures. Both sides are dealt with similarly.

OPERATIVE TECHNIQUE

Immediately prior to operation and before the patient is brought to the theater, the bladder is washed out with potassium permanganate and emptied. The catheter is removed from urethra and in doing so the urethra is also irrigated with the solution. The penis, scrotum, upper half of thighs, and abdominal wall are surgically prepared.

The operator stands on the left side. The left hand is covered with 2 gloves. The table is tilted into a modified Trendelenburg position, excessive lowering of the head not being considered advisable. The legs are separated to the full width of the table. The towels are arranged so as to facilitate access to the rectum and urethra. Thus the top sheet and side towels should be placed first. A long sheet completely covering the lower limbs and pressed down between the thighs comes next. A split towel through which the penis is drawn is placed over the pubic region and upper thighs. This is covered by a further towel, the upper border of which rests on the symphysis

FIG. 1. The extraperitoneal surface of the emptied bladder is pulled upward into the wound by tenaculum forceps and incised. A suction tube is passed down to the retro-prostatic area and any residual fluid is evacuated before the incision is extended in the bladder upward.

A median suprapubic incision is made the lower end of which starts 2 finger breadths above the symphysis. A small incision about 2 inches in length is favored but it may be desirable to extend it upward in a patient with a stout pendulous abdominal wall. The skin and subcutaneous fat are incised and the anterior wall of the rectus sheath is exposed and divided in the line of the

FIG. 3. Copy of illustration in article by the late Harry Hagar (*British Journal of Surgery*, January 1934) showing postmortem specimen of bladder and prostatic urethra opened from the front and indicating the intra-urethral method of enucleation. The broken black line and the arrows thereon indicate the course followed by the finger and *a* and *b* are opposite the antero-inferior aspect of each lateral lobe where the enucleation is begun on each side *d* and *e* the cut edges of the muscle of the anterior compartment *c* the membranous urethra *f* verumontanum.

FIG. 2. The right index finger is passed through the internal meatus and prostatic urethra and separation of the prostate is commenced at antero-inferior aspect of left lobe by forcing the finger through the urethra at this point.

incision. The fibers of the rectus muscles are separated in the middle line with blunt pointed scissors. The transversalis fascia is opened and the perivesical fat is brought to view. All bleeding points are now clipped and ligated. The next step is to expose the extraperitoneal surface of the bladder. As the latter is empty and as the abdominal incision and muscle separation do not reach to the symphysis this is somewhat more difficult than when carried out with the bladder distended and a downward extending incision. (In the excessively obese patient it may be preferable to have the bladder distended with about 12 ounces of lotion.) Exposure is facilitated by the use of a small sized, self retaining retractor. The perivesical fat and peritoneum are stroked upward from off the bladder with the aid of a small fold of gauze. The anterior wall of the bladder is usually recognized without difficulty and is grasped by tenaculum forceps. It is pulled upward and backward into the wound. By means of a further pair of tenaculum forceps the position of each is adjusted so that they hold the anterior wall of the bladder on either side of the middle line about one inch apart. While traction on the forceps is maintained a stab incision is made between them. A suction tube is immediately passed into the bladder and any residual fluid is evacuated (Fig. 1). A suture is inserted through each side of the bladder incision and the traction forceps are discarded. The incision in the bladder is sufficiently enlarged in an upward direction to enable the index and middle fingers to be passed through it. If the peritoneum encroaches on the line of incision it is stroked further upward. Any bleeding point on the bladder is ligated and the process of enucleation is carried out.

ENUCLEATION OF THE PROSTATE

As the abdominal incision and the opening into the bladder are small, the enucleation of the prostate is greatly facilitated by inserting the index and middle fingers of the left hand into the rectum and pushing the gland upward. Before doing this, the left arm is covered down to the wrist with a towel (The left hand is still covered with 2 gloves. The towel and outer glove are discarded as soon as the hand is withdrawn from the rectum). The index and middle fingers of the right hand are inserted into the bladder and the index finger is passed through the internal meatus and prostatic urethra down to the antero-inferior aspect of the left lobe of the gland. The plane of cleavage between it and the prostatic capsule is opened by forcing the finger through the prostatic urethra at this point (Fig 2). The finger is then swept round the lateral surface of the left lobe to the middle line of the posterior aspect of the median lobe. The finger is also made to pass around the inner surface to the middle line of the anterior aspect of the median lobe.

A similar maneuver is carried out on the right lobe (Fig 3). The attachment of the median lobe to the prostatic urethra may be broken with the finger. If this does not readily occur, it should be cut across with scissors. The gland is now delivered backward into the bladder and removed. If it is very large, it may have to be pulled forcibly through the bladder incision with forceps. In the majority of enucleations carried out in this manner, the gland comes away in one whole, consisting of 2 lateral lobes joined together posteriorly by the median lobe and open in front. If no median connecting isthmus is present, each lateral lobe has to be removed separately.

Fig 4 Drawing of Harns's electrically lighted self-retaining bladder retractor with posterior suction blade. The frame rests on the abdominal wall. The narrow blades of the retractor can be inserted into the bladder through a small incision and enable excellent visualization of the prostatic cavity to be obtained. The complete instrument, including lights and cord, is boilable.

CONTROL OF HEMORRHAGE

A fold of gauze is temporarily packed into the prostatic cavity whilst self-retaining bladder retractors are placed in position. If the bladder exposure has been made through the usual small incision, a Harns retractor (Fig 4) is used. Its narrow blades are easily introduced into the bladder. If a larger incision has been employed, a Morson retractor may be used. Excellent exposure and illumination of the prostatic cavity

Fig 5 Drawing of Harns's boomcrang needle and ligature carrier

Fig 6 Method for the insertion of the hemostatic sutures along the posterior segment of the rim of the prostatic cavity

is obtained with both these retractors, and as the posterior blade of each incorporates a suction aperture, the field is kept free of excessive blood.

A series of catgut sutures (plain catgut No. 2) varying in number from 4 to 7 are inserted through the posterior segment of the rim of the prostatic cavity. Each suture is made to pass through the prostatic capsule in addition to the muscular edge of the rim. The use of the boomerang needle and ligature carrier of Harris (Fig. 5) makes the introduction of these sutures a matter of simplicity. Forward and upward retraction on the anterior margin of the cavity by a long, narrow bladed retractor facilitates the excursions of the boomerang needle. Before the sutures are inserted any loose tags of mucous membrane or adenomatous tissue are cut away. Bleeding from all spurting vessels should be controlled after these sutures have been placed (Fig. 6). If any considerable ooze still occurs from the raw surface of the anterior portion of the prostatic bed a transverse suture is passed by means of a larger sized boomerang needle through the side walls of the urethra. It is inserted just proximal to the anterior margin of the cavity and tangent to it. When tied it causes an inversion of the rim of the cavity and thus further controls the bleeding (Fig. 7).

A two-eyed catheter, No. 22 F mounted on a stillette is then passed along the urethra into the bladder. Its tip is cut off transversely just beyond the distal eye. A long silkworm gut suture is introduced through the end of the catheter and the position of the latter is adjusted so that only the eyes project just within the bladder. The

Fig 7 An anterior transverse suture has been passed through side walls of urethra and tied. The catheter with tip cut off is in position and transfixed by the suture.

maintenance of this position until the catheter suture has been hitched to the abdominal wall is ensured by grasping the catheter with a light clamp just beyond the point of the penis. The retractors are removed and a Freyer's tube, size 18-20 millimeters, with a glass bend to which is connected a 16 inch length of rubber tubing, is inserted into the bladder. Along with the catheter thread the tube is delivered through the upper extremity of the bladder incision. The latter is closed by 3 or 4 interrupted chromic catgut sutures No. 2. The ends of the catheter suture are threaded on needles and passed through the skin on one side about half an inch lateral to the edge and about half an inch apart. They are tied over a piece of rubber. While making the knot, the catheter is pulled to the full extent that the forceps, which have been placed or it will allow. The tube is made to traverse the lower end of the abdominal incision which is closed above it by a continuous suture of No. 3 chromic catgut through the rectus sheath and interrupted sutures of silkworm gut through the skin.

Before the dressing is applied the bladder is irrigated through the urethral catheter and suprapubic tube with hot saline. The dressing is fixed to the abdominal wall by adhesive trapping with the glass bend left visible for inspection.

POSTOPERATIVE CARE

When the patient is returned to bed the catheter is connected by a wide glass connection to a length of rubber tubing which drains into a bottle containing anti-septic at the side of the bed. The rubber tubing connected to the glass bend of the suprapubic tube is drained into a separate receptacle (Fig. 8). One saline injection only is

given after operation, 10 ounces being allowed to run slowly into the rectum. At the first sign of restlessness on the part of the patient when coming out of the anesthetic, one third grain of omnopon with one hundredth grain of atropine is given. This may be repeated on 1, 2, or 3 occasions during the first 24 hours, after which it will probably not be required. Should any clotting take place, this will be apparent at once in the glass-bend and immediate irrigation with warm silver nitrate (1 to 10,000) is carried out. If this occurs at all, it rarely does so after the first 12 hours. A bladder wash-out, however, is given on the first and second days. On the second day the suprapubic tube is removed and a dressing is applied over the wound. If after a few hours any considerable suprapubic urinary soakage occurs, a suprapubic box is applied in lieu of the dressing. Otherwise changing the dressing twice a day will suffice. On the morning of the third day a ½ ounce of castor oil is given and 1 hour later 6 ounces of olive oil are gently run into the rectum.

The urethral catheter is removed on the sixth day by cutting across both ends of the suture which retains it, below the knot. On withdrawal of the catheter the suture comes away with it. During the period that the catheter has been in the urethra, the bladder is irrigated once daily with 2 pints of weak silver nitrate solution (1 to 10,000). It is convenient to have a suprapubic box placed over the wound during the wash-out if one has not been required for routine purposes. The patient is usually allowed up on or about the twelfth day when he is generally voiding urine. The majority are completely dry within 3 weeks.

Throughout the period of convalescence, diuresis is kept up to a maximum degree compatible with the patient's comfort. He is encouraged and, if necessary, cajoled to drink at least 5 pints of fluids daily. Starting with water, cold or warm, the fluids are varied after the first 2 days. Lemon water, lemon and barley, orange water, weak lemonade, and buttermilk are alternatives with which the patient is tempted to maintain his fluid intake. I have no hesitation in allowing 1 to 2 pints of weak lager beer daily. It is an excellent diuretic and to some is a welcome change from the above mentioned blander types of fluids. If for any reason, the fluid intake is not satisfactory and the urinary output is at a dangerously low level, intravenous infusion of normal saline or dextrose (5 per cent) in normal saline must be instituted. If this must be maintained, it is given by the "drip" method.

Satisfactory urinary antiseptic treatment in the early stages after operation is difficult, as the

Fig 8 Method of draining the bladder immediately after operation. The catheter suture is seen on the left side of the wound tied over a piece of rubber.

urine tends to remain persistently alkaline as long as a suprapubic fistula is present. The flushing effect of the diuresis and the bladder lavage are probably the best forms of antisepsis but the urine should be rendered acid as soon as possible with acid sodium phosphate or ammonium chloride. Hexamine is then also given.

TWO STAGE PROSTATECTOMY

If because of impaired renal function or other reason, a preliminary suprapubic cystostomy has been carried out, removal of the prostate should not be performed until the elapse of at least 4 weeks. By this time healing in the deeper layers of the suprapubic wound will have taken place and postoperative reaction subsided. In cases of marked renal impairment it may be necessary to wait several months until the maximum recovery of the kidneys has taken place. There are certain patients with permanent renal insufficiency indicated by repeatedly poor renal functional tests who, nevertheless, can be safely brought through a two stage prostatectomy. If diuresis can be forced up to about 100 ounces per day and stabilized, and if the clinical condition of the patient is otherwise satisfactory, I believe that the operation can be performed without undue increase of risk. A recent case of this type was submitted to a successful prostatectomy 10 weeks after a cystostomy with a blood urea which remained persistently around 65 milligrams per cent.

Fig. 9 left. The distended bladder has been punctured with a trocar and cannula. The trocar has been withdrawn and a Malecot tube stretched on an introducer has been passed through the cannula.

Fig. 10. With the tube still stretched on the introducer the cannula is withdrawn from the wound. The introducer is removed, thus allowing the tube to expand and the end to open out. The tube below cannula is steadied and later withdrawn. A water tight suprapubic drainage results.

The preliminary cystostomy opening should always be made as high as possible above the level of the symphysis. A distance of 2 inches should be aimed at. This facilitates the second stage and in addition will be advantageous to the patient in the event of either permanent or prolonged temporary drainage proving necessary, as it ensures the easier fitting of a suprapubic apparatus. My preference is to puncture the distended bladder with a trocar and cannula and to insert a Malecot tube size 28 Charrière through the cannula. This can be done through an incision 1 inch in length. The rectus sheath is incised and the fibers of the rectus muscles separated. The left index finger is passed down to the bladder and with it the perivesical fat and peritoneum are stroked upward. The trocar with cannula is sharply thrust into the bladder in front of the finger. The trocar is withdrawn and the Malecot tube stretched on an introducer is passed through the cannula. The tube is kept stretched and fixed in position while the cannula is withdrawn outside the incision. The hold on the tube is now relaxed the introducer is removed and grasping

the tube just outside the abdominal wall and steadying it the operator withdraws the cannula completely (Figs 9 and 10). One catgut stitch (or none) through the rectus sheath and 1 or 2 stitches through the skin completes the operation which can be done under local anesthesia. It is permissible to use this method through a small incision, only when the bladder can be satisfactorily distended and is palpable through the abdominal wall. When calculi have to be removed or when the bladder cannot be adequately distended, as is sometimes the case after it has been subjected to continuous urethral catheter drainage exposure through a larger incision will be necessary.

The incision for prostatectomy, when a cystostomy opening is present, passes for about 1 inch above and below the fistula which is encircled and excised. The bladder is separated by sharp dissection from off the under surface of the rectus muscle and is incised downward from the opening. The operation is then proceeded with after the manner described for the one stage operation. It may be found however that the abdominal wall is less pliable and that the bladder wall does not separate off easily. In these circumstances adequate retraction and good exposure of the prostatic cavity may be difficult. In the majority of two stage prostatectomies however there is less tendency to profuse bleeding after the enucleation of the gland and thus if visualization of the cavity is difficult insertion of the hemostatic sutures can be dispensed with. A larger tube size 22/24 millimeter, should be used however, to drain the bladder. If any anxiety is felt as to bleeding the prostatic cavity should be packed with gauze which is delivered through the wound alongside the tube.

The postoperative care is similar to that described for the one stage operation. If packing has been inserted the bladder is not irrigated until the second day when the packing and suprapubic tube are removed. Washing the bladder through the urethral catheter will soften the gauze and facilitate its removal.

CONCLUSION

The technique described is, I consider the safest method of performing suprapubic prostatectomy. It reduces to a minimum the risks of hemorrhage and infection and is least likely to be followed by any postoperative morbidity such as vesical neck contracture or secondary calculus formations.

IMMEDIATE FULL THICKNESS GRAFTS TO FINGER TIPS

JEWETT V REED, M D., F A C S , and A K HARCOURT, M D.,
Indianapolis, Indiana

A WORKINGMAN'S hands are one of his most valuable assets. Loss of any part or function of the hand reduces his potential earning power. Amputated fingers or painful finger-end scars manifest themselves in the pay envelope. Therefore, any step to improve results after injury of finger ends will be received gratefully by the workingman.

I wish to describe a minor operation to be used in certain types of injury to the finger end which averts necessity for amputation or its alternative, thin-skinned, painful scar. The type of injury for which this operation is applicable consists in loss of soft tissues of the finger end, usually without loss of bone, such injuries as are sustained in slicing machines, with saws, in punch presses, or by pinching. The tissue loss may involve only the distal tip, skin, and soft tissues, sometimes exposing the bone. It may include one side of the whole distal phalanx sometimes involving the nail. It may remove the whole palmar pad (Fig 1).

In each of these situations, bone shortening must be performed if the flaps are to be brought together over the bone. And if such lesions are permitted to granulate and heal in, the thick, dense, fibrous scar, covered by thin cicatricial skin, results in a permanently painful scar which, on a finger end, seriously impairs the function of the hand.

Such lesions can well be closed, I have found, with an immediate full thickness graft applied to the area of soft tissue loss. Full thickness grafts have been used with increasing frequency in recent years. Bunnell, Koch (5, 6), McWilliams, Padgett, and Updegraff, among many others, have cited their applicability in covering soft tissue defects. J S Davis, in 1926, did particularly interesting experimental work on the nutrition of transplanted skin tissue, concluding that in the first 24 hours a graft gets its nourishment from lymph flow from the bed, in the next few days by invasion of blood from the periphery, and that the graft does not develop adequate blood supply until 8 to 10 days. Blair emphasized the desirability of full-thickness grafts to avoid contracture. Koch (6), in 1931, and T S O'Malley, in 1934, described the use of grafts for amputated finger ends. They both, however, ap-

plied the grafts to already amputated fingers to prevent further shortening of bone. O'Malley in his paper gave interesting statistics from the Wisconsin Industrial Board on the economic loss due to amputations of fingers.

Immediate full thickness grafts to injured finger tips can be done in the office or in the home. The technique is simple. The results in our experience have been quite satisfactory (Figs 2, 3, 4, 5, and 7).

The whole hand is very thoroughly scrubbed including the base of the injured finger. A local anesthetic of 2 per cent novocain with adrenalin is injected on each side in the proximal segment of the finger. Then the donor site is selected. Usually this is the volar aspect of the proximal fourth of the same forearm. In females, the lateral aspect of the thigh near the ilium is chosen in an effort to place the scar where it will be at all times covered. In one man this site was selected because other desirable sites were covered with lesions of psoriasis. The donor site is shaved and scrubbed thoroughly clean. No antiseptic dyes are used because of the possibility that they might cause injury to the graft.

Fig 1 Types of injury requiring graft. A, Slice wound tip, not exposing bone. B, Loss of one side of distal segment and nail. C, Slice wound of pad without exposing bone. D, Loss of soft tissues side of digit without injuring nail. E, Avulsion of pad of finger exposing palmar aspect of distal phalanx. F, Loss of soft tissue exposing tip of phalanx.

ANALYSIS OF RESULTS IN 53 CASES

Case	Age	Date of injury	Date of admission to hospital	Date of discharge	Diagnosis	Mechanism of injury	Result
1	45	9-18-34	10-22-34	10-30-34	L.T.	Machine in teeth	No permanent impairment
2	54	1-34	12-31-34	1-5-35	R.M.	Machine between wrench and nut	No permanent impairment
3	45	2-2-34	2-11-35	2-12-35	L.M.	Caught in screw machine	No permanent impairment
4	21	1-11-35	2-25-35	2-8-35	R.R.	Caught in gear teeth	Impairment amounted to 25 per cent
5	51	18-35	1-2-35	2-3-35	L.M.	Caught in punch press	No permanent impairment
6	9	11-35	3-25-35	4-6-35	R.I.	Bit of part struck through skin near stomach	Impairment amounted to 30 per cent

†All patients were male with 2 exceptions

A horse shoe shaped line (open distally) is then injected with local anesthetic leaving within its perimeter an area of skin amply sized for the graft. By this time the injured finger end is numb. Loose tags of skin are trimmed and the finger very thoroughly scrubbed. No hemostasis is applied except pressure. The terminal arteries in the finger rarely require ligature. The knotted ligature beneath a graft is undesirable. The blood supply should not be impaired unnecessarily.

After the lesion is thoroughly cleansed, a pattern is made of the skin defect. This may be made by outlining the defect on sterile gold foil, mesh, or crinolin. A much simpler method may be used. A smooth gauze pad of about 2 or 3 thicknesses is pressed firmly on the lesion and immediately pressed on the donor site. The transfer of moisture and blood stain so accomplished outlines the size and shape of the graft very well.

The pattern is outlined with a sharp scalpel. Near the margin of the graft care must be taken to separate the skin from subcutaneous tissue accurately. This is not so important toward the center of the graft. In fact when the bone in the finger end is projecting or when the pad of the finger has been avulsed, it is desirable to include some subcutaneous fat attached to the center of the graft. The removal of the graft should be

done as rapidly as consistent with good surgery and handled as little as possible to preserve the vascular channels within the graft. Immediate full thickness grafts get their blood supply from the margins of their new site *only*, in the first 24 hours.

The graft is immediately transferred to the injured finger and sutured into place by means of very small cutting edge needles and "A" silk. The sutures should be interrupted, continuous sutures choke off blood supply. If the pattern has been made accurately, the graft will be under slight tension when the suturing is complete. The suture ends should be carefully directed away from the graft so that none of them adhere to it or press down in it. A dry gauze square is then placed over the graft and held in place with a moderately tight bandage. The donor site is closed in a straight line, either transverse or sagittal, by undermining the margins.

The patient is advised to keep the hand dependent a part of the time. The dressings are not changed for 5 days. The sutures are not removed from the perimeter of the graft for 2 weeks. Usually at the end of 5 days the graft is pink and dry. Dressings can usually be left off after about 4 weeks. On removal of the dressings, the graft appears similar to the surrounding skin except

ANALYSIS OF RESULTS IN 53 CASES

Case	Age	Date of injury	Date of return to work	Date of discharge	Disability	Manner of injury	Result
1	41	9-8-35	9-12-35	9-10-35	LT	Ma bed m tool p 1 rs	No permanent impairment

that fine hairs transferred in the graft may be seen (Figs 7, 8, 9 and 10).

In the practice of the Indianapolis Industrial Clinic this operation was performed 57 times between September 1934 and January 1, 1938 on 53 patients. In each instance, further amputation would have been necessary to avoid painful scar. Thirty three of these fingers healed without any permanent impairment. Of the 24 remaining 9 were adjudged permanently impaired because of material bony shortening occurring with the injury. In these instances the graft was performed to prevent further shortening. One was a pianist another played a stringed instrument.

In the 15 remaining, were complete failures of the graft. In 1 of these 3 another finger of the same hand required constant hot fomentations and the grafted finger was soaked with it. The graft sloughed completely and subsequent amputation was necessary. In the 2 others the graft sloughed because of lack of nutrition. The resulting scar was somewhat better than could have been anticipated without graft. The 22 others were considered 10 to 35 per cent impaired due to dystrophy of the nail or deformity of the finger end without shortening.

An interesting analysis of these 57 digits from an economic viewpoint is given in the accompanying

Fig 1 Digit ready for graft. Loose and contaminated soft tissue trimmed off.

ing table. Under the Indiana Compensation Law specific permanent impairment allowances are made for the loss of each digit: 60 weeks compensation for the thumb, 40 weeks for the index finger, 35 weeks for the middle finger, 30 weeks for the ring finger and 20 weeks for the little finger. Bone shortening distal to the proximal interphalangeal articulation calls for one half of the respective amount. The law specifies that a material bone loss from the distal end of the bone constitutes bone shortening.

In each of these cases then, if not grafted there would have been bone shortening with a loss to the insurance company of one half the digit. The total loss so incurred would have amounted to 104.5 weeks of compensation. The actual period of disabilities of these cases totaled 191 weeks. Additional compensation payments for permanent impairments in the whole series totaled 184 weeks. 375 weeks of compensation were paid. This operation then can be credited with saving 670 weeks of compensation besides the conservation of tissues and improvement of function for the patient.

CONCLUSIONS

An immediate full thickness graft applied to a finger end suffering soft tissue loss conserves length and averts painful scar.

Figure 1a is an enlarged view of the field of operation, it shows the marked normal shrinkage of the dermigrraft when the dermis is cut completely through to the fat, and also the retraction of the skin edges. Note that sutures have been placed at cardinal points through the dermigrraft, these sutures may be used instead of a hook for lifting the graft when dissecting it free from the underlying fat. They also may be rethreaded and used subsequently to suture the graft into its new bed.

Figure 2 shows the defect in the donor site recovered with its own skin, the reflected strips of epidermis having been returned to their original positions. If the grafts are large, V-shaped incisions are made in them here and there in order to allow the immediate escape of air bubbles and the subsequent discharge of serum. This is essential, as absolute contact of the graft to its bed is necessary for success.

When a subepidermal graft is prepared in the manner described—care having been taken to make the epidermal reflections as thin as possible—only a small amount of punctate bleeding will follow from the cut tips of the dermal papillæ, between these papillæ in the depths of the corium islands of the basal cell layer (rete pegs) are left behind, and it is from the remains of these rete pegs that the skin in the transplanted dermigrraft is regenerated, just as is the case in any sta-

tionary site from which Thiersch grafts are removed.

Following my experiments with this method, first upon the human cadaver, and later upon rabbits, Dr V H Kazanjian of Boston utilized it clinically. His patient was a man of 40 who required an extensive plastic operation on the side of his face. In one of the stages of operative reconstruction, an area on the side of his neck, measuring $\frac{1}{2}$ inch by $1\frac{1}{2}$ inches in diameter, was covered with a dermigrraft. The survival of the graft and the re-epithelialization of the donor area on the thigh were regarded as an experimental success, although the defect in this case was too small to prove the practical value of the method.

Details of the operative technique, dressings, etc., have been omitted from this preliminary discussion, since they may be subject to such wide variation in different hands. The main principles, however, are similar to those which have been laid down for the transplantation of skin in general. Although the method as described is, as yet, little more than a suggestion, it is hoped that it may prove to be an interesting addition to the armamentarium of the plastic surgeon.

Dr E B Potter, department of surgery, University of Michigan Medical School, rendered valuable assistance with the operative technique in the animal experiments.

THE DERMIGRAFT

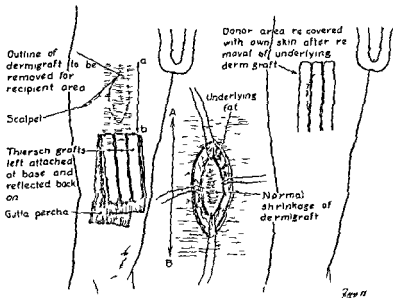

STANLEY ROCHELLE DEAN M.D. Newtown Connecticut

THE method of skin grafting that I am about to describe was developed experimentally for the purpose of correcting certain disadvantages inherent in the Wolfe Krause whole thickness graft. A thick graft is generally superior to a thin graft of the Ollier Thiersch type for the following reasons. It contains all the dermal elements and remains soft and natural in texture, it has a higher resistance to infection, a "take" is fairly certain with proper technique and a clean field, it gives better protection to weight bearing surfaces. A large surface may be covered with minimal contracture, a successful "take" will, in most cases closely simulate the natural cutaneous surface and, in a previously depressed area, some months later a thin layer of fatty tissue is deposited almost always beneath the graft so that it rises to the level of the surrounding skin. Thick skin grafts may be used in almost any situation but are especially useful for covering joints and other parts of extremities where there is constant exposure to trauma for example defects in the popliteal space, the elbow, the forearm, the leg

and both aspects of the hand. They are also useful in re-epithelializing raw surfaces after deforming scar contracture in the palms of the hands back of the neck, and on the face, after excision of nevus and for old chronic ulcers.

A serious disadvantage, however, lies in the fact that a Wolfe graft, if large leaves a fresh defect at the donor site which in turn may require further grafting. The dual rôle of the dermigraft is designed to overcome this shortcoming. On the one hand it provides a means of removing large thick skin grafts from a given area on the other, it enables one to re-epithelialize the resulting defect in this area with its own skin, and in one operation.

In Figure 1, strips of epidermis have been cut and reflected back upon a piece of gutta percha like Thiersch grafts, the bases of the strips however, remaining attached in order to retain the blood supply intact. In the rectangular, sub-epidermal area which has thus been exposed a graft is measured to fit the recipient defect. This graft is outlined with a scalpel, the incision going through the remainder of the corium.

CASE REPORT

B U I 25,174, T E H, aged 51 years, was seen October 6, 1936. He complained of recurrent colic-like attacks of pain in the right flank for 20 months. The pain was incapacitating and accompanied by frequency and urgency of urination and pyuria. A leg and the 5 lower ribs on the right side had been fractured in an automobile accident in 1924.

The abdomen was thin and relaxed and there was tenderness in the right flank and costovertebral angle. The genitalia were normal. The prostate was slightly enlarged. The hemoglobin was 95 per cent, white blood cells 10,200, blood pressure 108/70, and blood urea 40.

Cystoscopy showed a normal bladder and vesical orifice. From the right ureteral orifice exuded a thick, viscid, mucopurulent stream, the left ureteral orifice was normal and emitted clear urine. Catheterized specimens from both ureters were sterile on culture. The results of the phthalein test were as follows: right ureter, only a trace of phthalein, left side, appearance time 4 minutes, 25 per cent output in 15 minutes.

A plain urogram (Fig 2) showed what was thought to be a calcified hematoma inside the right kidney, which was practically functionless as a result of traumatic rupture.

Operation, October 12, 1936, was begun with the patient under spinal anesthesia, but nitrous-oxid, oxygen and ether were later necessary on account of pain. An incision to expose the kidney was made from just beneath the middle of the twelfth rib down to well below the tip toward the umbilicus. The external and internal oblique muscles were divided, thus exposing the lumbodorsal fascia, which was next opened, with retraction and preservation of the iliohypogastric nerve. Gerota's fascia did not have the normal appearance, but was replaced by a thick, fibrous scar, firmly adherent to the ribs and diaphragm (Fig 1). It was apparent that the kidney

had been previously ruptured, and the true capsule together with Gerota's fascia, perirenal fat, and peritoneum had been converted into a thick, dense, fibrous tissue. Approximately an hour was spent in attempting to find a plane of cleavage so as to identify the surface of the kidney. The ideal procedure would have been an intracapsular nephrectomy, but the renal fossa was so filled by cicatrix that the surface of the kidney could not be identified.

As nephrectomy was imperative, we then attempted to remove the fibrous mass in which the right kidney was situated. It was necessary to cut the scar away from the inner surface of the previously fractured lower ribs and the diaphragm, in so doing an opening into the diaphragm of about 3 finger-breadths was made (Fig 1). The usual sucking noise was heard. This opening was tightly packed with gauze because it was not feasible to attempt suture until the kidney was removed. The fibrotic kidney was finally located and the pedicle sufficiently isolated so that clamps could be placed. After the kidney was removed the stump of the pedicle was ligated with two No. 3 chromic catgut sutures.

As there were cavities containing purulent material surrounding the kidney, every effort was made to close the opening in the diaphragm. Eight sutures were placed through either side to bring the torn margins together, but without success. While this was being attempted, positive pressure was alternately carried out by the anesthetist with the inhalation machine so as to reduce the pneumothorax to a minimum and also to push the edges of the diaphragm down so they could be caught with the needle.

Fig 2. Roentgenogram showing large, irregular shadow in region of right kidney (B U I 25174).

Fig 3. Showing manner in which mattress sutures were placed to close large opening through diaphragm (B U I 25174).

DIAPHRAGMATIC INJURY COMPLICATING NEPHRECTOMY

A Method of Closure

SAMUEL A. VEST, M.D., Baltimore, Maryland

INJURY of the pleura during renal operations is not uncommon and traumatism to the diaphragm is not rare. Mayo reported that the pleural cavity was opened 13 times in 203 renal operations. Frequently insuperable obstacles to satisfactory closure have been reported by various operators. As a result gauze packing placed in the pleural and diaphragmatic tears has been used frequently.

We have recently had a case in which a previously ruptured kidney was surrounded by such dense adhesions that, while carrying out nephrectomy, an extensive tear was made through the diaphragm into the pleural cavity. Approximation of the torn edges was impossible. With full knowledge of the poor results that often followed the use of a gauze pack in such cases, we determined to make every effort to close the defect.

From the James Buchanan Brady Urological Institute, Johns Hopkins Hospital.

Being unable to approximate the edges, we finally discovered that by placing mattress sutures between the ribs and out through the skin so as to draw the inner edge of the ruptured diaphragm snugly against the chest wall, effective closure of the large diaphragmatic opening could be obtained without difficulty. The condition present (which will be described in the case report) is shown graphically in Figure 1. The large tear in the diaphragm is shown in Figure 2. The technique which effected complete closure and obliteration of the space in a simple way, is shown in Figure 3. The diaphragm was drawn by mattress sutures which emerged from the skin and held the diaphragm snugly against the chest wall. After a careful survey of the literature, it seems that this technique has not been employed previously. It has proved so satisfactory in handling an extensive diaphragmatic injury that a detailed report of the operation seems warranted.

Fig. 1. Schematic drawing showing small sclerotic kidney very adherent to diaphragm. 2. Showing condition after removal of kidney and ligation of pedicle. A large tear through diaphragm into pleural cavity (B. L. I. 25174).

phragm was caught by sutures and tied outside. The patient died immediately after operation. No case similar to ours has been found in the literature

CONCLUSIONS

Accidental injuries to the diaphragm and pleura are not infrequent occurrences during exposure of the kidney. Most of these are readily sutured and rarely cause serious complication, although reports of mortality from this simple accident have been made by Fronstein and others. More extensive injuries to the diaphragm incident to delivering the upper pole of the kidney in cases with marked perinephric adhesions and scar formation are rarely encountered, but when they do occur, the closure may present a difficult surgical problem. They have usually been packed with gauze, but such treatment is often followed by serious complications and should be avoided.

A case is herewith reported of extensive injury to the diaphragm during nephrectomy resulting from dense perinephric adhesions and scar. A technique is reported for the use of traction sutures

introduced transpleurally through the skin to draw the diaphragm against the chest wall and close the rent in the pleura. The operation is so simple that its value is emphasized in the operative handling of these diaphragmatic injuries.

It then occurred to us that the large tear could be obliterated by drawing the diaphragm against the chest wall. The technique employed was as follows: Five mattress sutures of heavy chromic catgut were placed in the medial margin of the diaphragmatic opening. With a large curved cutting needle these sutures were carried across the diaphragmatic defect transversely and through the intercostal muscles of the tenth and eleventh rib (Fig. 3) and brought out through the skin. When they were pulled taut we could feel the medial margin of the diaphragmatic defect shift laterally until it was brought tightly against the chest wall no further sucking noise was heard and the opening appeared to be tightly closed. The method employed was simple and effective.

After the sutures were tied over gauze (Fig. 3) it was realized that the lung had not been expanded enough to force air out of the pleural cavity. The pneumothorax was therefore reduced to a minimum by a piration through an intercostal space by using a large needle and a pirating syringe. The incision was then closed in the usual way.

The patient was given a transfusion in the evening after operation and placed in an oxygen tent for 48 hours because of moderate dyspnea. After the second day convalescence was uneventful. A proteus infection was found in the bladder urine after operation but disappeared after a course of mandelic acid. A roentgenogram of the chest at the end of 15 days showed evidence of a little fluid at the base but no aspiration was necessary. The patient was discharged well with the exception of a small sinus in the upper angle of the wound at the site of the drain which soon healed.

Eighteen months after operation the patient was in excellent health and had gained 60 pounds.

The most common cause for opening into the pleura during exposure of the kidney is an abnormally low posterior insertion of the diaphragm below the twelfth rib. The next in frequency is a short twelfth rib, so that the incision for exposure of the kidney is made under the border of the eleventh rib and directly into the pleural cavity. The pleura is also opened at times during rib resections made to increase the exposure but the diaphragm is usually not injured in such instances. Unless a suppurative renal condition is present, injuries to both pleura and diaphragm incident to exposure are generally sutured with out difficulty and if properly handled without mortality. Cabot has seen 2 patients in whom the pleura was injured at operation but the pneumothorax was not recognized until late in convalescence.

Injury to the pleura and diaphragm during actual mobilization and removal of the kidney is often more extensive than those made during incision and exposure. They are more inaccessible and may present a difficult surgical problem in closure.

Quinby states

In cases demanding nephrectomy there is infrequently any found condition external to the kidney itself which make an accidental opening of the pleural cavity very difficult to avoid. In such injury to the diaphragm

may occur in certain instances even under the most expert hand with the most skillful dissection even during an operation of the subcapsular type. This accident is most apt to arise when the perirenal tissue has been greatly infiltrated with inflammatory products thus fixing the kidney closely to its surroundings. An accidental rent in the diaphragm most often occurs while an endeavor is being made to deliver the upper pole.

Gaza has written on the dangers of nephrectomy in cicatricial paranephritis and advocates piecemeal removal of the kidney in such cases so as to avoid injury to the diaphragm.

Various methods have been employed by surgeons to close injuries in the pleura and diaphragm. Rathbun routinely employs fat transplants in placing his sutures. Hesse who collected 19 cases in which the diaphragm was deliberately resected because of invasion from renal tumors describes the method of Anshutz who sutured the diaphragm directly to the liver a method also employed by Oppel. Borchardt used lung to repair the opening in the diaphragm. Hesse reported a case in which a large defect exposed the pericardium. He used liver and lung to close the opening in the diaphragm. In his 10 collected cases of extensive defects in the diaphragm following nephrectomy for renal tumor Hesse states that button sutures were used in 6 to bring the margins together while in 3 cases portions of the abdominal wall were utilized. The thoracic wall was used in 1 case and the lung in 1. The liver was used in 4 cases. In 5 no data were given as to the method employed.

In our case it was impossible to approximate the diaphragmatic margins, but by means of traction sutures, which ran transpleurally and through the intercostal spaces and skin it was possible to pull the medial margin of the pleural and diaphragmatic defect out against the wall of the chest and to effect a tight closure. Maylard used transpleural sutures to fix the kidney in nephropexy. Since his first usage Moore, Foley and others have employed transpleural sutures in such cases without complications. It is therefore evident that there is no great danger in bringing sutures out transpleurally between the ribs and through the skin. Heuer in transplantation of the diaphragm in dogs has sutured the diaphragm to the intercostal muscles but such a method would not be effective in cases such as the one we have reported. In preparing to report our case we found in the literature that a method somewhat similar to that employed by us was used by Bryan in 1927 to anchor the diaphragm to the chest wall in a case in which there was complete evulsion of one sheath of the diaphragm. Through the intercostal approach the torn margin of the dia-

phragm was caught by sutures and tied outside. The patient died immediately after operation. No case similar to ours has been found in the literature.

centimeter was removed with the motor saw. It was rounded at its distal end by a rasp, and its proximal end was coned. The coned end was placed into the previously prepared funnel of the metacarpal stump, and the distal end was articulated with the proximal phalanx. The outer envelope was sutured over the graft and the areolar tissue carefully approximated around the extensor tendons. The skin was approximated with black, waxed silk. A plaster cast was applied with the middle finger slightly hyperextended.

The report from the pathology laboratory follows: The specimen, S 905-36, consists of a metacarpal bone transformed into a tumor mass 5 by 3 by 2 centimeters. It is firm and encapsulated, the distal end is smooth and the proximal end is roughened (Fig 2). On sectioning, the mass presents a uniform, grayish-white tissue. Microscopic examination revealed a tumor consisting of a dense fibrillar connective tissue (Fig 3) which in places shows metaplasia into osteoid tissue and bone (Fig 4). There are groups of multinucleated giant cells of osteoclast type (Fig 5) which are sometimes related to spicules of bone. The histological picture is distinctly different from a giant cell tumor in which the dense connective tissue is not encountered. A

diagnosis of dense fibroma with focal areas of osteoid metaplasia was made.

The wound healed by primary intention, and the patient was discharged from the hospital on March 7, 1936. The cast was removed on the twenty-eighth day and physical therapy, consisting of whirlpool, massage, and active and gentle passive exercises, was instituted.

The patient made an uneventful recovery with almost complete return of both form and function. The length of the finger was restored (Figs 6, 7, 8). Roentgenograms taken May 14, 1936 (Fig 6), 92 days after operation, show the early restoration, those (Fig 9) taken May 16, 1938, approximately 27 months after operation, show the transformation of the graft into a true metacarpal bone with notched head, neck, cortex, and marrow cavity formation, and the photographs (Fig 10) show the appearance and range of motion at this time.

Fibromas of bone are extremely rare and when so diagnosed frequently prove to be fibrosarcomas. Geschickter and Lewis state that "most of the

FIBROMA OF THE MIDDLE METACARPAL BONE

Resection and Reconstruction

DANIEL H. LEVINTHAL, M.D., F.A.C.S., and JACK D. KIRSHBAUM, M.D., M.S.
Chicago, Illinois

THIS rather unusual lesion of the metacarpal bone is presented because of its peculiar histopathological picture, radiological diagnostic difficulties and the unique reconstruction with an almost perfect end result.

The patient, a white female, 16 years of age, born in Italy, was admitted to the orthopedic service February 11, 1936, from the outpatient clinic. The past history, general physical examination, and serological examination were all negative. The complaint was a progressive swelling of the dorsum and palm of the right hand which was first noticed about a year prior to her admission to the Cook County Hospital. The local examination showed shortening of the middle finger of the right hand and a fusiform swelling about the size of a large walnut in the region of the middle metacarpal bone extending into the palm and on the dorsum. There was only a moderate limitation of motion of the middle finger due to the palmar swelling, but there was no associated pain except on pressure.

The roentgenogram showed a lytic expanding tumor of the middle metacarpal bone with absence of cortex along parts of the shaft (Fig. 1). The base of the metacarpal for about 1 centimeter appeared uninvolved. There was a tiny

crest of bone just beneath the distal articular surface. The rest of the shaft was completely destroyed. This middle metacarpal was shorter than the two adjacent ones. The pre-operative diagnosis was benign giant cell tumor.

Operation. On February 12, 1936, the right hand and left leg having been prepared previously in routine manner, the following operation was performed. Under general anesthesia and with a blood pressure cuff as a tourniquet, a longitudinal incision was made on the dorsum of the hand over the mass. The extensor tendons were gently retracted and the outer capsule of the tumor mass was incised. By careful dissection, the entire mass, including the head of the metacarpal, was freed from its bed and separated from the apparently normal proximal 1 centimeter which was allowed to remain *in situ*. This proximal stump was funneled. From the left tibia, a graft 7 by 1 by 1

From the Departments of Orthopedic Surgery and Pathology, Cook County Hospital.

Fig. 1. Roentgenogram before operation showing expanding lytic tumor of the middle metacarpal bone. Complete destruction of the shaft including cortex, some trabeculation. There is a thin remnant of bone of fairly normal density in the subchondral region of the head of the metacarpal and about 1 centimeter of normal appearing bone at the proximal end. Note the shortening of the metacarpal.

fibromas involving bone reported in the literature are either healing giant cell tumors, bone cysts or osteomas forming in a cellular matrix of connective tissue. Most of the fibromas encountered are found in connection with the bones of the face, especially the maxilla and mandible, the base of the skull and in a few instances the femur. The tumors probably have their origin from the periosteum. The desmoid type of

fibroma found in long bones may follow trauma. (2) Our case may be considered a sclerosing type of giant cell tumor. But against the diagnosis of a giant cell tumor is the lack of cellularity of the stroma and the absence of hemorrhage and young blood vessels. On the other hand Geschickter (3) believes that giant cell tumors of the small bones may show an unusual amount of reactive fibrosis and osteoid material. However, our experience in a careful study of all benign giant cell tumors encountered in our laboratory has been different in that we have never observed such a diffuse and dense fibrosis as in the case here reported. It was the opinion of the late Dr. R. H. Jaffe that the lesion was that of a benign fibroma and not a sclerosing giant cell tumor.

Fig. 8 Photographs showing extension and flexion. Note restored length of the finger.

Fig. 10 Photographs 27 months after operation showing restored length of right middle finger, full extension and very moderate limitation of flexion.

The roentgenogram of the tumor suggests a consideration of the differential diagnosis between enchondroma, myxochondrosarcoma, sarcomatous degeneration of a giant-cell tumor, in addition to benign giant-cell tumor and fibroma.

Heretofore lesions of this type were treated by a total extirpation of the metacarpal and the appended finger with a resultant three fingered hand.

SUMMARY AND CONCLUSION

A very unusual fibroma of the metacarpal bone, with resection and reconstruction is here described.

The case is also of interest because of the

diagnostic difficulties of the lesion, and the complete functional results obtained following surgery. The viability of an autogenous bone graft is proved. Its transformation into a metacarpal bone, in contour and internal construction, is apparent.

The similarity of benign fibromas and sclerosing giant-cell tumors is discussed.

A NEW AND SAFER METHOD OF CITRATED BLOOD TRANSFUSION

Professor A HUSTIN and A DUMONT MD Brussels Belgium

AMERICA has always remained faithful, even more so than Europe, to the citrate method of blood transfusion, ever since one of the above authors (2) advocated this method for the first time 25 years ago.

This method of blood transfusion has been attacked as having 2 major disadvantages (1) the blood used loses an important part of its properties (2) the method is likely to produce more frequent and grave reactions than that involving pure blood. The work of numerous research scientists has eliminated the first objection. It has been demonstrated that citrate alters neither the structure nor the functions of the globules and does in no way diminish the immunizing properties of the plasma.

Many statistics have been produced to prove that accidents due to blood transfusions occur more often (15 to 20 per cent) in the transfusion of citrated blood than that of undiluted blood (10 to 12 per cent). However, our experience gathered from the Centre de Transfusion des Hôpitaux de Bruxelles, has convinced us that the majority of these accidents were caused by defective technique rather than the method itself. In perfecting this technique we have been able to reduce the accidents from 12 to 3 per cent.

The following will set forth several details on the facts observed and will present a description of the technique employed.

During the year 1937, 85 liters of blood were transfused into 253 patients. Three different methods were successively utilized (1) the transfusion of pure blood, (2) citrated blood transfusion, and (3) the transfusion of citrated blood as in the second method but with a definitely improved technique.

The transfusion of undiluted blood was performed by means of an apparatus based on the "milking" principle (the French apparatus of Henry and Jouvelet is analogous to that of the American de Bakey).¹

Eighty-four cases were treated with this method and necessitated 26 liters of blood or 307 cubic centimeters per patient. Notwithstanding the apparent simplicity of the devices based on

(Since this paper was written one of us (Hustin) achieved a transfusion pump much simpler than that of de Bakey also based on the milking principle. This pump is reported in Figs. 2 and 3.)

the "milking" principle serious difficulties often presented themselves. In 7 cases, the transfusion was interrupted (8.4 per cent), in more than 20 cases, the vein of the donor, or of the receiver or of both had to be punctured several times. In 3 cases, air bubbles were introduced into the blood circulation by not staunching the tube connection of the needle of the donor. The reactions which occurred as a result of these transfusions numbered 6 or 9.5 per cent, 2 of which were serious.

The second method using citrated blood, was employed in 76 cases. This blood was collected by means of a newly tried contrivance. About 30 liters of blood were withdrawn and re-injected, or, on the average of 385 cubic centimeters per operation. The withdrawal of blood was interrupted 3 times, occasionally though not repeatedly, the vein had to be punctured more than once. Much of the blood used had been preserved in a refrigerator for several days before having been re-employed. The most careful inspections were made for the least trace of blood clots. Actually a few clots were found in 10 of the test tubes or in one quarter of the cases. Reactions occurred in 7 cases, one of which was serious, or in about 9.2 per cent.

We now come to our third and last classification. In these blood transfusions, the same method as in the preceding was utilized. However it was definitely improved and perfected. Thirty-three liters of blood were drawn from 18 donors on an average of 420 cubic centimeters from each and 31 of these liters were re-injected into 93 patients, averaging 330 cubic centimeters for each receiver. Of the original 33 liters of blood collected 6 were used as therapeutic measures on hypertensive patients.

Twice the withdrawal of blood failed. Only once were blood clots observed in the preserved blood and that blood came from a polycythemic individual whose blood was particularly coagulable. The accidents which arose in using this method amounted to 4 twice to the same patient because of agranulocytosis which occurred at the sixth and eighth transfusions. Once to a patient suffering from hemothorax and once in a serious case of hemarthrosis of the knee. Thus reactions occurred in 5.4 per cent of the cases in which this

method was used and were of the mildest variety. If, to the transfusions during 1937, in which this method was utilized, are added those made in January 1938, the percentage of reactions does not exceed 3 per cent.

The comparison between the cases of the second and third classifications, seems to show that the more the chances of coagulation during the collection of the blood are reduced, the more the gravity of transfusional accidents will be diminished. This leads us to the conclusion that many of these reactions are due to the formation of blood clots in the blood withdrawn.

Clots do not cause transfusional reactions by acting as emboli, as in our experience they were always eliminated by a careful filtration of the blood containing them. However, they are dangerous because of toxic substances released from their mass. From certain experiments made on animals, it was shown that the addition of fibrin extracts to the reinjected blood often results in grave symptoms. This opinion is corroborated by the observations of Petroff and of Kasumov. They bring out the fact that the injection of preserved and filtrated blood, having once contained blood clots, causes vomiting, fever, leucocytosis, etc.

It is also probable that a number of the reactions observed after the use of pure blood are due to the presence of blood clots formed in the needle after injection into the vein of the donor. This opinion has been acquired in the course of numerous collections of blood made with the aid of our own apparatus.

The latter has been constructed so that it is possible to note continually the least change in the flow of blood from the needle. Very often, even under the most favorable conditions, this flow diminishes considerably when about 200 cubic centimeters of blood have been withdrawn.

It has been found that this slackening does not occur if the needle is frequently washed with a citrate solution, thus, the only explanation seems to be that blood clots form on the sides of the needle.

Having been convinced of the toxic rôle played by the clots, or, rather by the factors causing their formation, the next step was to try to reduce the frequency of coagulation. This was brought about with some success by the citration of the blood from the very moment it left the needle, and also, of course, a careful washing of the needle at frequent intervals.

However, another important factor undoubtedly had much to do with the improvement in our results. This was the care taken to avoid injuring

the globules in the process of introducing the citrate into the collected blood. With the technique in general use, the blood and the anticoagulant mixture are mixed together rather forcefully by means of a glass stirring rod. In the course of this action, the globules of the blood, especially the platelets, are greatly damaged and react to such violence by secreting toxic substances.

Freund has shown that a suspension of platelets in a citrated solution can be injected into cats without producing a reaction. But if the same suspension is previously shaken by means of several beads, violent vasomotor reactions are caused. Undoubtedly it is the same substance derived from the platelets which make the blood toxic, as it is well known that the globules play but a primary rôle in the coagulation of the blood.

In every transfusion, there is the danger of accidents proceeding from 2 different sources. The first of these may be the incompatibility of the blood drawn. In such cases reactions occur immediately during the re-injection into the receiver and cause cyanosis, palpitation of the heart, heat flushes, pain in the lumbar region, etc. The other types of accident are those caused by the liberation of toxic substances by the platelets and the blood clots. The reactions from this type come some time after the transfusion and occur in the form of chill, fever, urticaria, edema, and erythema.

PROCEDURE

The following is the authors' procedure, which they have followed for almost 6 months, and which has given excellent results.

The apparatus, illustrated in the diagram, consists of the following. A 500 cubic centimeter graduated glass container, provided with a rubber stopper, pierced in 3 places for the insertion of 3 glass tubes labeled *a*, *b*, and *m*. The tubule which is connected to the wider tube *a*, or the canalization of entry, is inserted in the bottle so that it barely extends further than the neck. Externally, it is bent at a right angle, close to the stopper. The tubule of tube *b*, has the same diameter as that of *a*, but in contrast to that of *a* reaches almost to the bottom of the bottle. This will be designated by the term canalization of outlet. Thus, the internal orifice of the tubule of *a*, is inserted in such a manner that the blood passes directly from the tubule to the bottom of the container without the slightest dribbling against the vertical stem of the tubule of *b*, or against the walls of the bottle itself.

The third canalization *m*, is of smaller diameter than the 2 others. The purpose of this canalization is to allow air out of the glass container when

Fig. 1. Diagram of the apparatus illustrating the principle of the method of citration of the blood in the needle.

blood comes in the bottle. It is extended externally by fine rubber tubing. To the rubber tubing is joined a glass tube which is plunged into a test tube half full of sterile water *d*. A piece of adhesive tape keeps it braced to the bottle. The size of the end of this tube is such that when 1 cubic centimeter of blood enters the glass container a bubble is drawn out by the tube. Thus the intake of the container can be controlled instantaneously by the outflow of air bubbles into the test tube.

Tubes *a* and *b* are both extended outside of the bottle by small rubber joining devices or unions whose other extremities are connected to very narrow glass tubes. On these rubber devices are placed Mohr clips labeled 1 and 2.

In addition the apparatus has two rubber tubes 50 centimeters in length and with resistant walls joined one to the inflowing tube *b* and the other to the outflowing tube *E*, the transfusion apparatus of Henry and Jouvet or that of de Bakey and a needle having 2 projections ending in open ings. The needle has bevelled edges and the diameter of the interior is eight tenths millimeters. The needle has 2 openings, the one in direct continuation has the same interior diameter as

the rubber tube the other placed laterally has a smaller caliber (Record). The point of the needle may be closed by a hermetic cover.

Sterilization. Fifty cubic centimeters of 5 per cent sodium citrate is poured into the glass container which is carefully closed with the stopper. The incoming and outgoing tubules are attached by joining devices described to the rubber tubes. Their ends are protected by wads of gauze. The whole apparatus is covered with a cloth and is sterilized in the autoclave.

Preparation. The glass container and its accessories are taken out of the protecting cloth. The aspirating tube, *E*, is placed in the Henry and Jouvet apparatus and the two ends of the rubber tubes are attached to the projections from the needle. Because of the difference in sizes of the two projections, one can be sure that the ingoing tube will be joined to the main projection and the outgoing tube to the smaller one. Several cubic centimeters of sterile water are poured into the test tube *d*, attached to the glass container. The needle has been carefully recovered with its hood so that by operating the Henry and Jouvet apparatus all the tubes are filled with the citrate solution. The liquid can be seen rising into the outgoing tube but soon falls back again from the incoming tube. During this action, no air bubbles rise to the level of the lateral tube *m*.

The equipment for the donor is completed by the use of the Pachon pneumatic wristband as a tourniquet. This is kept inflated under minimum pressure during the entire operation. Thus, conditions are created which produce the largest possible outflow of blood from the donor.

Collection of the blood. The needle is taken from its protective hood. The handle is given a half turn in a direction opposite to its normal direction. The citrated liquid flows out of the needle and, in so doing, leaves it filled with the anti-coagulant liquid.

Next the rubber tube *D* running from the lateral projection of the needle is disconnected and the vein is punctured. Blood rises to the lateral projection. The connection between the rubber tube and the lateral projection is reestablished. The handle is turned and bloody liquid can be seen falling to the bottom of the glass container from the inflowing tube *a* and then rising again into the outflowing tubule of *b*. At the same time large bubbles of air leave the test tube. Thus we can be sure of the progressive filling of the glass container. The latter is shaken gently from time to time, to insure the thorough mixing together of the blood and the citrated fluid. At regular intervals, the outflowing tube *D* is cut off

Fig 2 Collecting the blood

Fig 3 Reinjection of the blood to recipient

The handle of the pump is turned two or three times in the direction opposite to normal. A small amount of citrated blood is thus driven back into the vein of the donor while at the same time, the passage in the needle is washed. As this goes on, the receiving tubule *a*, empties itself of the bloody mixture it contains. After the needle is washed, the connection with tube *D* is resumed and the process of suction continues.

What happens during these processes?

It can easily be seen that the Henry and Jouvet apparatus produces a suction of venous blood at the level of the needle, and a suction of citrated solution through the lateral projection. The mixture of these two liquids very near the point of the needle, imparts a quality of stability to the blood which has just been drawn from the vein. Thus, at the very beginning of the process the venous blood is diluted with the pure citrate solution. Afterward, however, strongly citrated blood from the glass container is substituted.

The proportions of blood and citrate solution used depend upon several factors, particularly the size of the needle and its lateral projection, and the blood pressure of the vein. In practice, the size of the needle and of its lateral projection has been calculated in such a manner that for a venous pressure of from 8 to 10 cubic centimeters of mercury, blood and the anticoagulant liquid must be used in the proportions 2 to 1. This proportion can be varied during the process of collection, by varying the degree of constriction of the outflowing tube. If the tube is completely closed off, only pure blood is secured, but if it is contracted less, the quantity of pure blood collected, diminishes. The proportion of the two constituents can be noted from the number of air bubbles leaving the bottle by the reagent tube. Thus, when pure

blood is collected, a bubble of air can be seen forming at each turn of the pump's handle. However, should the mixture contain two parts blood to one part of the citrated liquid, the handle must be turned three times in order to produce two air bubbles. In this way the operator is constantly kept informed as to the functioning of the apparatus and also as to the permeability of the needle. Any obstruction in the latter, even partial, immediately brings about a diminution in the number of air bubbles in proportion to the turns of the handle.

The technique described permits the easy collection of a huge quantity of blood by only one puncture of the vein. The collection can also be accelerated, if desired, by completely shutting off the outgoing tube. In this case, pure blood alone, is temporarily collected.

The procedure is as follows: during thirty turns of the handle, the outflowing tube is closed by the fingers. It is then opened again for ten turns of the handle. After that, the needle is washed by making three turns in the opposite direction, taking care that the outgoing tube is again closed off. Thanks to this little device, a half liter of blood can be collected from most of the donors within 10 minutes.

Finishing the collection. When the desired quantity of blood has been obtained, the needle is withdrawn from the vein and is covered with its stophood. Then, several more turns of the handle, in the natural direction are made in order to fill the tubes with citrated blood and to mix the fluid in the glass container.

The removal of about 40 cubic centimeters of blood which remains in the tubes is accomplished by simply turning the Henry and Jouvet apparatus backward until several bubbles of air form

Fig. 1. Diagram of the apparatus illustrating the principle of the method of citration of the blood in the needle.

blood comes in the bottle. It is extended externally by fine rubber tubing. To the rubber tubing is joined a glass tube which is plunged into a test tube half full of sterile water, *d*. A piece of adhesive tape keeps it braced to the bottle. The size of the end of this tube is such that when 1 cubic centimeter of blood enters the glass container a bubble is drawn out by the tube. Thus the intake of the container can be controlled instantaneously by the outflow of air bubbles into the test tube.

Tubes *a* and *b* are both extended outside of the bottle, by small rubber joining devices, or unions, whose other extremities are connected to very narrow glass tubes. On these rubber devices are placed Mohr clips labeled *i* and *j*.

In addition the apparatus has two rubber tubes 50 centimeters in length and with resistant walls joined one to the inflowing tube *b* and the other to the outflowing tube *E* the transfusion apparatus of Henry and Jouvet or that of de Bakay and a needle having 2 projections ending in openings. The needle has bevelled edges and the diameter of the interior is eight-tenths millimeters. The needle has 2 openings, the one in direct continuation has the same interior diameter as

the rubber tube the other placed laterally has a smaller caliber (Record). The point of the needle may be closed by a hermetic cover.

Sterilization. Fifty cubic centimeters of 5 per cent sodium citrate is poured into the glass container which is carefully closed with the stopper. The incoming and outgoing tubules are attached by joining devices described to the rubber tubes. Their ends are protected by wads of gauze. The whole apparatus is covered with a cloth and is sterilized in the autoclave.

Preparation. The glass container and its accessories are taken out of the protecting cloth. The aspirating tube *E*, is placed in the Henry and Jouvet apparatus and the two ends of the rubber tubes are attached to the projections from the needle. Because of the difference in sizes of the two projections one can be sure that the going tube will be joined to the main projection, and the outgoing tube to the smaller one. Several cubic centimeters of sterile water are poured into the test tube, *d*, attached to the glass container. The needle has been carefully recovered with its hood so that by operating the Henry and Jouvet apparatus, all the tubes are filled with the citrate solution. The liquid can be seen rising into the outgoing tube but soon falls back again from the incoming tube. During this action no air bubbles rise to the level of the lateral tube *m*.

The equipment for the donor is completed by the use of the Pachon pneumatic wristband as a tourniquet. This is kept inflated under minimum pressure, during the entire operation. Thus conditions are created which produce the largest possible outflow of blood from the donor.

Collection of the blood. The needle is taken from its protective hood. The handle is given a half turn in a direction opposite to its normal direction. The citrated liquid flows out of the needle and in so doing leaves it filled with the anti-coagulant liquid.

Next the rubber tube *D* running from the lateral projection of the needle is disconnected and the vein is punctured. Blood rises to the lateral projection. The connection between the rubber tube and the lateral projection is reestablished. The handle is turned and bloody liquid can be seen falling to the bottom of the glass container from the inflowing tube *a* and then rising again into the outflowing tubule of *b*. At the same time large bubbles of air leave the test tube. Thus we can be sure of the progressive filling of the glass container. The latter is shaken gently from time to time to insure the thorough mixing together of the blood and the citrated fluid. At regular intervals the outflowing tube *D* is cut off

fessional donors This has resulted in quite a saving for the center

Our method has made possible a saving of almost 25 per cent in the use of professional donors Each time 450 cubic centimeters of blood has been withdrawn from them It has been observed that this rather large drain has been withstood very well, in fact, patients recovered practically as they would have done from a much less severe loss of blood in a direct transfusion

A bottle containing 500 cubic centimeters of citrated blood will supply the amount necessary

for several cases An amount as small as 50 cubic centimeters can be withdrawn from the bottle provided the precaution is taken to filter the air that enters the bottle, the residue in the bottle will then remain aseptic

THE EFFECT OF LIPIODOL IN THE SUBARACHNOID SPACE

HOWARD A BROWN, M D, F A C S, and JESSE L CARR, M D,
San Francisco, California

DURING the past few years there has been a great increase in the use of lipiodol in the spinal canal, chiefly as a result of the increasing attention directed toward the syndrome arising from dislocations of the intervertebral discs and enlargement of the ligamentum flavum In most instances, a final diagnosis in these conditions requires careful fluoroscopic study following the injection of lipiodol into the lumbar subarachnoid space

Recently we had an opportunity to make a careful study of the contents of the spinal canal in a patient who had had lipiodol injected 6 months previously Little recent comment has been made on the effects of lipiodol in the spinal canal and there is a surprising scarcity of pathological studies on human nerve structures subsequent to the use of this substance In fact, following the admonitions of Craig in 1929 and the experimental studies of Davis, Haven, and Stone in 1930, we found little in the English literature until the report by Globus in 1937 It seems to us worthwhile, therefore, to review briefly the literature on this subject

Sicard and Forestier began the use of lipiodol as a diagnostic aid in 1922 Since that time, they have used it for a variety of purposes, including its injection into the subarachnoid spaces It has remained their conviction that the oil is in no way harmful to the nerve elements in the spinal canal

In 1924, Ayer and Mixter reported experimental results on the effects of iodized oil in the spinal subarachnoid system in cats Their animals showed an increase in the cell count of the spinal fluid and 1 death resulted in the 6 animals studied Sicard and Forestier, at a later time, commented on the fact that the amount of lipiodol used by Ayer and Mixter was excessive for the size of the animals and was in no way comparable to the amount used in human beings

Klose and Peiper, in 1925, reported that clinically they had seen transient headaches and root pains but, after 2 years' observation, had encountered no other ill effects They also made some experimental observations on rabbits and reported pathological changes in the ganglion cells in which the Nissl bodies were clubbed and pale The contents of the cells stained poorly and the sharp outline was lost There were also changes around the central canal, characterized by necrosis of the tissue and a wall of leucocytes next to this necrotic layer

In the same year, Krause reported a case of tumor of the spinal cord in which increased pain followed the injection of lipiodol At operation he described a marked redness and injection of the nerve roots which he had not previously encountered and which he attributed to the oil He commented further on a case of Egas Moni, in which increased cell count, more pain, and a temporary increase in paraplegia occurred after injection The primary pathological process was not mentioned

on top of the contents in the bottle. This shows that all the tubes have been completely emptied.

Mohr clips are placed on the small rubber joining devices on the outgoing and ingoing tubes and on the rubber tube used for the evacuation of the air. Then all three tubes are detached from the glass container. The latter is stirred gently to insure the homogeneity of its contents and then placed in the refrigerator.

Reinjection. After having carefully stirred the blood again to insure its homogeneity, the bottle is placed neck downward in a tripod supporting apparatus. The rubber connection at the end of the receiving tube, is removed and replaced by a rubber pipe which passes into a Henry and Jouvet *let apparatus*.

The Mohr clip is removed from the outflowing tube. The canalizations are filled with blood by one or two turns of the handle. The receiver's vein is entered and the projection of the needle is joined to the small outlet at the end of the rubber tube. By manipulating the handle of the pump the speed with which the blood enters can be regulated to that desired. Only a part of the contents of the bottle may be injected. If care has been taken to filter the air entering the bottle by means of cotton wadding the remainder of the contents may be used for another patient. Before reinjection one must make sure that the receiving tube is level with the stopper. Thus the last drop of blood of the container can be used.

The apparatus of Henry and Jouvet may be replaced by a blast of thermocautery that can be attached to the end of the outflowing tubing.

THE ADVANTAGES OF THE APPARATUS

The apparatus described seems to the authors to have all the desired qualities combined with a maximum of simplicity.

The bottle having a capacity of 500 cubic centimeters sufficient for the withdrawal of a maximum amount of blood is used for all the steps in the process: the collection, preservation and reinjection of the blood. The sodium citrate is introduced before the bottle is sterilized. The bottle is sterilized and is provided with the tubing when it is ready for use. When the blood has been collected the only preparation necessary before transfer to the refrigerator is the closing of three clips. Thus the liquid is kept constantly in a rigorously sterile environment, so that all chances of contamination are eliminated.

The collection of the blood is made in a circuit entirely citrated so that coagulation is eliminated. The blood drawn from the vein and the citrate are mixed in a projection from the needle itself.

The supply of citrated fluid can be regulated to the quantity desired.

At a moment's notice, the needle itself can be cleansed with a minimum amount of preparation by means of the anticoagulant liquid. The use of the Pachen pneumatic wristband slightly inflated puts the donor in the best possible conditions for the withdrawal of blood. Finally, the device for the evacuation of air, adapted to the glass container, shows how rapidly the blood is being collected and permits the operator to watch the progress of the operation and to modify it when necessary. The apparatus of Henry and Jouvet or of de Bakey provides a simple and adjustable method of motorizing the circuit. The quantity of citrate liquid and the quantity of blood to be withdrawn can be easily proportioned. By a few turns of the handle the excess citrated fluid can be evacuated before hand.

All these conditions make possible the facile collection of a large quantity of blood (450 cubic centimeters) without coagulation and within an extremely short space of time.

The technique of reinjection is greatly facilitated by the use of the tripod support. By overturning the bottle the contents can be used even to the last drop. By inserting a filter to cleanse the air, only part of the blood contained in the bottle need be used at one time. Therefore, the contents of the bottle can be used in a series of transfusions in large or small amounts as needed.

At the transfusion center of Brugmann Hospital the authors have succeeded in making by this method more than 150 collections of blood. At each collection blood to the amount of 450 cubic centimeters has been withdrawn so that a much larger number of reinjections than with draws have been made. The authors have found the device fully satisfactory.

Thanks to the system of co operation between the different departments of the hospital all phlebotomies for therapeutic purposes are done in the transfusion center. Here, by means of the technique described the operation is accomplished swiftly, cleanly and with the least disturbing effect on the patient. The quantity of blood withdrawn corresponds exactly to the requirements of the attending physician. The blood so obtained is preserved in a refrigerator. The blood group to which the accidental donor belongs is immediately determined. The qualities of the blood are analyzed and a Wassermann test is performed. If the analyses show that the blood is satisfactory it is used for reinjection. It has been possible in more than one fourth of the transfusions performed to use blood so obtained instead of blood from pro-

reaction with malaise, sluggishness, and loss of appetite. These symptoms disappeared in from 24 to 48 hours in all but 1, and that animal died in 3 days. One other animal developed spasticity of 1 hind leg a week after injection, which lasted 6 months. Pathological studies showed a leptomeningitis with accumulations of large mononuclear and plasma cells. No organisms were found. Fat substances and inert matter were seen as inclusions in the macrophages. Van Gieson's stain showed enlarged vessels and thickening of their walls in the anterior aspect of the cord. Encysted fat was found in the leptomeninges. The ganglion cells in the anterior horns, especially in the cervicodorsal area, were decreased to about one-half of normal. The rest of the cells in that region were shrunken and irregular. The cell processes stained indistinctly or not at all, the nuclei were dimly stained and, in many, cells were eccentric and occasionally absent. The cytoplasm of the shrunken cells was either excessively stained or not at all. The vascularity of the anterior horns was increased with many new capillaries, and vessels of the anterior half were often thrombosed. The posterior horns showed no change. Davis, Haven, and Stone concluded that the use of lipiodol was attended by some danger of damage to the nervous system.

In 1931, Lindblom (15) conducted further experimental studies with rabbits and concluded that there was considerable variation in the susceptibility of individual animals of the same type to iodized oil. His experiments further led him to the conclusion that irritation of the nerve structures was directly proportionate to the amount of free fatty acid in the oil used. The same type of oil, with varying degrees of acidity, produced varying degrees of irritation, increasing as the free acid content was raised. He reported changes over the cortex in rabbits 6 months after injection showing some pachymeningitis with encysted oil in the leptomeninges. He advised careful use of the oil.

Bruskin and Propper, in 1931, reported changes occurring from 2 to 3 months after the injection of lipiodol in dogs. Pathological studies showed a proliferative reaction in the meninges of the cerebrum and cord where the preparation had come to rest. There were some small extravasations of blood, especially in the gray matter of the spinal cord, and degeneration of cells was noted in the spinal roots. These authors concluded that lipiodol caused changes in the spinal cord both by its chemical action and by behaving as a foreign body.

Fumarola and Enderle, 1932, reported 26 cases of myelography with lipiodol. In 6 cases there was some febrile and meningeal reaction with increased pain, and motor and sensory disturbance. They reported 1 death after myelography and believed that the lipiodol produced a mechanical and chemical irritation. They also stressed the importance of the relation between acidity and the irritative effect.

In spite of these various experimental and clinical reports, however, Sicard and Forestier, in 1932, completely exonerated lipiodol of any harmful effects in the human subarachnoid system.

Donat, in 1937, reported the case of a patient with metastatic sarcoma involving the brain. Lipiodol had previously been injected in the spinal canal with an increase in the amount of pain. The patient died 1 month later and examination of the spinal cord revealed chronic inflammatory changes in the leptomeninges with some blood in the pia arachnoid. Peripherally, the spinal cord showed areas of degeneration. The axis cylinders stained poorly and showed a granular dissolution with general detachment at the periphery of the white substance. Donat believed that the changes were caused by the lipiodol, except the bleeding which he considered secondary to the meningitis.

In contrast, Globus reported, in 1937, 138 cases in which lipiodol had been used. Only 2 patients had a relatively severe immediate reaction, but rapidly recovered. A few had transient headaches and slightly increased pain temporarily. The condition of 65 patients was checked after several years—10 years in 1 instance. Only 1 patient had any complaint that might be referred to lipiodol, namely, increased pain in the back. Roentgenographic examinations were made of 34 of these patients. There was no appreciable reduction in the amount of the lipiodol and it moved freely. Three patients who subsequently died were examined at autopsy. Globus reported that no evidence of leptomeningitis was found, though no further pathological details were given. He concluded that lipiodol is entirely safe as a diagnostic aid in man.

One would conclude from the various reports that, in animals, there is evidence to indicate that lipiodol may produce not only irritative changes, but permanent alteration in the leptomeninges, spinal cord, and nerve roots. Clinically, many of these animals seemed entirely normal in spite of the pathological findings described. Sicard and Forestier pointed out that, in the majority of animal experiments, the amount of

In this country, Maclaire in 1915, described a case in which both cisternal and lumbar injections of lipiodol had been made in a patient with injury to the cord from kyphosis. His operative report mentioned thickening of the dura and the arachnoid which were left open after operation. Re-operation because of increased symptoms, revealed dense leptomeningeal and meningomyelitic adhesions and two arachnoidal cysts containing lipiodol. The patient became progressively worse. Maclaire attributed the bad results to lipiodol and advised against its use apparently overlooking the original pathological process as well as the natural sequence of changes following laminectomy without closure of the dura. This report drew further comment from Sicard and Forestier in defense of lipiodol, as well as in criticism of Maclaire's failure to analyze properly the various factors concerned.

In 1926 Wartenberg reported a case in which respiratory difficulty and unconsciousness followed the injection of lipiodol by both cisternal and lumbar routes. The symptoms cleared when the head was elevated. Later, metastatic carcinoma of the spine was found at autopsy.

In the same year, Sharpe and Peterson reported 3 cases in which the symptoms increased following the use of lipiodol. These were not entirely convincing for 2 of the patients apparently suffered from a progressive disorder of the nervous system in which an increase in symptoms was to be expected and 1 patient had a painful amputation stump and later developed pain in the opposite leg.

Faugh and Mella also in 1926 reported on 13 patients with a variety of disorders of the nervous system, in whom 2 cubic centimeters of lipiodol had been injected in the basal cistern. Aside from transient pain in the leg in 4, a slight rise in temperature in 3 and nausea and headache in 1, they observed no ill effects.

Lindblom, in 1926 (14) injected lipiodol in rabbits and produced a clinical picture resembling meningitis, which cleared in 2 weeks. Histological studies showed a sterile leptomeningitis characterized by leucocytes and lymphocytes in abundance in the meninges wherever iodized oil was located. After from 2 to 3 weeks, only single leucocytes and lymphocytes and plasma cells were present. After months no changes could be seen in spite of the fact that iodized oil could still be demonstrated in large quantities in the meninges.

Burgethoff in 1927 reported a case in which there was encapsulation of the iodized oil by many adhesions of connective tissue appearing,

as if a compression myelitis were present at the site.

Nonne, in the following year reported his experiences in a great number of myelographies done with iodized oil. He recorded a rather frequent increase in symptoms with regard to pain and motor, sensory, and sphincter disturbances though again the injection was done frequently in patients with progressive disease of the nervous system. He reported 1 case of chronic meningitic compression of the spinal cord. Lipiodol was subsequently injected and, at postmortem 4 weeks later, was found to have penetrated into the spinal cord. Microscopic study revealed active glial proliferation around the centrally located lipiodol.

Schoenbauer, in 1919, reported the case of a patient who had pachymeningitis hemorrhagica interna. The ascending type of lipiodol was injected and this patient subsequently died of meningitis.

Globus and Strauss also in 1920 reported 5 cases in which lipiodol had remained in the spinal canal for over 2 years. They stated that repeated neurological examinations were negative and that the lipiodol remained free and without adhesions. Only 1 patient, who had a tumor of the spinal cord, showed transient symptoms of increased pain. These authors concluded that the oil was entirely without ill effects and could be used safely.

In the same year Elsberg stated that in his experience the oil acted as a distinct irritant to the meninges. At operation he observed nerve roots which were congested and inflamed, and there were similar changes in the pia. In his opinion however permanent effects occurred only occasionally.

Further warning came from Craig in 1929, against the indiscriminate use of lipiodol in view of the temporary irritative effect which it produced in experimental animals. He advised particularly against its use in inflammatory conditions. He thought come to mind that in 1 case in which the condition was considered to be inflammation and pain was increased after the injection of lipiodol a diagnosis of dislocated intervertebral disc might be made today.

Dr. I. Haven and Stone carried on further experimental work on 10 dogs. An artificial block was produced in the spinal canal by laminectomy and insertion of a rubber dam. Later 1.5 cubic centimeters of lipiodol was introduced in the basal cistern. Another group of dogs served as controls. The animals were killed in from 3 to 22 days. Eight showed clinical evidence of irritative

reaction with malaise, sluggishness, and loss of appetite. These symptoms disappeared in from 24 to 48 hours in all but 1, and that animal died in 3 days. One other animal developed spasticity of 1 hind leg a week after injection, which lasted 6 months. Pathological studies showed a leptomeningitis with accumulations of large mononuclear and plasma cells. No organisms were found. Fat substances and inert matter were seen as inclusions in the macrophages. Van Gieson's stain showed enlarged vessels and thickening of their walls in the anterior aspect of the cord. Encysted fat was found in the leptomeninges. The ganglion cells in the anterior horns, especially in the cervicodorsal area, were decreased to about one-half of normal. The rest of the cells in that region were shrunken and irregular. The cell processes stained indistinctly or not at all, the nuclei were dimly stained and, in many, cells were eccentric and occasionally absent. The cytoplasm of the shrunken cells was either excessively stained or not at all. The vascularity of the anterior horns was increased with many new capillaries, and vessels of the anterior half were often thrombosed. The posterior horns showed no change. Davis, Haven, and Stone concluded that the use of lipiodol was attended by some danger of damage to the nervous system.

In 1931, Lindblom (15) conducted further experimental studies with rabbits and concluded that there was considerable variation in the susceptibility of individual animals of the same type to iodized oil. His experiments further led him to the conclusion that irritation of the nerve structures was directly proportionate to the amount of free fatty acid in the oil used. The same type of oil, with varying degrees of acidity, produced varying degrees of irritation, increasing as the free acid content was raised. He reported changes over the cortex in rabbits 6 months after injection showing some pachymeningitis with encysted oil in the leptomeninges. He advised careful use of the oil.

Bruskin and Propper, in 1931, reported changes occurring from 2 to 3 months after the injection of lipiodol in dogs. Pathological studies showed a proliferative reaction in the meninges of the cerebrum and cord where the preparation had come to rest. There were some small extravasations of blood, especially in the gray matter of the spinal cord, and degeneration of cells was noted in the spinal roots. These authors concluded that lipiodol caused changes in the spinal cord both by its chemical action and by behaving as a foreign body.

Fumarola and Enderle, 1932, reported 26 cases of myelography with lipiodol. In 6 cases there was some febrile and meningeal reaction with increased pain, and motor and sensory disturbance. They reported 1 death after myelography and believed that the lipiodol produced a mechanical and chemical irritation. They also stressed the importance of the relation between acidity and the irritative effect.

In spite of these various experimental and clinical reports, however, Sicard and Forestier, in 1932, completely exonerated lipiodol of any harmful effects in the human subarachnoid system.

Donat, in 1937, reported the case of a patient with metastatic sarcoma involving the brain. Lipiodol had previously been injected in the spinal canal with an increase in the amount of pain. The patient died 1 month later and examination of the spinal cord revealed chronic inflammatory changes in the leptomeninges with some blood in the pia arachnoid. Peripherally, the spinal cord showed areas of degeneration. The axis cylinders stained poorly and showed a granular dissolution with general detachment at the periphery of the white substance. Donat believed that the changes were caused by the lipiodol, except the bleeding which he considered secondary to the meningitis.

In contrast, Globus reported, in 1937, 138 cases in which lipiodol had been used. Only 2 patients had a relatively severe immediate reaction, but rapidly recovered. A few had transient headaches and slightly increased pain temporarily. The condition of 65 patients was checked after several years—10 years in 1 instance. Only 1 patient had any complaint that might be referred to lipiodol, namely, increased pain in the back. Roentgenographic examinations were made of 34 of these patients. There was no appreciable reduction in the amount of the lipiodol and it moved freely. Three patients who subsequently died were examined at autopsy. Globus reported that no evidence of leptomeningitis was found, though no further pathological details were given. He concluded that lipiodol is entirely safe as a diagnostic aid in man.

One would conclude from the various reports that, in animals, there is evidence to indicate that lipiodol may produce not only irritative changes, but permanent alteration in the leptomeninges, spinal cord, and nerve roots. Clinically, many of these animals seemed entirely normal in spite of the pathological findings described. Sicard and Forestier pointed out that, in the majority of animal experiments, the amount of

Fig. 3 Roentgenogram of the spine 6 months after the injection of lipiodol showing the diffusion and encystment of the globules of oil throughout the lumbar subarachnoid space

lipiodol used is much greater, in proportion, than that used in human beings. In addition there is a difference between animals and man in their susceptibility to the oil another factor which renders comparison difficult.

The observations made on human beings are difficult to evaluate. Many of the studies have been made on patients with progressive disease of the nervous system and it is impossible to place on lipiodol the responsibility of subsequently increasing symptoms. The reports of irritative phenomena seen at operation are unquestionable, but it is difficult to tell whether these phenomena are only temporary or whether they produce permanent changes in the nervous system. Again it is hardly fair to attribute all the pathological processes found at operation to the presence of lipiodol and disregard the cause for which the operation is being done particularly if a second stage operation is performed.

Pathological studies on human beings after the use of lipiodol are few. Donat recorded marked changes in the cord of a patient dying from sarcoma but did not indicate the part played by the wasting disease either directly or in regard to the patient's susceptibility to the oil. Globus reporting three autopsy studies in

which there was no evidence of leptomeningitis, gave no description of pathological changes.

Such a review leaves one in much doubt as to the facts with regard to the effect of lipiodol in the spinal subarachnoid system in man.

CASE REPORT

The following case report is made, not with the idea that it will solve our problem but merely to offer additional information on a subject which in recent years has been rather neglected.

H. D., a man 35 years of age fell from a haystack on February 13, 1931, and fractured the tenth and eleventh thoracic vertebrae. A plaster cast was applied. There was temporary numbness in the left leg which soon cleared. Residual periodic pain and paresthesia persisted in the left leg. After the removal of the cast a radiation of pain developed around the area of the tenth and eleventh roots on the right side. Paravertebral injection of the nerve roots with novocain gave temporary relief. On August 15, 1937, 4 cubic centimeters of lipiodol was injected and roentgenograms showed a normal spinal canal in the thoracic and lumbar regions. The only complaint following the use of lipiodol was a temporary increase in discomfort over the sacrum and buttocks but this disappeared in 2 or 3 weeks. The symptoms in the left leg gradually subsided several months after lipiodol had been injected. Due to persistent pain referable to the tenth and eleventh dorsal roots a hemilaminectomy was done some 6 months after the injection of lipiodol and some encroachment on the intervertebral foramen by a displaced pedicle was found.

Fig 4 Drawing showing adhesions about the lower part of the cord and the cauda equina

with traction on the 2 involved roots. A fusion was done following the laminectomy. Nitrous oxide anesthesia, followed by ether, was used. The patient's breathing was poor throughout and his color dusky. The anesthetic was stopped at 10 30 a m, but the patient did not recover consciousness, and died at 6 30 p m the same day.

The roentgenograms taken immediately following the introduction of the oil showed the smooth canal and the

Fig 5 Photomicrograph of the adhesions between the cord and the dura

Fig 6 Photomicrograph showing thickened dura, with lymphocytic infiltration

unity of the globule of oil (Figs 1 and 2). Those taken on the day of his death, however (6 months after the injection of lipiodol), showed the oil to be strung out and caught in small globules throughout the subarachnoid space (Fig 3).

Autopsy report. The findings were essentially normal and irrelevant to this paper except for the pathological changes in the central nervous system. For this reason the general protocol is omitted.

Fig 7 Photomicrograph showing adhesions about the spinal nerves

On examination of the central nervous system the brain was found to be edematous weighing 1550 grams. It measured 13 by 16 by 12 centimeters and the convolutions were somewhat flat from edema. There was no sclerosis at the base of the brain and the leptomeninges were normal. Sections through the brain showed normal symmetrical undilated ventricles lined with smooth ependymal membrane and there were no gross pathological changes in the cerebellum or stem.

The spinal cord in the upper thoracic portion and in the area of recent operation showed considerable congestion and edema on the surface. Beginning at the level of the first lumbar vertebra and extending down around and over the cauda equina were numerous very fine filmy adhesions which ran throughout the leptomeninges and onto the surface of the spinal cord proper. These fine adhesions enveloped the cord and extended down along the dorsal and ventral nerve roots into and almost through the dura (Fig. 4). Only a few fine droplets of oil were seen enmeshed in these adhesions which were all old. Grossly there was no evidence of old blood pigment either staining the under surface of the dura in the adhesions mentioned above or in the leptomeninges proper and there was no evidence of recent infection.

Microscopic description. The brain was very edematous. The leptomeninges also showed moderate edema. The ependymal linings were smooth and normal. There were open spaces about the pyramidal cells which showed a little early postmortem degeneration.

Sections of the spinal cord above the level of the twelfth thoracic showed a normal dura and a pia arachnoid in which the vessels were congested but in which there was no cellular infiltration or evidence of old inflammation or repair. The structure of the spinal cord was normal and there was no visible change in the ganglion cells either in the anterior or the posterior horns, no chromatolysis and no definite changes in the axis cylinders or myelin sheaths. Sections taken below the level of the twelfth thoracic vertebra however showed numerous fine filmy fibrous adhesions running from the surface of the cord throughout the leptomeninges and into the dura. The dura was very definitely thickened and many lymphocytes were found both in the leptomeninges in the adhesion and in the inner part of the dura (Figs. 5 and 6). Fibrous adhesions ran out along, and invested the spinal nerves and in loose adhesions all lymphocytes were lightly scattered (Pl. 7). After frozen sections fat stains showed tiny droplets of oil in the adhesions described. In these areas however there was no evidence of old blood pigment or other foreign material which would act as a stimulating substance.

From the findings at autopsy, a diagnosis of chronic pachymeningitis of the lower dorsal cord and cauda equina was made and the changes in the meninges of the lower cord were ascribed to the irritating action of the lipiodol which had been held there for approximately 6 months.

While such a proliferative reaction in the lower portion of the spinal cord could take place subsequent to old bleeding in this area it is felt that the absence of old blood pigment both in the dura and pia arachnoid reasonably excludes former bleeding as a cause of the adhesions. On the other hand the presence of droplets of oil in the fine fibrous mesh and their localization to a dependent portion of the spinal cord indicate that this proliferative reaction and chronic inflammatory change occurred subsequent to the presence of the lipiodol in the region. As far as can be determined microscopically and in correlation with the history these adhesions had caused no appreciable symptoms but owing particularly to their position about the nerve roots any contraction in the ensuing years might have resulted in symptoms from compression in these

areas. Inasmuch as the operations for laminectomy and spinal fusion were done on the day of death they were to a chronological sense exonerated from any contribution to these pathological development.

SUMMARY AND CONCLUSIONS

A considerable diversity of opinion now exists as to the effect of lipiodol upon the nervous elements of the spinal canal. The bulk of evidence indicates that both gross and microscopic pathological changes may occur in the nervous system following injection of iodized oil into the subarachnoid space. There is no doubting the permanency of the oil in the spinal canal for there is very little evidence of absorption after several years. It is equally true that the oil frequently becomes encysted and adherent in the arachnoid and along the nerve roots as was demonstrated in this case. The clinical symptoms which such changes may produce are neither definite nor specifically characteristic and in this particular case in spite of the adhesive changes present no persistent subjective complaint or objective neurological finding appeared which might have been attributed to the oil. Undoubtedly arachnoidal adhesions of considerable degree such as those occurring after laminectomy, may exist without clinical symptoms. In one of our recent cases a lumbar laminectomy was done on a patient to relieve compression of the nerve by an enlarged ligamentum flavum. Reoperation a year later, to obliterate a false meningocele revealed marked adherence of the roots of the cauda equina to the dura with numerous arachnoidal adhesions but the patient's only complaint had been that of headache upon flexion of the spine or local pressure over the operative site. This symptom disappeared following obliteration of the meningocele. There were no subjective complaints or objective findings referable to the adherent nerve roots.

Nevertheless the use of any substance which may produce such changes in the nervous system cannot be regarded as entirely harmless and while lipiodol is an extremely valuable diagnostic aid in the localization of intraspinal lesions in carefully selected cases its indiscriminate use should not be encouraged.

On examination of the central nervous system the brain was found to be edematous weighing 1550 grams. It measured 17 by 16 by 12 centimeters and the convolutions were somewhat flat from edema. There was no sclerosis at the base of the brain and the leptomeninges were normal. Sections through the brain showed normal symmetrical undilated ventricles lined with smooth ependymal membrane and there were no gross pathological changes in the cerebellum or stem.

The spinal cord in the upper thoracic portion and in the area of recent operation showed considerable congestion and edema on the surface. Beginning at the level of the first lumbar vertebra and extending down around and over the cauda equina were numerous very fine filmy adhesions which ran throughout the leptomeninges and onto the surface of the spinal cord proper. These fine adhesions enveloped the cord and extended down along the dorsal and ventral nerve roots into and almost through the dura (Fig. 4). Only a few fine droplets of oil were seen enmeshed in these adhesions which were all old. Grossly there was no evidence of old blood pigment either staining the under surface of the dura in the adhesions mentioned above or in the leptomeninges proper and there was no evidence of recent infection.

Microscopic description. The brain was very edematous. The leptomeninges also showed moderate edema. The ependymal linings were smooth and normal. There were open spaces about the pyramidal cells which showed a little early postmortem degeneration.

Sections of the spinal cord above the level of the twelfth thoracic showed a normal dura and a pia arachnoid in which the vessels were congested but in which there was no cellular infiltration or evidence of old inflammation or repair. The structure of the spinal cord was normal and there was no visible change in the ganglion cells either in the anterior or the posterior horns, no chromatolysis and no definite changes in the axis cylinders or myelin sheaths. Sections taken below the level of the twelfth thoracic vertebra however showed numerous fine filmy fibrous adhesions running from the surface of the cord throughout the leptomeninges and into the dura. The dura was very definitely thickened and many lymphocytes were found both in the leptomeninges in the adhesions and in the inner part of the dura (Figs. 5 and 6). Fibrous adhesions ran out along and invested the spinal nerves and in these adhesions also lymphocytes were lightly scattered (Fig. 7). After frozen sections, fat stains showed tiny droplets of oil in the adhesions described. In these areas however there was no evidence of old blood pigment or other foreign material which would act as a stimulating substance.

From the findings at autopsy a diagnosis of chronic pachymeningitis of the lower dorsal cord and cauda equina was made, and the changes in the meninges of the lower cord were ascribed to the irritating action of the lipiodol which had been held there for approximately 6 months.

While such a proliferative reaction in the lower portion of the spinal cord could take place subsequent to old bleedings in this area, it is felt that the absence of old blood pigment both in the dura and pia arachnoid reasonably excludes former bleeding as a cause of the adhesions. On the other hand, the presence of droplets of oil in the fine fibrous mesh and their localization to a dependent portion of the spinal cord indicate that the proliferative reaction and chronic inflammatory change occurred subsequent to the presence of the lipiodol in this region. As far as can be determined microscopically and in correlation with the history, these adhesions had caused no appreciable symptoms but, owing particularly to their position about the nerve roots, any contraction in the ensuing years might have resulted in symptoms from compression in these

areas. Inasmuch as the operations for laminectomy and spinal fusion were done on the day of death, they were in a chronological sense exonerated from any contribution to these pathological developments.

SUMMARY AND CONCLUSIONS

A considerable diversity of opinion now exists as to the effect of lipiodol upon the nervous elements of the spinal canal. The bulk of evidence indicates that both gross and microscopic pathological changes may occur in the nervous system following injection of iodized oil into the subarachnoid space. There is no doubting the permeability of the oil in the spinal canal for there is very little evidence of absorption after several years. It is equally true that the oil frequently becomes encysted and adherent in the arachnoid and along the nerve roots, as was demonstrated in this case. The clinical symptoms which such changes may produce are neither definite nor specifically characteristic and, in this particular case, in spite of the adhesive changes present, no persistent subjective complaint or objective neurological finding appeared which might have been attributed to the oil. Undoubtedly, arachnoidal adhesions of considerable degree such as those occurring after laminectomy may exist without clinical symptoms. In one of our recent cases a lumbar laminectomy was done on a patient to relieve compression of the nerve by an enlarged ligamentum flavum. Re-operation a year later to obliterate a false meningocele revealed marked adherence of the roots of the cauda equina to the dura with numerous arachnoidal adhesions but the patient's only complaint had been that of headache upon flexion of the spine or local pressure over the operative site. This symptom disappeared following obliteration of the meningocele. There were no subjective complaints or objective findings referable to the adherent nerve roots.

Nevertheless the use of any substance which may produce such changes in the nervous system cannot be regarded as entirely harmless and while lipiodol is an extremely valuable diagnostic aid in the localization of intraspinal lesions in carefully selected cases its indiscriminate use should not be encouraged.

CARCINOMA OF BARTHOLIN'S GLAND

Report of a Case of Squamous Cell Epithelioma

E A SIMENDINGER A B, M D Cincinnati Ohio

UP to the present time there have been only 38 cases of primary carcinoma of Bartholin's gland reported, and of these adenocarcinoma has been the predominant type, only 9 have been squamous cell carcinomas.

Probably the first case reported was that of Kolb (8) in 1864. Sin recorded a case in 1880 followed by Geist in 1887, Schweitzer and Machenrodt in 1893, O V Frisch in 1904 and Sitzenfrey in 1906 all of whom reported similar cases. H R Spencer reviewed the literature in 1913 collecting 15 cases reported to that date one of which was a squamous cell carcinoma. In 1923, F H Falls collected 20 cases, 12 of which were adenocarcinoma, 1 a squamous cell epithelioma, and 7 undiagnosed as to type. Since then similar cases have been reported by Hunt and Powell in 1926, Schneider in 1930, J Rabinovich in 1932, Harer, H Strauss, C W Mayo and Barber in 1933, H H M Lyle in 1934, Grynfeldt and Godlenski in 1936, P E Hoffman and O Margarucci in 1937. There were only 3 cases of carcinoma of Bartholin's gland found in a review of cases at The Mayo Clinic from July 1923 to July, 1933, according to C W Mayo and Barber.

In 1923 F H Falls presented, in graph form the cases he had found. Using a similar graph I have added 18 cases reported since that date up to March, 1938.

REVIEW OF THE LITERATURE

In a review of cases reported it was found that the ages of the patients varied between 29 and 91 years. The average age was 51.0 years in 30 cases reported in which the age of the patient was given. The majority of cases occurred between the ages of 40 and 55 years.

Infection is apparently not a predisposing factor in neoplasms of Bartholin's gland as in only 2 cases those of Sitzenfrey and Falla was there a past history of infection. Chronic infections of the gland are quite common and often lead to mistakes in diagnosis as in many cases an early

neoplasm was thought to be a chronic infection of the gland.

Hereditry is not an important factor according to Harer who was able to find only 2 cases in which there was a family history of carcinoma. In only 1 case was there a definite history of trauma to the gland however the glands undoubtedly must be the site of frequent trauma. Harer reports that the condition is commonly found in married women, and may occur in unmarried women but never in virgins.

Carcinoma of Bartholin's gland is usually first noticed as a small hard painless, nodular swelling lying deep in the labial fat. The lesion is usually quite movable at first but sooner or later enlarges according to the degree of malignancy, and becomes attached to the surrounding tissues. The skin is usually not involved until late so that when the tumor is first noticed the skin is freely movable over it. With enlargement of the tumor pain develops which is commonly referred to the coccyx and groin and is made worse by coitus and menstruation. Pain is usually the symptom which causes the patient to seek medical attention and by this time the tumor is usually quite well established. As the skin becomes involved the tumor becomes painful to the touch, and the skin reddened and edematous. It is common for parts of the growth to become necrotic and semi fluctuant, thus giving one the impression of cyst of the gland. This is more common in rapidly growing neoplasms. Sooner or later the growth involves the skin either of the vulva or vagina and when the skin is destroyed the tumor becomes secondarily infected, giving rise to a chronic discharging sinus. The mass tends to grow deep rather than superficial involving the surrounding fat muscle tissue and later the pubic bones.

The most important points in diagnosis are the age of incidence, hardness of the tumor with tendency toward fixation, pain, and later edema of the vulva, failure to respond to treatment and a biopsy.

According to Falls one must bear in mind in differential diagnosis that chronic infections of the gland are apt to undergo regressions in size and are most frequently bilateral. Carcinomas

TABLE I—CASES OF CARCINOMA OF BARTHOLIN'S GLAND

Author	Age	Previous evidence of glandular infection	Operation	Type of growth	Metastasis to inguinal glands	Result
1 Kelly	55	None	Incised and later excised	Adenocarcinoma	*	*
2 Eden	40	None	Radical removal of gland and part of pubic ramus	Adenocarcinoma	Enlarged	No re-occurrence in 3 yrs
3 Spencer	43	None	Excision with inguinal glands	Adenocarcinoma	Not enlarged	No re-occurrence in 22 mos
4 Lynch	43	None	Removal of inguinal and vaginal metastases	Squamous	Metastasis to brain and inguinal nodes	Death 2½ years later
5 Martin (3)	70	None	Removal with glands	*	Inguinal nodes enlarged	Recovered in 4 yrs
6 Geist	59	None	Removal of tumor	Adenocarcinoma	None	*
7 Schweizer	58	Chronic infection 3 yrs	Refused	Carcinoma parvicellular	None	*
8 Machenrodt	54	None	Removal of tumor	*	None	No re-occurrence in 4 mos
9 Honan (3)	40	Discharging sinus 1 yr	Removal of tumor	*	Opposite inguinal gland	No re-occurrence in 2 mos
10 Godart	40	None	*	*	*	*
11 Trotta	30	None	Removal of tumor	Chancroid carcinoma	None	No re-occurrence in 6 yrs
12 R. Schaffner	73	None	Removal of tumor	Adenocarcinoma	Inguinal glands enlarged	Re-occurred in 2 yrs
13 Burghelle	50	None	*	Adenocarcinoma	*	Re-occurrence in 6 mos
14 Sitzenfrey	29	Bilateral chronic glandular infection	Removal of tumor with thermocautery	Adenocarcinoma	None	Re-occurrence in 6 mos
15 Pape	91	None	Removal of tumor	Adenocarcinoma	None	*
16 O. V. Frisch	77	None	Removal of tumor with local anesthesia	Adenocarcinoma	Inguinal nodes enlarged	*
17 Falls	39	Previous chronic glandular infection	Removal with left inguinal gland	Adenocarcinoma	None	No re-occurrence in 14 mos
18 Casler (3)	*	*	*	Adenocarcinoma	*	*
19 Sin (22)	*	*	*	Melanocarcinoma	*	*
20 Taussig	43	*	Two stage Basset procedure 2 wks later cautery excision	Squamous	Inguinal glands enlarged	No re-occurrence in 14 mos
21 C. V. Hunt	36	None	Excision followed by 14,386 mg hr radium	Adenocarcinoma	Not enlarged	No re-occurrence in 2 yrs
22 L. D. Powell (3)	71	None	Radical removal	Squamous	*	*
23 Rabinovich	71	None	Excision of tumor	Adenocarcinoma	Not enlarged	*
24 Harter	33	None	Excision of tumor with 1200 mg hr radium	Adenocarcinoma	Not enlarged	No re-occurrence in 3 mos
25 Strauss (2 cases)	61	None	Excision with 1200 mg hr of radium plus x-ray therapy	Anaplastic carcinoma	Not enlarged	No re-occurrence in 1 yr
26	48	None	Two stage Basset procedure 2 weeks excision	Squamous	Not enlarged	No re-occurrence in 1 yr
27 Lyle	30	*	Endothermic vulvectomy	Adenocarcinoma	*	No re-occurrence in 2 yrs
28 Healy (reported by Lyle)	*	*	*	3 Cases adenocarcinoma	*	*
29						
30						
31 C. W. Mayo and Barber (3 cases)	36	*	Partial excision	Adenocarcinoma	*	Re-occurrence after 7 yrs
32	41	*	Radium therapy	Adenocarcinoma	*	No re-occurrence after 2 yrs
33	50	*	Excision and x-ray therapy to inguinal glands	Squamous	Right inguinal gland involved	No re-occurrence after 3 mos
34 Schneider (3)	*	*	*	Adenocarcinoma	*	*
35 Grynski and Godlewski	*	*	*	Squamous	*	*
36 P. E. Hoffman	*	None	*	Squamous	*	*

38 E. A. Simendinger	74	None	Radical excision of mass plus lymphatic glands	Squamous	Not enlarged	No re-occurrence in 8 mos
			X-ray therapy followed by complete vulvectomy			

*Information lacking

Fig. 1 Low power photomicrograph showing sheets of wildly growing epithelial cells in the center of which degeneration is taking place. There is a marked increase in fibrous tissue with many collections of lymphoid cells scattered throughout. $\times 5$

Fig. 2 High power photomicrograph showing early pearl formation and cell structure found generally throughout the tumor. $\times 340$

of the skin of this region are always squamous, while those of Bartholin's gland are predominantly adenomatous. Sarcomas are found in younger individuals and show a mesoblastic cell on biopsy. Benign tumors are slow in growth and do not invade or metastasize. Gonorrheal infections are diagnosed by an acute course, the history and a positive smear. Carcinomas arising from the vulvar skin involve it primarily, while those arising from Bartholin's gland involve the skin late.

There are 2 types of carcinoma of Bartholin's gland possible: the squamous cell epithelioma and the adenocarcinoma. This is possible according to Rabinovich because the acini of the gland and deeper parts of the ducts are lined by 2 distinct types of cells, the columnar and the cuboidal, while the superficial ducts are lined with squamous epithelium. Carcinomas of these superficial ducts are squamous, while those of the gland acini are adenomatous. Sitzenfrey believes that the transitional and columnar epithelium, which lines the deeper portions of the ducts, may, by a process of metaplasia, become squamous in the presence of chronic infection, thus giving rise to squamous cell carcinomas.

Most authors agree that carcinoma of Bartholin's gland like other vulvar carcinomas metastasizes early. Metastasis most frequently occurs in the inguinal nodes of the same or of the opposite side. Lynch reported a case in which cerebral metastasis occurred. Involvement of the penoscrotum of the ramus of the pubis occurs early and by direct extension. There have been no reported cases of bilateral involvement of the glands.

Prognosis in carcinoma of Bartholin's gland is unfavorable. The almost uniform failure of early diagnosis is the most important factor in the poor prognosis. According to Taussig carcinoma of Bartholin's gland is almost uniformly fatal as contrasted with the everting type of vulvar carcinomas arising from vulvar leucoplacia. Rabinovich believes that early the tumor is encapsulated and if the neoplasm be excised before the stage of encapsulation has passed prognosis will be good. In 21 cases reported in which information is available there was no recurrence in 1 case in 6 years, in 1 case in 4 years, in 5 cases in 2 years, and in 4 cases in 1 year, 5 cases recurred and 5 cases were recorded too early after removal of the growth to make any lack of recurrence of value.

In the minds of most authors the proper therapy of carcinoma of Bartholin's gland is a combination of radiation and surgery. Taussig advises a Basset's procedure with removal of the inguinal glands followed in 2 weeks by excision of the tumor by cautery. Strauss reports that at Radiumhemmet in Stockholm good results have been obtained from electrocoagulation and radiotherapy. Kelly advises endothermic vulvectomy and electrocoagulation of the glands *in situ*.

Lyle states that epitheliomas of Bartholin's gland are as radioresistant as vulvar epitheliomas and advises wide excision of the vulva and secondary dissection of the inguinal and femoral glands followed by regional and local radiation. Removal of the inguinal and femoral gland followed closely by endothermic removal of the tumor mass with preoperative and postoperative irradiation is perhaps the most suitable form of therapy.

CASE REPORT

Case No 75712 Mrs D B, a white woman, aged 74 years, married, was admitted to the gynecological service of the Cincinnati General Hospital on June 11, 1937, with a complaint of "painful lump between my legs." The patient had suffered from a cardiac ailment for the past 10 years, but otherwise she felt well until approximately December 25, 1936. At that time she noticed a small, hard, painless lump about 1 by 1.5 centimeters in size located deep in the posterior portion of the left labium, which was quite hard and fixed in position. She could recall no history of injury to the part but thought injury was probably the cause.

About the middle of April, 1937, approximately 4 months after she first noticed the growth, she began to have aching pains in the region of the tumor which radiated to the groin and low back. The mass during the 4 months had increased to approximately 4 by 4 centimeters in size. During the same period there appeared another mass the size of a golf ball posterior and lateral to the original tumor and closely approximated to it. The second mass was soft, fluctuant, and very tender. During the course of the ensuing 2 weeks it became quite large and about May 1, 1937, ruptured through the overlying skin, discharging about 200 cubic centimeters of a colorless, odorless, mucinous fluid. A small sinus formed at the point of rupture which failed to heal, and mucinous, later purulent, material constantly drained from it. The sinus, however, did not increase in size.

Approximately 5 months after the onset the patient first sought medical attention and was advised that she had an infected Bartholin's gland and that hot fomentations should be applied. This therapy was of no avail and by June 1, 1937, the mass had increased in size until it was about 5 by 6 centimeters in size and was very painful, rendering the patient bed fast and unable to use her left leg without pain. The overlying skin was swollen, red, and painful to palpation in the region of the tumor. Up until this time the vulvar skin had been quite healthy, nontender, and freely movable over the hard nodular mass. On June 11, 1937, she was sent to the Cincinnati General Hospital for treatment. From December until June she had lost 10 pounds in weight and in the past 3 months had noticed gradually increasing, general weakness.

Past history The patient had suffered from arteriosclerotic heart disease for the past 10 years but with no history of decompensation. Five years ago she was admitted to a mental hospital and a vaginal examination at that time was negative. There was no past history of lues or gonorrhea. The family history was negative aside from the fact that her mother died of carcinoma of the breast. There was no other history of malignancy in the family. Two brothers were living and well.

Menstrual history Menses began at the age of 16, were regular each 28 days and lasted 4 days. She suffered with no menorrhagia or metrorrhagia, menopause occurred at the age of 40. There was no discharge except at menstrual periods. The patient had two children living and well and had had one miscarriage. There was no history of gonorrhea or lues.

Physical examination Blood pressure 220/110, pulse, 70, respiration, 22. The patient was a poorly developed, undernourished, senile, white woman. She was mentally clear, intelligent, and quite co-operative. On pelvic examination the left labium was found to be greatly enlarged and bulged over the introitus. No vaginal discharge was present. The skin over the left labium was injected, tender to the touch, and slightly edematous, but freely movable over a more deeply situated, hard, nodular mass. The mass was buried in the fatty tissues of this region, painful to

pressure, stony hard, fixed, and not well outlined. The surrounding tissues were slightly indurated except for a small area at the posterior portion of the mass which was soft, slightly fluctuant, and tender to palpation. There was a small draining sinus on the posterior inner portion of the left labium from which small amounts of purulent material drained, especially when pressure was exerted on the above described fluctuant area. The vaginal mucosa was normal and the vulvar skin showed no evidence of kraurosis, being healthy aside from the above described sinus and mild inflammatory changes. The cervix was small, of normal color and consistency, and showed no areas of erosion. The uterus was small, in normal position, and not tender. The adnexa were not palpable. Rectal mucosa was normal and movable, sphincter tone, good, with no bleeding. On deep palpation rectally a mass could be felt on the left anteriorly. It was quite hard, nodular, and very painful but did not involve the rectal wall. The inguinal nodes were enlarged bilaterally, quite tender and freely movable, but were soft rather than shotty to palpation.

Laboratory findings Wassermann and Kahn tests were negative, hemoglobin, 75 per cent (Haden Hausser), white blood count, 11,600, urine, negative.

Course in the hospital A tentative diagnosis of malignancy with superimposed acute and chronic infection was made on admission. A biopsy was taken on June 16, 1937, and a diagnosis of squamous cell carcinoma of the vulva was made. From June 18 to June 26, 1937, she was given x-ray therapy to the tumor for the superimposed infection. This was given through anterior pubic, posterior sacral, and direct perineal fields. There were no burns and the skin was in good condition following this treatment. A total of 900 roentgen units was given, 200 through the anterior pubic, 100 through the posterior sacral, and 600 directly to the tumor. Treatment factors were 200 kilovolts, 15 milliamperes, 1 copper and 1 aluminum filter with a 50 centimeter skin test dose.

On July 3, 1937, under gas-oxygen-ether anesthesia a complete vulvectomy was done by Dr. Ralph Eddy. At operation there was a large indurated nodular mass deep in the left labium. It was approximately 6 by 8 centimeters in size. In the skin overlying the tumor there was a granulating wound, the result of incision made when the biopsy was taken. Posteriorly, near the opening of the duct, there was a small area 0.5 centimeter in diameter where the neoplasm had involved the skin. The tumor mass itself was found to extend from within 0.5 centimeter of the urethra anteriorly to the rectal sphincter posteriorly. Laterally it had involved the levator muscle on that side. The inguinal glands were not removed at operation.

Pathologist's report Case No 75712. By Dr. Francis Woods, surgical pathologist. "The gross specimen consists of a mass of skin tissue composed of labia majora and minora which show a distinct brownish pigmentation.

"Under the skin on the left side is a large, firm mass buried deep in the fatty tissue. The mass measures approximately 5 centimeters in diameter. It is not encapsulated and on cut surface appears white and fibrous. A large sinus runs through the center of the mass and in many areas pus is easily expressed from it. Microscopic examination reveals many areas of fibrous tissue in which are scatterings of lymphoid cells (Fig 1). In other areas there is evidence of acute inflammation with infiltration of polymorphonuclear cells and areas of degeneration. Other areas show sheets of wildly growing squamous epithelial cells. In the center of most of these there is definite degeneration. Broken up cells and polymorphonuclears are seen in such areas and in the surrounding portions of these sheets of cells. Some of the nuclei appear to be shrunken and others to be fragmented. The degree of pigmentation of the

nuclei varies to a marked degree in these areas. A very few mitoses are seen (Fig. 2). In a number of areas in the fibrous tissue multinucleated giant cells are seen chiefly in areas where there is degeneration of tissue. There are no endothelial groups of cells to suggest tuberculosis. In some areas of the fibrous tissue the outlines of former acini can be made out but no normal gland tissue can be seen anywhere.

Diagnosis. Squamous cell carcinoma of Bartholin's gland. Sec No 777-881. The diagnosis of squamous cell carcinoma was confirmed by Dr. R. S. Austin, professor of pathology at the University of Cincinnati College of Medicine.

The patient was seen again October 3, 1937, 3 months after operation. At this time the wound was completely healed with no evidence of recurrence or metastasis. The inguinal lymph glands were not palpable.

The patient was again seen on March 3, 1938, 8 months after operation. The wound was in good condition, completely healed with no areas of tenderness or induration. There were no inguinal glands palpable and no evidence of local recurrence or metastasis could be elicited. X-ray examinations of the pelvis on October 13, 1937, and again on March 3, 1938, were negative.

PARASAGITTAL MENINGIOMAS: OPERATIVE TECHNIQUE SUGGESTED FOR EXPOSURE

JAMES L. POPPEN, M.D., Boston, Massachusetts

THE exposure of a large parasagittal meningioma may be the most difficult part of the operation in attempting its removal. Several helpful methods have been employed in the past few years which have facilitated the work on the bone and at the same time have given adequate exposure for the removal of the tumor.

Large bony defects resulted after operation in many of the cases of parasagittal meningiomas such defects depending, of course, on the extent of the bony involvement as well as on whether the tumor involved the sagittal sinus. It was felt that the better part of valor was to rongeur bone away as the exposure was needed. This increased both the operating time as well as the loss of blood, since each bite with the rongeurs opened up large vascular spaces.

The following 3 methods of attack may be used, depending on the conditions found at the time the procedure is carried out. With this technique, a satisfactory exposure may be made avoiding the sanguineous struggle which may ensue if an attempt is made to go through part of the vascular bony enostosis which is frequently present.

From the Department of Neurosurgery, The Lahey Clinic

OPERATIVE PROCEDURE

Since it is difficult to be certain before operation that the tumor does not extend across the midline, the medial portion of the scalp incision is made well beyond the midline. The scalp and periosteum are reflected as far as is necessary so that the extent of the bony involvement, as determined by a definite area of increased vascularity, may be determined. The course of the sagittal sinus may also be readily noted by the external appearance of the bone. The burr openings are then made as shown in Figure 1, the only change from the ordinary bone flap being that the medial portion of the bone flap is well past the midline, allowing excellent exposure of the tumor even if it should extend across the sinus. Emphasis is placed on the fact that a burr opening should be made immediately to either side of the sinus in both the anterior and posterior limbs of the bone flap, so that they may be readily connected with a Montevesi bone cutting instrument, thus avoiding possible injury to the sinus with the Gigli saw. The remaining burr openings are connected with a Gigli saw, starting the saw cut with the conventional bevel and continuing in this manner for two-thirds of the distance and then abruptly

Fig 1 a, Outline of scalp incision well beyond midline and site of tumor b, Scalp flap with periosteum reflected to allow burr openings to be made around involved bone overlying tumor Also the relationship of burr openings to the sagittal sinus is illustrated

Fig 2

Fig 3

Fig 4

Fig 2 The bone flap elevated as a whole. Note bevel of sinus. The bone flap is turned down in this manner only when the dura is not adherent and roentgenograms demonstrate minor bony attachment to tumor.

Fig 3 Entire bone flap raised with exception of the cutting the rest of the bone at an acute angle. If the latter is done with each cross cut it creates a slot effect making it impossible for the bone flap to slide out of position after it is once in place.

bony attachment to tumor. Note window in bone flap.

Fig 4 a Bone flap with sinus and tumor turned down none over tumor and still intact. b The bone segments removed in 2 pieces. The 2 steps are used when the dura is adherent to the inner plate of the

During the process of passing the sinus from one bony opening to the other the surgeon has become acquainted to some extent with the degree of adherence of the dura to the inner plate of the

Fig 5 a, Dural defect filled in with a periosteal graft removed from inner surface of scalp flap after tumor has been removed b, Bone segment replaced and kept anchored with a few black silk sutures taken through tiny burr openings through the edges of the bone

calvarium with exception, of course, of the bony enostosis. Also much will have been learned about the degree of vascularity. If it has been noted that the dura is readily separated from the inner plate and previous roentgenograms have given evidence of only a mild enostosis overlying the tumor, the entire bone flap (Fig 2) may be safely elevated if the staphylorrhaphy has been used to free the sagittal sinus through 2 or 3 burr openings made along one side of the sinus. It is always wise of course to have muscle at hand which has been collected from previous general surgical patients operated on that same day.

If a rather large or deep enostosis has been demonstrated roentgenologically, it is likely to be firmly adherent to the tumor making it unwise to elevate the entire bone flap as a whole. Therefore, provided that the dura is not adherent elsewhere, many burr openings are made encircling the well demarcated vascular area in the bone. These burr openings are readily connected with a bone cutting forceps. This allows the bony attachment to the tumor to remain *in situ* as the rest of the bone flap is elevated (Fig 3). The fragment of bone then may be left in place while the tumor is removed or may be carefully separated from the surface of the tumor with a periosteal elevator before the dura is opened.

If the dura has been found to be firmly adherent throughout, as evidenced by difficulty in the guides for the Gigli saw through the burr opening, the technique in Figure 4 should be followed. The bone flap is elevated in 3 segments. The portion corresponding more or less to the ordinary

type of bone flap is turned down with the segments covering the tumor and sinus left attached. These may be gently freed with a periosteal elevator, with care to avoid tears in the dural sinus.

After the intracranial tumor has been removed by the Cushing technique, which is well known, the resulting defect in the dura may be readily repaired by removing a strip of periosteum (Fig 5, a) from the inner surface of the scalp flap. The fragments of bone are replaced after the portion overlying the tumor has been boiled or a corresponding segment removed from the inner plate of the bone flap to replace the portion involved with the tumor, the latter may then be discarded. These bone segments may be anchored with a few black silk sutures as shown in Figure 5, b.

The above procedures allow adequate exposure of the tumor even if a portion of the sinus has to be resected due to invasion of the tumor. Also, any tumor can be taken care of that may have crossed the midline. A minimal amount of defect is left since bone dust may be saved from the burr openings which are well away from the tumor and be used to fill in the openings at the time of closure.

SUMMARY

- 1 Parasagittal meningiomas may be difficult to remove especially if enostosis is present.

- 2 Three methods that may be followed are given. Decision as to which to follow can be made only at the time of craniotomy.

- 3 The general principles may be followed in any convexity meningioma that has an adherent bony stalk.

NEPHROPEXY

IT is quite generally understood by physicians that stone in the upper urinary tract may cause symptoms and exhibit all the signs of acute lesions of the abdominal organs particularly those of the appendix and gall bladder. Twenty five years ago and more rarely during recent years, it was not an uncommon occurrence mistakenly to remove the appendix or explore the gall bladder in cases of urinary calculi. Numerous reports of cases and discussions of this question have convinced the present generation of surgeons of the need for a roentgenogram and an examination of the urine before resorting to an abdominal exploration. If no evidence of urinary tract disorders is found the abdomen is opened and at least the appendix is removed with a certain feeling both of finality and of security.

What is not so generally recognized is that a low lying shifting kidney can simulate most of the lesions occurring in the right side or more rarely the left side of the abdomen. It

is not necessary to have a Dietl's crisis to implicate the kidney. Evidence of ureteral obstruction or pelvic dilatation may not be demonstrable. Tension due to the traction of a dislocated but otherwise comparatively normal kidney may obstruct the bile ducts or constrict the duodenum, initiating a chain of symptoms which may be indistinguishable clinically from primary disease of these organs. Such cases while rare have not been found to be unusual.

In the period between 1900 and 1910 nephropexy next to appendectomy was the procedure of choice for pain in the right side of the abdomen. It was a simple clean cut procedure which was easily performed with a low mortality even by operators of little training. Many developed their own methods of suspension and medical periodicals contained numerous descriptions of bizarre and spectacular procedures the very number and variety of which suggested neither satisfactory nor uniformly good results. In fact unfavorable results were frequently seen. In some cases the nephropexy was done when not indicated, in others the suspension was poorly executed and did not hold the kidney in a sufficiently high position. Occasionally improper fixation permitted the kidney to pull loose, carrying other structures with it in its trip downward, thus causing further disability. In rare carefully selected cases, excellent cures were obtained but the few favorable outcomes were overshadowed by numerous unfortunate results.

Such unfavorable results were bound to cause a reaction, and from 1910 to 1920 almost no reports of cases appeared in the literature. From 1917 to 1924, in 7 years of observing

surgery at several of the larger surgical centers, I saw only four nephropexies performed, and these were done hurriedly, with a great deal of reluctance as well as with many apologies

The operation had been discredited, and in the minds of many of the older surgeons, it is still a procedure to be performed only as a last resort. More recently, reports of cases of patients successfully operated upon are again beginning to appear in the literature, usually qualified by a discussion of the limitations of the procedure and the desirability of properly selected cases. Many of these articles are by leading urological surgeons, and the success they have met with in treating these patients must be considered in our handling of similar cases.

Partially due to the early bad repute of this procedure, nephropexy is still rarely considered as the initial procedure. All other measures are exhausted before renal suspension is considered. In a recent review of cases of nephropexy, all done on the right kidney, 57 per cent had some previous abdominal operation for the relief of right-sided abdominal pain. Almost one-third of those who had been operated upon previously had two, three, four, or more operations. In all cases but one, nephropexy was the last operation, and all but two patients were relieved of their pain by the operation.

I am not entering a plea for widespread adoption of the operation of nephropexy, but I do offer the suggestion that the low-lying, movable kidney which is so frequently symptomless may also be the primary cause of the patient's disability. It is my belief that there is a small group of patients in whom urological investigation might save needless surgery and also that nephropexy is the only procedure that will give these patients relief.

A. J. SCHOLL

THE IMMEDIATE TREATMENT OF COMPOUND INJURIES

MANY a medical student and hospital interne has dreamed of the day when his big moment would come—when the opportunity to demonstrate his ability would suddenly, and perhaps dramatically present itself; and he has told himself again and again just what he would do under such circumstances. Today one can promise him with assurance that the opportunity will probably come very early in his career—in the form of a badly lacerated forehead or face, a hand or forearm with division of nerves and tendons, an extensive avulsion of skin and soft tissues from upper or lower extremity, a compound fracture of both bones of the leg. The summons will probably come in the dark of the night or in the early hours of the morning. He will not be asked to present his credentials of membership in the College of Surgeons or any other organization, a plain "M D" will suffice. There will be no question of calling older and wiser colleagues into consultation; or of referring the patient to some one with more experience. He will only be implored to hurry, and asked for the assurance that life will be saved and that there will not be hideous and deforming scars as a result of the injury.

Will he accept the chance and "field the ball" perfectly? Much depends upon his understanding of two golden principles of good surgery—patience and gentleness. Patience, because the transformation of a lacerated badly contaminated wound into a clean surgical wound, susceptible of immediate repair, is no task for the impetuous and irritable surgeon whose motto is "Speed." Gentleness, because living tissues are delicate fragile structures that respond in remarkable fashion to gentle handling, but that can be destroyed by

chemical and mechanical trauma as easily as the petals of a fragile flower. If patients always came to the surgeon in the form of a Greek god or goddess it might be easier to visualize living tissue as a delicate, wonderfully fragile and strangely beautiful structure. To realize that the blood stained, crushed and distorted mass of flesh and bone which often confronts the surgeon after a serious injury can be restored into a useful and symmetrical face or hand or leg requires imagination, and a certain genius for patience and gentle care.

More specifically, an increasing experience has fortified us in the opinion that for the patient with a compound injury the most satisfactory first aid dressing is the simple application of a sterile dressing and a pressure bandage to stop oozing of blood, and *nothing more*. Why? Because forceps not completely sterilized, catgut ligatures applied in haste in an emergency room, interested bystanders with uncovered mouths and noses talking excitedly over an open wound—these possible sources of infection we have come to fear more than the knife or the glass or the metal that caused the wound.

At the *earliest possible moment and under suitable conditions* the area about the wound should be carefully cleansed with plain white soap, which is less irritating than green soap or tincture of green soap and with soft sterile cotton, held in hands covered with sterile gloves. When the area about the wound is cleansed the wound itself is gently, patiently, and thoroughly cleansed in the same fashion, and thoroughly irrigated with warm saline solution. If the wound is clean cut, the result of a knife wound or glass cut and looks perfectly clean to the naked eye, the soap and water cleansing of the wound itself can be omitted, and the irrigation with warm saline carried out as soon as the cleansing of the area about the wound is complete. A blood pres-

sure band to secure hemostasis in an extremity, sterile retractors to *expose the depth* of the wound during the process of irrigation, careful masking of everyone in the room—are all important details that help to secure the desired result.

When cleansing of the wound is complete, if the surgeon is satisfied that he has converted the contaminated wound into a clean wound, repair is in order. This includes the careful preservation of tissues whose blood supply is intact, reduction of fractured bones or fractured tendons and nerves, complete hemostasis, accurate wound closure, a large dressing so as to apply uniform and elastic pressure over the wound area, a splint to immobilize the injured tissues and favor healing.

If one is doubtful as to the completeness of the cleansing process or if the "safe interval" has passed, the repair of structures that involves dissection and further exposure of tissues should be omitted. The same careful cleansing, the same reduction of fractured bones should be carried out, the covering tissues can be left open or loosely sutured—as judgment and experience indicate. Our own practice tends more and more toward wound closure if hemostasis is satisfactory and the injury has not been of the crushing type.

After operation the carefully immobilized part is left alone for 3, 4, 6 days unless some definite indication arises for disturbing the dressings. If a patient is comfortable afebrile, resting well at night one can wisely restrain his curiosity to see what is going on underneath the dressings. The patient should be watched with the greatest care, the wound is best left alone until the sutures should be removed.

The question of shock, the necessity for transfusion, the careful pre-operative examination of the patient, not the wound to determine the extent of injury are important con-

siderations that cannot be discussed here. The actual care of the compound injury—from the moment the patient comes to the doctor—is the responsibility of the man who first sees the patient. If his treatment is wise, painstaking, well considered often nothing more than time and simple after-care is

needed to restore the patient to health and normal activity. If not, it too often happens that nothing in the way of skillful surgery or prolonged treatment can compensate for haphazard or unthinking care immediately after the injury has been sustained.

SUMNER L. KOCH

ACROSS THE EDITORIAL DESK

IT SEEMS too bad that custom habit, and the laying down of certain rules of form and order have all combined to discourage the development of an individual style of writing by medical authors. There is unquestionably one writer on purely scientific material who is a stylist and he succeeds in making his articles living interesting stories of his experimental and clinical investigations. That author is, of course, Dr Harvey Cushing. Since most of us are wholly unable to approach Dr Cushing's accomplishments in the field of medical writing perhaps it would be better if we wrote simply, directly, briefly, and to the point. Tradition and custom have required the use of extensive historical reviews and citations of literature which in many instances are not pertinent, simply because the author is fearful that his readers will not recognize that he has made a careful and complete study of the subject about which he is writing.

A GOOD example of what is meant by concise brief statement of a problem and the points to be emphasized is BLACKFIELD'S paper on burn contractures of the hand which will be published in the near future. Blackfield's important points that contractures may be prevented by early and proper skin grafting and his clear description of the essential technique of the types of grafts to be used in early and late cases and the principles covering the use of grafts are not hidden by unnecessary verb age.

WE FEEL sure that all of our readers will be interested in three papers which make up a very careful study of 70 patients with cancer of the cervix who have been treated at the Pondville Hospital. This is the Cancer Hospital of the Massachusetts Department of Public Health. Seventy cases of cancer of the cervix treated by x-ray and radium have now been traced for 5 years and longer and the results are given by Dr MEXES and his associates. In another paper the extreme importance of the genito-urinary system in cancer of the cervix is emphasized, and another interesting fact resulting from a study of these cases is the authors belief that one may be able to choose cases for surgery because of the patients' reaction to radiation rather than simply because they are early cases.

Besides being well written these papers are excellent examples of careful detailed study of a group of cases which offer more than a statistical study of percentages.

ARTICLES by WERNICKE and BECKMAN and SULLIVAN deal with that perennial problem of the treatment of hernias. Wernicke's paper is a good, clear, and fair statement of the value of the injection treatment of hernia and seems appropriate at this time when enough material should be available upon which to base a judicial statement as to its value. Everyone recognized from the beginning that it was not a simple and foolproof method and that it was not without danger even in experienced hands. That the injection treatment has merit in certain cases is true, even though the ideal solution for injection has not yet been developed. Wernicke however, believes that the method cannot supplant surgery in the majority of instances and he warns against the indiscriminate use of solutions by those unskilled in the technique.

In connection with this paper the analysis of Beckman and Sullivan of the immediate post-operative complications in 2000 cases of inguinal hernia in relation to infections anesthesia suture material used and other factors is particularly worthy of attention. The pendulum swings a long way in both directions in surgical therapy. Sometimes it is difficult to wait until it has settled down to its midposition.

IT IS unfortunate that the cost of reproducing colored illustrations is so great to the author and to us because an article on the study of 200 specimens of human endometrium is accompanied by colored illustrations which would lend themselves particularly well to reproduction, but Dr CLEVELAND of Vanderbilt University has decided and we agree after our initial disappointment that black and white reproductions of his illustrations showing the study of nuclei and the chromatin distribution in these specimens of endometrium will accurately reproduce his findings. Cleveland's observations suggest that the difference in the threshold response of the gland and stromal nuclei of the human endometrium to hormonal stimulation may furnish a basis for determining fluctuations in endocrine levels.

JOSEPH C BLOODGOOD
1867-1935

MASTER SURGEONS OF AMERICA

JOSEPH C. BLOODGOOD

ON October 22, 1935, the medical profession, and particularly that part dealing with surgical diagnosis, lost one of its most dynamic members. Born in 1867 on the first of November in Milwaukee, Wisconsin, Dr Bloodgood began his professional career by graduating from the University of Wisconsin in 1888 and receiving his medical degree at the University of Pennsylvania in 1891. His whole professional life was spent in connection with Johns Hopkins Medical School and Hospital, where he was assistant resident surgeon, later resident, assistant instructor, associate, and finally associate professor of clinical surgery.

As a young prospective surgeon his environment was filled with the enthusiasm of his master, W. S. Halsted, one of the pioneers of modern surgery. Dr Halsted approached his own progress from two angles, animal experimentation and surgical morbid anatomy. It was the latter approach which apparently appealed to Dr Bloodgood. He became the instructor of surgical pathology which continued to be his field throughout his life. He was probably the first physician in the United States to devote the major part of his time to surgical morbid anatomy and who was to gain recognition as a great surgical pathologist. A review of his published articles, as well as of his many demonstrations for his colleagues and the profession, shows clearly that surgical pathology and surgical diagnosis were his main interests. Quite naturally these interests dealt largely with all forms of malignant tumors, he became known, therefore, as an authority on cancer and he spent the last years of his life publicly and professionally enlightening all upon this destructive disease—its nature, diagnosis, and treatment.

In the last part of the nineteenth century William Ostwald, distinguished chemist and philosopher, divided men into two main groups—*die Klassiker* and *die Romantiker*. He described the first as being rather slow at observation, correlation, generalization, and utilization, not unusual in childhood, producing rather slowly, and not as a rule great teachers. The second group was composed of those rapid in their reaction time, they produced work in large quantity, and rapidly. This group contained the enthusiastic teachers. If this be a correct division of men, then I feel that Dr Bloodgood must have belonged to the second or romantic group. Certainly he did great quantities of work and this very rapidly. Certainly he inspired a great following. He was not a creator of new ideas nor a discoverer of new facts, but he was an extremely valuable teacher of selected facts he quickly saw in his abundant material and deemed valuable for

his profession and his fellow countrymen. He took an active part in all movements leading to the diffusion of knowledge of cancer. No member of the profession had closer contact with, and a greater influence over, the lay press than did Dr Bloodgood. This, his tremendous enthusiasm led him to use for popular education which is neglected too frequently by our profession.

I, personally, feel no one will take his place in the many medical meetings where one almost always was certain to hear him bring his enthusiastic plans for early diagnosis of cancer. His great personality as well as his carefully studied statistical facts relative to prognosis in neoplastic diseases will be missed not only by specialists in his field but by the average general practitioner throughout the country. They knew him personally, believed in his diagnostic ability, and had the greatest respect for his abundant and concentrated professional experience which lasted well over forty busy and useful years.

WILLIAM CARPENTER MACCARTY

THE SURGEON'S LIBRARY

REVIEWS OF NEW BOOKS

THE new, seventh edition, of Kanavel's *Infections of the Hand*,¹ completed just before the author's death, carries on the tradition of previous editions of this authoritative work. The arrangement follows the same splendid plan as in the previous edition. There is first a consideration of the anatomy of the hand and forearm, especially as related to infections and their spread as determined by anatomical dissections, by cross sections, by injection experiments, and by clinical observations. The outlines of the principal fascial spaces are described and illustrated in relation to surface and deep landmarks, together with their relations to one another, to the flexor tendon sheaths, to the lumbrical canals, and to the major forearm space. This complex subject is so handled that it can be readily comprehended by the attentive reader. This is followed by a brief description of the superficial and deep lymphatics. The importance of placing the infected hand in the "position of function" throughout the course of treatment is emphasized by devoting one entire, though short, chapter to this important topic which is referred to again and again throughout the book. It is described as the position in which "maximum power can be exerted with least effort" and in which "many important motions can be carried out with a minimum of motion."

The general principles of treatment are next considered, some of the more important being the following. Incisions in a bloodless field under general anesthesia to allow adequate opening, accurate dissection and avoidance of vessels and nerves, incisions sufficiently large so that drains can be reduced to a minimum, immobilization of the hand in the position of function in a massive wet dressing, the use of passive hyperemia for 18 to 24 hours following incision, removal of all drains after 24 to 48 hours, the making of all dressings under strict aseptic precautions, the time for discontinuance of wet dressings, the use of arm baths from 20 to 30 minutes each day, followed by dehydration by dry heat, then a light dry dressing, and physical therapy to restore function at the earliest possible moment.

A very valuable chapter is the one on prophylactic treatment of injuries, emphasizing as it does gentle cleansing of the injured parts with soap and water with no strong antiseptics in the open wound, and débridement of devitalized tissues followed by immobilization in the position of function.

The diagnosis and treatment of specific infections are next discussed first, felon, paronychia, carbuncle,

mycotic and other superficial infections, next, abscesses in the minor spaces, then infections about the metacarpophalangeal joint which are due chiefly to a tooth penetrating the skin over the knuckle in a fist fight. This is followed by a consideration of gangrenous infections, streptococcal, symbiotic, and gas bacillus.

Part III contains separate chapters on the diagnosis and treatment of lymphangitis and infections of the separate tendon sheaths, and of the major fascial spaces, together with a description of possible extensions from a given point of infection, and specific direction as to how to incise each sheath and each of the fascial spaces. Slight modifications in the incisions recommended in previous editions for drainage of the thenar and middle palmar spaces are described.

The final division of the book, Part IV, is concerned with the complications and sequelae of infections of the hand, such as osteomyelitis, hemorrhage, ankylosis, and contracture, discussing their prevention, diagnosis, and treatment. The last few chapters describe methods and apparatus for physical therapy and the types of basic but easily made splints to be used during treatment.

The book is well printed on excellent paper, is profusely illustrated and each chapter is ended by a résumé of the entire chapter, which is a considerable help to the reader and should be of value to students.

MONT R. REID

IF the reviewer believes his task in reviewing such a voluminous work as Meakins' *The Practice of Medicine*,² is somewhat arduous, he may console himself with the thought that it is infinitely more laborious to write such a book. This book is the product of Dr. Meakins' own effort. A few sections have been written by his associates but under the critical supervision of the author. It has been said that the present status of medicine has made it impossible that a satisfactory textbook of medicine be written by a single author. Dr. Meakins has upset this statement. Indeed, his book may be cited to show that in many respects single authorship is superior to any other.

The book consists of twenty-one chapters in which the non-surgical maladies of the body are discussed. Included in this discussion are short sections on diseases of the nervous system and of the locomotor system. The author has jettisoned the usual stereotyped approach to and consideration of individual diseases. He adopts the much more logical method

¹INFECTIONS OF THE HAND, A GUIDE TO THE SURGICAL TREATMENT OF ACUTE AND CHRONIC SUPPURATIVE PROCESSES IN THE FINGERS, HAND AND FOREARM. By Allen B. Kanavel, M.D., Sc.D. 7th rev. ed. Philadelphia: Lea & Febiger, 1939.

²THE PRACTICE OF MEDICINE. By Jonathan Campbell Meakins, M.D., LL.D. 2d ed. St. Louis, Mo.: The C. V. Mosby Co., 1938.

of setting forth a general description of the symptoms produced by disorders of the portion of the body under discussion. For instance the discussion of diseases of the stomach is prefaced by a general consideration of appetite anorexia pain nausea, and so on. Later these symptoms are fitted into the pictures of ulcer, carcinoma syphilis, and so on. This method of approach is used throughout the book wherever possible. It makes a much more readable book and saves much of repetition. It is difficult to single out any one portion of the book for special commendation. Diseases of the hematopoietic system with excellent plates is especially good. The discussion of cardiac arrhythmias is very clear and concise. The approach to the subject of heart failure is very well done.

In any work of this sort in which the author must crowd a vast amount of information into a relatively small space the problem of selection of material becomes paramount. The author must decide what to omit, not what to include. Whatever sins there are in this book would seem to be sins of omission. A few examples follow. In the treatment of neglected diphtheria no mention is made of the inestimable value of large amounts of intravenous glucose. The efficacy of vein ligation as a prophylactic against pulmonary infarction complicating thrombophlebitis is not brought out. The value of muscle biopsy in the diagnosis of Buerger's disease seems to have escaped notice. The work of Beck and O'Shaunnessy in the treatment of coronary artery disease has apparently not impressed the author. There is no mention of the erythrocyte sedimentation rate as an aid to the diagnosis of coronary occlusion. The brilliant results of pericardiectomy for compressive pericarditis are dismissed with a single line. The administration of dilute hydrochloric acid to patients with pernicious anemia still gives symptomatic relief.

There will also crop up certain differences of opinion in the matter of treatment. It is doubtful that the treatment of pulmonary tuberculosis may be adequately presented in three scant pages. The treatment of aortic aneurysm carries an optimistic note that may bring disappointment. There is certainly no unanimity of opinion that coronary dilators are of little value after the coronary infarction has occurred.

There are some startling innovations in the classification of disease. Lobar pneumonia and typhoid are no longer acute infectious diseases. They are respectively diseases of the respiratory and gastrointestinal tract. It would seem equally logical to treat erysipelas as a disease of the skin. It is difficult to see why agranulocytic angina is a disease of the hematopoietic system while acute mononucleosis is an acute infectious disease.

These minor criticisms should not be allowed to militate against the general excellence of the book. It is obvious that perfection is unattainable but Dr. Meakins has come as close to it as any one perhaps a wee bit closer. The student and the practitioner will find this book filled with essential in-

formation presented in a delightful fashion and well worth careful perusal.

G. K. FENN

A MONOGRAPH by an experienced anesthetist written for anesthetists is Maxson's *Spinal Anesthesia*.¹ It contains a thorough discussion of the problems which confront one in spinal anesthesia. Simple black and white diagrams elucidate the anatomical and physiological considerations pertinent to this method. The various drugs used in the technical variations, the failures, difficulties, dangers and mortality, the complications and late sequelae, advantages and disadvantages, indications and contra-indications, and finally special techniques are given due consideration.

The use of hypobaric instead of hypotonic solutions sounds a little unfamiliar. The bradycardia observed in high spinal anesthesia is attributed to a partial block of the cardiac accelerator fibers, which is not confirmed by experience with the paravertebral block of the upper dorsal sympathetic ganglia. A more likely explanation is a central vagal stimulation caused by the fall in systemic blood pressure. While the author emphasizes the importance of maintaining blood pressure during anesthesia, he does not seem to stress the harmful effect on cerebral and coronary circulation of even temporary and moderate dips of the pre-anesthetic level. Not only the novice as the author recommends but the experienced anesthetist can benefit by blood pressure determinations as they frequently precede the clinical signs and symptoms of acute hypotension.

The author modestly refrains from recommending a definite type of technique and quotes verbatim many authorities. This may be an advantage to experienced anesthetists. It must be remembered however that thousands of general surgeons throughout the country are in need of a simple safe and generally applicable technique. It is to be hoped that in a future edition the author will recognize this existing need. Even if large institutions will continue to build up efficient departments of anesthesia, surgeons in smaller communities will have to be doing their own spinal anesthesia with a control of blood pressure by a nurse. The method has its place in surgical practice.

CRAZ DE TAPATS

THERE has been a complete revision of the text of *Urology*² since the last edition a years ago. The book retains the former divisions of chapters according to the individual components of the urinary tract as applied to both sexes and those of the male genital tract. The chapter on gonorrhea in the female has been revised by Irving F. Stein.

The new edition is profusely illustrated and contains some excellent new views of genital lesions. In this connection there is included an outline of treatment of early syphilis as adopted by the Co-Opera-

¹SPINAL ANESTHESIA. By LOUIS H. MAXSON, A.B., M.D. Foreword by W. WAYNE HARBROOK, M.D., LL.D., F.A.C.S. Philadelphia: L. & W. 1936. 164 pp. \$2.50. (P. 1936) 1936.
²UROLOGY. By D. WELSH N. LIPPINCOTT, M.D., and HARRY C. ROBINSON, M.D. 4th ed. Philadelphia: J. B. Lippincott Co. 1936.

tive Clinical Group of the United States Public Health Service. This revision embraces the newer studies of the male sex hormones and the gonadotropic principle found in the urine as applied to diagnosis and treatment.

There is an excellent chapter by Maurice Muschat on neurogenic dysfunction of the bladder. The space devoted to non-tuberculous and tuberculous infections, nephrolithiasis and renal tumors, includes the recent changes in the concepts of their etiology, diagnosis, and treatment. The medical aspect of nephritis receives its just place in the urologic textbook. Special chapters are devoted to urology in the female and in children.

It is gratifying to note that the sections on gonorrhea have been condensed into two chapters. In the former editions, as well as in most urologic texts, the large amount of space devoted to this subject is confusing to the student. The authors have long been noted as authorities on anomalies, and on the genital tract, so naturally the sections are monographs on these subjects. The two chapters on sterility in the male and the sex neuroses are handled in a direct and simple manner without the usual confusion. The short section on anesthesia is admirably managed and complete, although surprisingly brief.

An inspiring innovation is the introduction of a page before each section, entitled "Orientation," in which the student and practitioner are briefly acquainted with the subject matter and purpose of that section. Each chapter is headed by a short list of its contents and relative position in the text. The table of contents is in great detail and the index is complete. This edition omits the use of heavy type for emphasis, which adds greatly to the appearance of the page.

Eisendrath and Rolnick's book is the best of its kind for the student and practitioner.

L. L. VESEEN

EVERY medical student and physician is well aware of the fact that neurophysiology is a complex subject. One reason for this is that very few comprehensive and well organized treatments of the subjects have been available, and none have been available which contain the important recent advances in this field. Most reviews and discussions of the subject include such a wealth of uncorrelated detail and the presumption of an intimate knowledge of the subject that the average reader is unable to see the forest because of the trees. Fulton in *The Physiology of the Central Nervous System*¹ has very successfully correlated the details of neurophysiology in an intelligible and logical manner. The book begins with the sensory receptor organs and nerves, proceeds to a discussion of the intimate behavior of the reflex arc and its component parts, then takes up the activities of the spinal cord, medulla, pons, mesencephalon, the autonomic system, the hypo-

thalamus, thalamus, the various functional areas and systems of the cerebrum, and concludes with an exposition of the functions of the cerebellum.

Each chapter begins with an informative historical note and concludes with an excellent and most helpful summary. The liberal use of subheadings, italics, and illustrations are of considerable aid to the reader. Where necessary, sections or whole chapters are devoted to anatomical description. The book is invaluable if for no other reason than that its complete and accurate bibliography contains 1361 titles.

The book is thoroughly up-to-date for it covers the literature up to within several months of its own date of publication. The reader cannot fail to be impressed with the rapid advances that have been made in recent years in this field, for the greater proportion of the text is concerned with material reported within the past eight years.

Throughout the text the comparative viewpoint is emphasized. Where species differences occur, they are clearly indicated and their significance is pointed out. In this way the differences instead of being confusing are illuminating, for they reveal the gradual transition from lower forms to man. In this connection the more recent findings in the higher primates are carefully considered, since they provide the important link between the lower mammals and man.

The outstanding characteristic of this book, and one which will earn it many grateful readers, is its splendid organization. Although one might take exception to some of the views expressed by the author, the fact that a high degree of order has been introduced is sufficient reason to render the book very valuable to anyone who desires to know more about the physiology of the nervous system.

A. C. IVY

CABOT'S *Physical Diagnosis*² needs no introduction to the medical profession. The first edition offered in 1900 and now entirely re-edited in its twelfth edition is indeed worthy of the part it has taken as an outstanding reference book for the practitioner of medicine and especially as a textbook for the medical student in the correlation of physical findings and organic disease. Dr. Adams has collaborated with the author in the composition of this edition and now the book in its twelfth edition bears the double authorship.

Some three hundred more pages of material has been added over the eleventh edition, although the opening chapters are similar, with emphasis on the importance, method and plan of history taking, followed by general consideration of the patient as a whole. Then regional examinations are taken in order, with clear and complete discussion of the technique of percussion and auscultation greatly amplified with numerous illustrations. Following are separate chapters devoted to rheumatic heart dis-

¹PHYSIOLOGY OF THE CENTRAL NERVOUS SYSTEM. By J. F. Fulton, M.A., B.Ph. (Oxon), S.B., M.D. London, New York, and Toronto: Oxford University Press, 1938.

²PHYSICAL DIAGNOSIS. By Richard C. Cabot, M.D., and F. Dennette Adams, M.D. 12th ed. Baltimore: William Wood & Co., 1938.

ease cardiac decompensation, systemic hypertension and coronary disease. Throughout the chapters on pulmonary disease, and the abdomen the same plan of presentation is continued with correlation of the findings and underlying pathology. The chapter on Examination and Diseases of the Joints has been greatly enlarged with diagrams of the normal joint movements and their degrees of rotation, flexion or extension. The final chapter has been devoted

to the nervous system and is much more detailed than in earlier editions illustrating with pictures the method of obtaining reflexes and ending with the disease entities and the pathological findings.

Throughout the entire twelve editions no one edition has been rewritten with more benefit to the reader and it will undoubtedly continue in its established place as an outstanding modern conception of this subject.

CORRESPONDENCE

THE FRANCIS AMORY SEPTENNIAL PRIZE OF THE AMERICAN ACADEMY OF ARTS AND SCIENCES

IN compliance with the requirements of a gift under the will of the late Francis Amory of Beverly, Massachusetts, the American Academy of Arts and Sciences announces the offer of a septennial prize for outstanding work with reference to the alleviation or cure of diseases affecting the human genital organs to be known as the Francis Amory Septennial Prize. The gift provides a fund the income of which may be awarded for conspicuously meritorious contributions to the field of knowledge.

During the said septennial period next preceding any award thereof through experiment, study or otherwise in the diseases of the human sexual generative organs in general. The prize may be awarded to any individual or individuals for work of extraordinary or exceptional merit in this field.

In case there is work of a quality to warrant it the first award will be made in 1940. The total amount of the award will exceed ten thousand

dollars and may be given in one or more awards. It rests solely within the discretion of the Academy whether an award shall be made at the end of any given seven year period and also whether on any occasion the prize shall be awarded to more than a single individual.

While there will be no formal nominations and no formal essays or treatises will be required the Committee invites suggestions which should be made to the Arts and Sciences Committee care of the American Academy of Arts and Sciences, 28 Newbury Street, Boston, Massachusetts, U.S.A.

A TECHNIQUE OF THYROIDECTOMY PERMITTING THE USE OF SILK

A CORRECTION

In the article by Drs. Donald Guthrie and M. J. Brown entitled "A Technique of Thyroidectomy Permitting the Use of Silk" which appears in the April issue, p. 801, an error has been made in the names of the muscles in the text on pages 806 and 808. In the illustration and the caption of Figure 13 and in the caption of Figure 6 the word "thyroid" muscle should read "sternothyroid" muscle.

AMERICAN COLLEGE OF SURGEONS

A REVIEW OF THE CLASSIFICATION OF BONE TUMORS

JAMES EWING, M D, New York, New York

IN 1928, The Bone Sarcoma Registry of the American College of Surgeons prepared a classification of bone sarcomas and recommended its adoption by surgical clinics. While the classification was not entirely satisfactory to the committee, it was felt that its tentative adoption would facilitate the interchange of views and the progress of knowledge of this complex group of diseases.

The classification was as follows

- A Osteogenic Sarcoma
 - 1 Medullary and subperiosteal
 - 2 Telangiectatic
 - 3 Sclerosing
 - 4 Periosteal
 - 5 Fibrosarcoma, medullary, periosteal
 - 6 Parosteal, capsular
- B Giant Cell Tumors
- C Endothelioma
 - 1 Angiosendothelioma
 - 2 Diffuse endothelioma
- D Myeloma
 - 1 Plasma cell myeloma
 - 2 Myelocytoma
 - 3 Erythroblastoma
 - 4 Liposarcoma

Liposarcoma was omitted from the original list because of scanty material, and the existence of well defined reticulum cell lymphosarcoma was not sufficiently established to warrant its recognition at that time.

This classification received rather wide approval in American clinics and its influence in foreign clinics was apparent in many subsequent contributions in this field. After this rather long interval and trial it has seemed to the committee that it should be reviewed and any changes introduced which later experience may have suggested.

During the past few years a few other classifications have been proposed and have received certain recognition, and these may be discussed here.

The committee's classification and its proposed revision are based on histogenesis, and it will be observed that this principle has been followed

rigidly throughout. The designation of subvarieties is based on pathological anatomy because this method lends itself to the practical needs of surgeon, radiologist, and pathologist. However, it is not possible to subdivide the true myelomas on pathological anatomy because gross features of the myelomas are much alike, and here the designation of subvarieties is based on histogenesis or cell of origin. These principles accord with those now employed in the classification of tumors in general and of most other pathological processes. In 1931, Geschicter and Copeland proposed another classification, somewhat similar to the other, but based ostensibly on the embryology of bone.

TUMORS RELATED TO OSTEOGENESIS

A Tumors derived from precartilaginous connective tissue

1

- 1 Osteochondroma or benign exostosis
- 2 Chondroma or benign chondromyxoma
- 3 Primary chondromyxosarcoma
- 4 Secondary chondromyxosarcoma

B Tumors related to subsequent cartilaginous growth

2

- 1 Chondroblastic sarcoma
- 2 Osteolytic osteogenic sarcoma
- 3 Bone cyst and osteitis fibrosa
- 4 Benign giant cell tumor

3

- 1 Primary lymphoma of bone (Endothelial myeloma of Ewing)
- 2 Multiple myeloma
- 3 Metastatic carcinoma
- 4 Fibrosarcoma and neurogenic sarcoma

There are several substantial defects in this classification. It departs radically from all previous usage and introduces new and novel conceptions which are not well established facts. It overemphasizes the participation of cartilage in bone sarcomas, five of nine subdivisions being types of chondroma or chondrosarcoma. It subordinates the important features of pathological

A Report from the Committee of the Registry of Bone Sarcoma, of the American College of Surgeons

anatomy which are of the greatest practical importance to surgeon, radiologist, and pathologist and which as a rule must form the basis of clinical diagnosis. Osteoblastic and osteolytic osteogenic sarcomas probably arise from the same cells, the rate of growth and other physiological properties determining the presence or absence of bone. The term *osteolytic sarcoma* invites inaccuracy and confusion, since so many different tumors of bone are osteolytic. It would seem better to recognize the osteolytic sarcomas as the higher grades of malignancy of the essential varieties rather than as a special group.

Osteitis fibrosa is not a neoplastic process except when associated with giant cell tumors. Too little attention is given to the various forms of fibrosarcoma. Nothing is gained by omitting the well defined periosteal fibrosarcoma. On the other hand the separation of neurogenic from other form of fibrosarcoma is properly emphasized. Lymphoma is too general a term to designate any of the specific tumors of bone marrow. The various subdivisions of true myeloma can hardly be omitted from any adequate list of tumors of bone marrow. Endothelioma was probably assigned to the lymphoma class because of inadequate data.

On the other hand the questions raised by these authors emphasize the need of a special grouping of the series of cartilaginous tumors, and also the probable participation of embryological disturbances in the origin of certain sarcomas of bone.

Another classification has been recently suggested by Dahl:

- A
 1 Periosteal or sclerosing sarcoma
 2 Periosteal chondromyxosarcoma
 3 Central osteolytic sarcoma
 4 Central osteolytic chondroblastic sarcoma
 B Endothelioma (Ewing's sarcoma)
 C Myeloma
 D Periosteal fibrosarcoma
 E Osteitis fibrosa and sequel

This classification emphasizes certain clinical and pathological features which are undoubtedly of interest such as the variations in structure of tumors in or under the periosteum, the osteolytic property of certain cartilaginous tumors and the separate position of osteitis fibrosa and its sequel. Yet we cannot see the grounds for separating between periosteal fibrosarcoma and periosteal sclerosing sarcoma. Sclerosing sarcoma is a term firmly attached to the central sclerosing osteogenic sarcomas. When cartilage forms in tumors connected with periosteum the cartilage seems to

arise from the underlying bone and not from the periosteum proper. Central osteolytic tumors are of several types. The response to Dahl's classification is not apparent.

COMMENTS ON THE COMMITTEE'S CLASSIFICATION

Considerable discussion has occurred regarding the validity of the term "osteogenic" to designate tumors derived from bone. It has been asserted that this term may signify only "producing bone." Yet Webster's dictionary (1937) defines osteogenic as meaning "originating in bone." This is exactly the sense in which that term is employed in the committee's classification. There are other familiar instances in which the same use is made of the suffix genetic, as hemato-genous jaundice, bronchiogenic carcinoma, etc.

The term osteosarcoma was rejected as unsatisfactory as a general term because it has long been identified with bone production and applied more specifically to the bone forming sarcomas and particularly to the sclerosing forms.

Medullary and subperiosteal osteogenic sarcoma is the term applied to the typical form of bone sarcoma which arises from the shaft of the bone and grows freely into the marrow cavity and also underneath the periosteum. It lifts the periosteum and produces the characteristic triangle of Codman. The committee endorses the use of this term as accurately reflecting the origin of the tumor and meeting the needs of pathological anatomist, surgeon and radiologist. Sclerosing osteogenic sarcoma has been recognized as one of the best defined types of bone tumors ever since its original description by Virchow. Periosteal sarcoma of spindle cell structure varying grades of malignancy, absence of bone production and peculiar metastatic tendencies presents such notable specific features as to require recognition as a separate type of bone sarcoma. The origin from the outer layer of the periosteum and preservation of the shaft serve to distinguish it roentgenographically from the destructive forms of bone tumors. The Registry now contains several cases which emphasize the remarkable predilection of this tumor to produce multiple metastases in the periosteum of many other bones, a feature rather exclusively enjoyed by this process and suggesting peculiar physiological properties. Very wide differences in grades of malignancy are presented in this group, some being fibrous, others large spindle cell, and many very small spindle cell structures with increasing malignancy and metastatic powers.

The medullary fibrosarcomas constitute a limited group of processes the exact nature ori-

REVISED CLASSIFICATION OF BONE TUMORS 1939

	Malignant	Benign
1 Osteogenic series	1. Medullary and subperiosteal	1 Exostosis
Osteogenic sarcoma	2 Telangiectatic	2 Osteoma
	3 Sclerosing	
	4 Periosteal	
	5 Fibrosarcoma	
	(a) Medullary	
	(b) Periosteal	
2 Chondroma series	6 Parosteal, capsular	1 Chondroma
	1 Chondrosarcoma	
	2 Myxosarcoma	
3 Giant cell tumor series	1 Malignant	1 Epiphyseal giant cell tumor
4 Angioma series	1 Angioendothelioma	1 Cavernous angioma
	2 Diffuse endothelioma	2 Plexiform angioma
5. Myeloma series	1 Plasma cell	
	2 Myelocytoma	
	3 Erythroblastoma	
	4 Lymphocytoma	
6. Reticulum cell lymphosarcoma		
7. Liposarcoma		

gin, and relations of which require further study, but the existence of peculiar tumors of this type, not related to any other medullary process, such as central *chondroma* or *endosteal* proliferation, must be conceded. The Registry contains a few such cases which have been recognized as peculiar but have been passed over without any serious attempt at elucidation. Very widespread lesions of this type have been observed. A possible connection with Paget's disease has been suggested.

Steiner has registered a remarkable case of diffuse spindle cell medullary fibrosarcoma affecting chiefly pelvis and sternum but appearing in other bones and associated with peculiar fibrosarcomatous lesions in several organs. A possible relation to Paget's disease, or neurofibrosarcomatosis, may be considered in explanation of such conditions, as of other medullary fibrosarcomas.

Capsular and parosteal sarcomas may with difficulty be given admission to the elite group of osteogenic sarcomas. They arise from fibrous capsules of joints and deep fasciæ, often produce bone and cartilage, and may be intimately attached to the bone, but they do not originate from true bone tissue. Practically it may be very difficult for surgeon or radiologist to detect their spurious claims. The capsular tumors must be distinguished from fibrocellular synoviomias and chondromas. The fibrous, cartilaginous, osseous or cellular fascial sarcomas of Virchow belong with the parosteal group, but the deep intermuscular myxosarcomas do not, although they may contain metaplastic areas of cartilage. Various forms of bony metaplasia may be seen in the deep neurofibrosarcomas, which compose the majority of parosteal sarcomas.

Telangiectatic bone sarcoma, a form of malignant bone aneurism, is a very characteristic bone tumor, but its exact origin and relation to other bone sarcomas have not been satisfactorily determined. There is considerable evidence suggesting that this process belongs with the tumors of blood vessels of bone and is a cavernous angiosarcoma, and that the rich proliferation of malignant cells and scanty atypical bone deposits are to be interpreted as phases of reactive productive osteitis. Typical cases, such as those depicted in *Neoplastic Diseases*¹, are not common in the Registry. These tumors tend to remain circumscribed, some are very malignant and destructive, producing no bone, while a few grow more slowly and lay down some reactive bone. There seem to be transitional stages between benign aneurismal giant cell tumors and the cases now being classed as vascular osteogenic sarcoma. Further data seem necessary before the true nature and relations of the so called telangiectatic bone sarcoma can be determined, and these data should relate to the part played by blood vessels in the origin and growth of other osteogenic sarcomas. Their intimate clinical connections with other malignant bone tumors seem to warrant their retention, for the present, in any complete grouping of bone sarcomas.

Cartilaginous bone sarcomas. Considerable basis exists for the recognition of a special group of bone tumors derived from cartilage and producing cartilage. These tumors arise from pre-existing normal cartilage or from remnants of cartilage displaced by rickets, or from chondromas or ecchondroses. The growths tend to be bulky and

they may reach very large dimensions. In the roentgenogram they are usually circumscribed, multilobed, and translucent and very opaque calcific deposits are characteristic. All these features have been emphasized especially by Pheister.¹ There are many structural varieties and all grades of malignancy. Some resemble normal hyaline cartilage and are benign, others cellular with mucinous and cystic degeneration, many exhibit a typical scanty matrix, many cells and definite malignancy, a few show advanced or complete mucinous degeneration yielding pure myxosarcomas. Calcification overtakes some areas in many tumors of this type, and giant cells of epulis type appear in certain cases. Cartilaginous material may be entirely missing in malignant tumors derived from cartilage, in which case the cells show a peculiar polyhedral or epithelioid form. The benign calcifying giant cell tumor of the head of humerus, previously mentioned, may well belong in this group of calcifying degenerating chondromas. The periosteal and the medullary myxosarcomas are probably of cartilaginous origin. If the cartilaginous series of tumors is to be separated from other osteogenic sarcomas, the list would include the following forms:

A Benign echondrosis, chondroma and osteochondroma, periosteal and medullary

B Chondrosarcoma

C Myxosarcoma

Giant cell tumors. It can hardly be said that the accumulated efforts of surgeons, radiologists, pathologists, endocrinologists, and chemists, during the past decade have succeeded in simplifying our interpretation of the complex group of processes included under this term. Probably the outstanding contribution is the proof that single and often multiple typical giant cell tumors are dependent on the mobilization of calcium from the bones under the influence of parathormone secreted in excess by overactive and generally hyperplastic parathyroid glands. Whether solitary giant cell tumors of identical structure and behavior are also the sequels of previous but transient disturbance of calcium metabolism is less certain but would seem to be a reasonable assumption. In that case the great majority of giant cell tumors would fall readily in one grand class without too much regard to minor differences of structure and clinical behavior. Against this simple solution lies the fact that many observers have noted definite and apparently primary changes in the blood vessels of bone and have attributed the giant cell reaction to the sequels of an angiomatous process. The promi-

nence of blood vessels was noted by early students of giant cell tumors and recently Pühr has likened these early stages to cavernous angioma of the liver (and to the so called hemangiomas). In a well known group of giant cell tumors the gross structure is much like that of benign cavernous angioma, in which the giant cell reaction is merely a sequel of the absorption of bone by the angioma. It would seem possible that such low grade angiomatous processes might follow calcium absorption dependent primarily on parathyroid disturbances but this explanation applies less readily to the more active vascular tumors. In some giant cell tumors, the blood vessels are not prominent and the tumor is solid and cellular. While a traumatic history is often obtained in cases of giant cell tumor, a traumatic origin has not been satisfactorily proved and attempts to produce such tumors of bone by trauma have failed. Whatever may be the true pathogenesis of giant cell tumors the main group remains quite compact and characteristic and varies chiefly in grade of malignancy. It is now readily apparent that there are all grades of malignancy among giant cell tumors and that in certain not infrequent cases the structure changes from a benign to a malignant type, especially after curettage or interstitial radiation, and sometimes in the normal course of very prolonged cases.² Some of the tumors are malignant from the first and some become so and since it is highly important to recognize such variations, the best plan would seem to be the adoption of the simple method of grading the tumors in the usual manner according to degrees of malignancy. Grade 1 would then signify the benign simple essentially inflammatory process which many authors have refused to recognize as neoplastic. Grade 2 would designate the ordinary benign but progressive cases. Grade 3 would refer to the aggressive cellular forms with scanty giant cells and grade 4 the primary atypical hyperchromatic large spindle cell and giant cell malignant metastasizing growths of which there are now not a few cases on record. Aneurismal growths do not fall into this scheme and may be specially designated.

There remain several variants or related forms of benign medullary tumors with giant cells which are not so easily disposed of. Certain benign circumscribed spindle cell myxosarcomas with few or no giant cells are observed which run the usual course of giant cell tumors and should probably be included in this group.

The benign calcifying giant cell tumors of the head of the humerus and occurring in other bones

reported at the International Cancer Congress in London, 1928, and first fully described by Codman,¹ are characteristic benign processes, generally mistaken for malignant osteogenic sarcomas and treated as such by amputation, whereas they are readily cured by radiation. In order to avoid this unfortunate error it is desirable that this peculiar tumor should receive special recognition and a distinguishing designation. The structure presents strands of calcifying cartilage, cords of small polyhedral cells, and a moderate number of giant cells. As emphasized by Geschichter and Copeland, giant cells also occur in malignant chondrosarcomas in this and other regions, and these tumors must be distinguished histologically from the benign process here described.

Endothelioma (Ewing's sarcoma) The existence of a specific variety of bone sarcoma of this general type has been widely accepted but its histogenesis is still under active debate. Oberling and Raileanu² and others have presented evidence to show that this tumor arises from the reticulo-endothelial system and that the tumor cells exhibit capacity to differentiate into plasma cells, myelocytes, lymphocytes, and even erythroblasts. According to this view, the tumor represents a form of totipotent myeloma capable of forming any one of the specific types of myeloma. This interpretation seems to have been rather widely accepted in Europe.

The writer cannot accept this view and believes that the eminent French investigators have failed to distinguish between a specific type of endothelial tumor and other rarer round cell myelomas among which may probably be some that arise from the hematopoietic cell system or indifferent lymphoid reticulum cells. The writer believes that the typical endothelioma of bone arises from capillary endothelium and never exhibits any other properties than those belonging to vascular endothelium. The pseudo-rosettes, the characteristic perithelial structures, and the cords of polyhedral cells lining elongated spaces are the outstanding structural features of this tumor and they never appear in any tumor derived from hematopoietic cells or reticulum cells. Plasma cells, granular leucocytes and lymphocytes are notably absent from tumors presenting these features, and when they are present the tumor should be excluded from the group of endothelioma. Moreover, in many cases of endothelioma there are associated with the above structural features, dilated blood channels of various sizes composed

of the typical tumor cells, disclosing the angio-blastic properties of the cells and connecting the tumor with other angiomas or angiosarcomas. Similar features are observed in capillary angiosarcomas of other organs, notably the skin.

According to the present available observations, it seems desirable to recognize a special class of bone tumors arising from blood vessels, with varying structure and degrees of malignancy, as follows:

- A. Cavernous angioma
- B. Plexiform angioma (sun-ray radiological type)
- C. Angio-endothelioma, with fine blood channels lined by single rows of endothelial cells
- D. Diffuse endothelioma, with pseudorosettes, and perithelial units, (Ewing's sarcoma).

The contribution of Oberling and Guerin is important in emphasizing the variety of cell types which appear in true myelomas of the hematopoietic series and attention to which may permit the more accurate separation between true myelomas arising from specific marrow cells, and endothelioma arising from the capillary endothelium of bone tissue.

Myeloma The group of true myelomas, arising from specific marrow cells, not connected with bone, remains an alluring and difficult field for histological exploration, but the main varieties of these neoplasms have become more firmly established during the past decade. The chief contribution has been that of Oberling and Raileanu, who have furnished substantial basis for the recognition of a group of reticulum cell sarcomas, or lymphosarcoma. They have also apparently shown that some tumors arising from the reticulum cells of the bone marrow may differentiate toward plasma cell, or lymphocytic, or myelocytic, or erythroblastic subvarieties. Yet all observers have not accepted this wide potency of the simple reticulum cell of the bone marrow, and certainly the main varieties of myeloma previously recognized, are generally quite distinct. These varieties are, plasma cell myeloma, myelocytoma, lymphocytoma, erythroblastoma. The existence of a pure reticulum cell lymphosarcoma of bone marrow was recognized many years ago by Kaufmann. He stated that the cells were larger than plasma cells, resembled large or small reticulum cells, with giant cells, and a reticular matrix was present. Craver and Copeland³ have reported 16 cases of this class, in some of which the disease was primary in the bone marrow, the patients did not suffer from cachexia or anemia of myeloma but were generally in fair condition

¹Codman Surg., Gynec. & Obst., 1931, 52: 543

²Oberling, Raileanu Bull. franc. Cancer, 1932, 21: 333

³Craver and Copeland Arch. Surg., 1934, 28: 809

they may reach very large dimensions. In the roentgenogram they are usually circumscribed, multilobed, and translucent and very opaque calcific deposits are characteristic. All these features have been emphasized especially by Phemister.¹ There are many structural varieties and all grades of malignancy. Some resemble normal hyaline cartilage and are benign, others cellular with mucinous and cystic degeneration may exhibit a typical scanty matrix, many cells and definite malignancy, a few show advanced or complete mucinous degeneration yielding pure myxosarcomas. Calcification overtakes some areas in many tumors of this type and giant cells of epulis type appear in certain cases. *Cartilaginous material may be entirely missing in malignant tumors derived from cartilage, in which case the cells show a peculiar polyhedral or epithelioid form.* The benign calcifying giant cell tumor of the head of humerus previously mentioned may well belong in this group of calcifying degenerating chondromas. The periosteal and the medullary myxosarcomas are probably of cartilaginous origin. If the cartilaginous series of tumors is to be separated from other osteogenic sarcomas, the list would include the following forms:

A. Benign *enchondroma*—*chondroma* and *osteochondroma*, periosteal and medullary

B. Chondrosarcoma

C. Myxosarcoma

Giant cell tumors. It can hardly be said that the accumulated efforts of surgeons, radiologists, pathologists, endocrinologists and chemists, during the past decade have succeeded in simplifying our interpretation of the complex group of processes included under this term. Probably the outstanding contribution is the proof that single and often multiple typical giant cell tumors are dependent on the mobilization of calcium from the bones under the influence of parathormone secreted in excess by overactive and generally hyperplastic parathyroid glands. Whether solitary giant cell tumors of identical structure and behavior are also the sequels of previous but transient disturbance of calcium metabolism is less certain but would seem to be a reasonable assumption. In that case the great majority of giant cell tumors would fall readily in one grand class, without too much regard to minor differences of structure and clinical behavior. Against this simple solution lies the fact that many observers have noted definite and apparently primary changes in the blood vessels of bone and have attributed the giant cell reaction to the sequels of an *angiomatous* process. The promi-

nence of blood vessels was noted by early students of giant cell tumors and recently Fuhr has likened these early stages to cavernous angiomas of the liver (and to the so called hemangiomas). In a well known group of giant cell tumors the gross structure is much like that of benign cavernous angioma in which the giant cell reaction is merely a sequel of the absorption of bone by the angioma. It would seem possible that such low grade angiomatous processes might follow calcium absorption dependent primarily on parathyroid disturbances but this explanation applies less readily to the more active vascular tumors. These varieties are, plasma cell myeloma, myelocytoma, lymphocytoma, erythroblastoma. The existence of a pure reticulum cell lymphosarcoma of bone marrow was recognized many years ago by Kaufmann. He stated that the cells were larger than plasma cells, resembled large or small reticulum cells, with giant cells, and a reticular matrix was present. Craver and Copeland³ have reported 16 cases of this class, in some of which the disease was primary in the bone marrow, the patients did not suffer from cachexia or anemia of myeloma but were generally in fair condition

¹Codman Surg., Gynec. & Obst., 1931, 52, 543

²Oberling, Raileanu Bull. franc. Cancer, 1932, 21, 333

³Craver and Copeland Arch. Surg., 1934, 28, 809

until shortly before death, the usual extensions of the disease to lymph nodes was observed and the structure was that of pure reticulum cell sarcoma. Parker has described a series of such cases primary in the bone marrow.

The committee therefore recommends the recognition of pure reticulum cell lymphosarcoma and urges the further study of this entire group along the lines pursued by Oberling and Raileanu. The committee is inclined to exclude this tumor from the group of true myelomas.

Since the report of liposarcoma of bone marrow in 1928 (London Cancer Congress), there have been few examples of this characteristic malignant tumor recorded, but enough to warrant its recognition in the present classification. Since it has no connection with specific marrow cells, the committee would exclude it from the group of true myelomas. Stewart¹ has reported in detail one case and another has been reported by Rehbock and Hauser. This tumor is probably more frequent than is now recognized.

The main results of the present review may be stated as follows. The validity and practical value of the classification originally proposed by the committee are in general, confirmed, but certain changes and additions are required to meet observations made during the past decade.

The introduction of a separate group of tumors derived from cartilage and producing cartilage is theoretically justified and would be of practical advantage. A new group of tumors of blood vessels is introduced and diffuse endothelioma is assigned to this group.

Malignant giant cell tumors are recognized, and their occasional occurrence is emphasized. Epiphyseal giant cell tumors generally running a benign course are given a special entry.

The group of myelomas is limited to those tumors arising from specific marrow cells.

Reticulum cell lymphosarcoma arising in bone marrow is accepted as a well established variety.

Liposarcoma, arising from the fat cells of bone marrow is accepted as a definite entity.

The benign tumors of bone are included in the classification.

Secondary tumors of bone are excluded although the claims of certain neurosarcomas and of adamantinoma may be noted.

A review for the literature on bone sarcoma of the past decade reveals the fact that we are still struggling with the complexities of simple pathological anatomy and histology and that there are few attempts to penetrate the field of etiology and pathogenesis. The accurate diagnosis of a bone sarcoma remains a rather difficult task. There is little doubt that the adoption of an adequate classification of these tumors, with as many subdivisions as necessary, would be a distinct step forward. Unless the surgeon and pathologist are familiar with what may happen in the bone, he is hardly able to recognize what has happened. Yet the time would seem to have arrived when more definite efforts should be made to investigate the etiology of these processes by all means available. The recognition that giant cell tumors may be the sequel of parathyroid hyperactivity, and that malignant bone sarcomas inevitably result from the deposit of radium in the bones are outstanding contributions, which point the way to further investigations. Studies of the relation of phosphatase to bone growth have also thrown some light into a very obscure field and should be pursued further. The subject of traumatic bone sarcoma has made little progress but it would seem very desirable that no report of a supposed traumatic bone sarcoma should receive a hearing unless the case has been rigidly scrutinized according to recognized medical criteria. No one has produced a bone sarcoma by trauma. The relation of infection to bone tumors has seldom been considered but many such tumors are infected from the first. Some very interesting instances of two or even three bone sarcomas in the same family have been reported. Accordingly the Registry Committee is disposed to limit the registration of cases in the future to those which present some unusual and instructive feature or in which special studies have been made in the field of etiology.

PLANS FOR 1939 CLINICAL CONGRESS IN PHILADELPHIA

THE American College of Surgeons announces the twenty-ninth annual Clinical Congress when the surgeons, medical schools, and hospitals of Philadelphia will be hosts to interested visitors from all parts of the United States and Canada during the five days October 16-20. Preparations for the meeting are being carried forward under the leadership of a representative committee of Philadelphia surgeons.

This group is assured of the full co-operation of the clinicians at the five medical schools and more than forty hospitals that will participate in the clinical program. There will be provided an ample and well arranged schedule of operative clinics demonstrating the technique of a wide variety of surgical procedures. The committee also plans to arrange a series of symposia and demonstration clinics at the medical schools and in the larger hospitals for the presentation of all phases of the work which is being done in general surgery, neurosurgery, traumatic surgery, thoracic surgery, plastic surgery, orthopedic surgery, genito-urinary surgery, obstetrics and gynecology, and other allied specialties. The programs will be so correlated that the visiting surgeon may be assured of an opportunity to devote his time continuously to clinics dealing particularly with the special subjects in which he is most interested. The final program will be published and classified according to the various specialties in order to aid the visiting surgeon in the selection of the clinics which he desires to attend.

A preliminary schedule of the operative clinics and demonstrations is being prepared by the committee for publication in the June issue of *SURGERY, GYNECOLOGY AND OBSTETRICS* and the *Bulletin* of the College. Clinics will be arranged for each day of the meeting beginning Monday afternoon and continuing each morning and afternoon of the following four days. All departments of surgery will be represented therein.

The Executive Committee of the Board of Regents is preparing programs for the scientific sessions to be held each evening. At the opening meeting on Monday evening the retiring president, Dr. Howard C. Naffziger, of San Francisco, will deliver the Presidential Address, and the new officers—Dr. George P. Muller, of Philadelphia, president, Dr. Henry W. Cave, New York, and Dr. D. Edwin Robertson, Toronto, vice-presidents—will be inaugurated. The 1939 class of in-

mates will be received into fellowship at this meeting. On Tuesday, Wednesday, and Thursday evenings eminent surgeons of the United States and Canada, together with a number of visiting surgeons from foreign countries, will present and discuss papers dealing with surgical subjects of timely importance.

Special attention is being given by sub-committees on ophthalmology and otolaryngology in arranging complete programs on these subjects. It is planned to hold clinical demonstrations at headquarters each morning and operative clinics and demonstrations at the local hospitals in the afternoons for those interested in these specialties. Evening sessions will also be held at headquarters, at which visiting ophthalmologists and otolaryngologists will present papers of special interest.

Other features of the 1939 Clinical Congress will include afternoon conferences and symposia dealing with cancer, obstetrics and gynecology, fractures and traumatic surgery, urology, and other subjects. An extensive series of round-table conferences are to be held at headquarters each day. These conferences will cover a wide variety of important subjects of vital interest.

The annual hospital conference will open the Congress with a session at 10 o'clock on Monday morning when the approved list of hospitals, cancer clinics and medical services in industry will be announced. A list of hospitals approved for graduate training in surgery will also be announced at this meeting. In keeping with the importance of these programs of the College, there will be held a series of round table conferences and practical demonstrations, both at headquarters and in the local hospitals, dealing with the many problems related to hospital efficiency, management, and education. It is proposed to make this year's session of wide interest and practical character through a careful selection of subjects to be presented and discussed by surgeons and hospital executives. Particular emphasis will be directed toward the educational programs of hospitals in the training of surgeons.

Headquarters for the Congress will be established at the Bellevue-Stratford Hotel where the several meeting rooms on the top floor have been reserved for conferences, symposia, and clinical assemblies. The evening scientific sessions will be held at Irvine Hall on the campus of the University of Pennsylvania, for which special bus transportation is being arranged.

The Technical Exhibition will be located on the first floor in the Grand Ballroom its large foyers, and adjacent rooms. Here also will be placed the registration and clinic ticket bureaus, and the bulletin boards on which the daily clinical program for the following day will be posted each afternoon. Leading manufacturers of surgical instruments, x ray equipment, operating room lights, hospital apparatus of all kinds, ligatures, dressings, pharmaceuticals, and publishers of medical books will be represented.

The hospitals and medical schools of Philadelphia afford accommodations for large numbers of visiting surgeons, but to insure against overcrowding attendance at the Congress will be limited to a number that can be comfortably accommodated at the clinics. It is expected and urged therefore, that those surgeons who wish to attend the Congress will register in advance.

A registration fee of five dollars is required of each surgeon attending the Clinical Congress. A formal receipt for the fee is issued to each surgeon registering in advance, which receipt is to be exchanged for general admission card upon his registration at headquarters. This card is non-transferable and must be presented in order to secure clinic tickets and for admission to the evening meetings and other scientific sessions.

Admittance to clinics and demonstrations at the hospitals will be controlled by means of special clinic tickets. Such a plan provides the only efficient means for the distribution of the visiting surgeons among the several clinics and insures against overcrowding as the number of tickets issued for any clinic will be limited to the capacity of the room in which that clinic is given.

NUMBER 6

THE SURGICAL TREATMENT OF CHRONIC CONSTRICTIVE PERICARDITIS

GEORGE J HEUER, M D., F.A.C.S., and HAROLD J STEWART, M D.,
New York, New York

IN previous communications¹ the authors presented a study of the circulation in 9 patients with chronic constrictive pericarditis. At the time, 6 of the 9 patients had been subjected to the operation of decortication of the heart so that it was possible in two-thirds of the number to compare the measurements of the circulation before and after the heart had been partially freed of its constricting envelope. Briefly, it was found in this group of patients that the arteriovenous oxygen difference was increased, the venous pressure elevated, and the circulation time prolonged, while the cardiac output per minute, the stroke volume, and the cardiac index (cardiac output in liters per square meter of body surface per minute) were diminished. In the 6 patients subjected to subtotal pericardiectomy, these values tended to, or actually did, return to normal. The plan followed in making these observations and the methods employed are detailed in these communications. These observations have added to our knowledge of the pathological physi-

ology of a disease which, in this country, has been studied particularly by White, White and Churchill, Beck and his associates, and Burwell and Blalock. The clinical manifestations of this syndrome have been well described by White, and it may be of interest again to bring together briefly the symptoms and physical signs which have contributed toward our recognition of this disease.

The diagnosis of chronic constrictive pericarditis should be considered in the presence of signs of congestive heart failure not associated with the common etiological causes. Organic valvular lesions have conspicuously been absent. Enlargement of the liver and ascites usually are present. Edema of the extremities and pleural effusions occur, but less frequently. Distention of the peripheral veins is a constant finding. The cardiac silhouette may be small, approximately normal, or moderately large. The paradoxical pulse has been present in every case in our experience. The pulse usually is small in volume, the blood pressure and pulse pressure low. The point of maximal impulse of the heart may not shift. Under the fluoroscope, decrease in or absence of motion of the several chambers of the heart may be observed, and absence of shifting of the heart may be confirmed. Calcification of the pericardium may

From the Surgical and Medical Departments of the New York Hospital and Cornell University Medical College.

The studies reported in this paper formed the basis of the 15th Arthur Dean Bevan Lecture in Surgery, given by one of us (G J H) in Chicago, Illinois, October 7, 1938.

tissues and body cavities had been removed as much as possible.

ANESTHESIA

Of the 7 patients subjected to operation, 4 were anesthetized by the simple open drop ether method, 2 with drop ether administered through an intratracheal tube (Magill) and 1, with an ethylene-oxygen-ether mixture. All the anesthetics were smooth, satisfactory, and without cyanosis. In 3 of the 5 patients in whom the intratracheal method was not employed, the left pleura was slightly torn in exposing the pericardium. The small openings were immediately closed with fine silk and neither cardiac nor respiratory upsets occurred as a result of these misadventures. In the 2 cases in which the intratracheal method was used, the pleura was not torn. In all cases the pulse was rapid, ranging between 100 and 160, in the majority being 130 or over. It was usually not only rapid but in 2 cases irregular in rhythm. On the other hand, the respiration remained regular, adequate, and unaccompanied by cyanosis. While our experience is too limited to compare different methods of anesthesia in the operation of pericardiectomy, it can be said that ether has been highly satisfactory. In no case did we have the slightest anxiety regarding this part of the procedure. While we did not use intratracheal anesthesia in the majority of cases and our patients failed to suffer any ill effects from the slight opening of the pleura in 3 instances, we are inclined to think that intratracheal anesthesia is desirable. Our experience would indicate that in spite of the greatest care, the left pleura particularly is likely to be opened in exposing the pericardium for resection; and that the opening might be sufficiently large to cause respiratory embarrassment.

In reviewing the literature on this phase of the subject it appears that Schmieden, who has had the largest experience of any single individual abroad, favors local anesthesia. He is of the opinion that the difficulties of the operation are greatly diminished by its use and it is well tolerated by the patient since the pericardium and cardiac musculature are completely insensitive. Churchill favors intra-

tracheal ether anesthesia, believing it desirable to employ general rather than local anesthesia because of the magnitude of the operative procedure and the possibilities of tearing the heart muscle and opening one or both pleural cavities. Beck raised the question whether the exposure of the heart and great vessels to atmospheric pressure was not harmful and concluded from his experimental work that this "pneumocardiac tamponade" caused a dangerous reduction in cardiac output. As a result he suggested a revival of the Sauerbruch negative pressure chamber in operations of this sort. Beck's view that failure of the peripheral circulation due to a reduced filling of the heart is a dangerous aspect of the operation is opposed by that of Churchill who finds that the real hazard of the operation lies in the possible overfilling of a weakened heart suddenly released from the support of its surrounding pericardium. Mindful of the two views we have, in our 7 cases, made particularly careful observations during the course of the operative procedure when the heart and great vessels were exposed to atmospheric pressure. We have been unable to determine that such exposure during the operation was harmful. On the other hand, the rapid enlargement of the heart after the removal of the pericardium, causing it to herniate through the pericardial defect, has been at times distinctly disquieting and has caused us to fear that the heart was being subjected to too great a strain. Churchill operates with patients in the semi-sitting position and keeps them semi-upright during their convalescence with the idea of reducing the venous return to the heart during and immediately after operation. In 7 patients we have seen no ill effects from a recumbent position during the operation and postoperative period. Nevertheless, we think that Churchill's point is well taken; and certainly conditions should be such as to permit changes in the position of the patient on the operating table and in the wards.

A study of the cases reported in the literature shows, as previously noted, that of the 143 patients subjected to operation, 19 died upon the operating table and 28 died during the immediate postoperative period. Of the former, some data regarding the cause of

be seen, or special x ray studies, particularly lateral views may be necessary to demonstrate it. The electrocardiograms are of low voltage of the QRS and T waves, and the latter may be "cove" in form in leads I and II. The electrical axis may not shift or may shift only slightly, but too much emphasis is not to be placed upon this finding. There may be slight left or slight right axis deviation. Normal sinus rhythm is usually present although auricular fibrillation may occur. Since 3 of our patients were observed during the stage of acute pericarditis with pericardial effusion and followed through the successive stages of absorption of fluid and constriction of the pericardium, this sequence of events probably is not uncommon. Patients with pericardial effusion in the absence of rheumatic heart disease should be kept under observation in order to detect the development of constrictive pericarditis. Tuberculosis as a cause of the disease was proved in only 1 of the 7 patients subjected to operation. We have already called attention to the pathological physiology of the circulation in this disease.

The surgical treatment of chronic constrictive pericarditis dates back to 1913 when Rehn and Sauerbruch both resected the pericardium for this disease. Schmieden followed their lead in 1918 and has not only maintained his interest in the surgical aspect of this condition, but has stimulated other surgeons abroad. In this country, Churchill in Boston was the first to perform the operation, and he Beck in Cleveland, and Blalock in Nashville, have shown particular interest in the subject. While the results of surgical treatment undoubtedly are striking, a study of the cases of patients subjected to surgery as reported in the literature shows that the primary mortality following decortication of the heart is still high (33 per cent). Of the 143 cases we have assembled (exclusive of our own) 19 died upon the operating table and 28 died during the immediate postoperative period, in short one third of the entire number subjected to operation. It becomes, then of importance to discover, if possible the factors concerned in the immediate mortality as well as those which influenced the late results. It is with the hope of adding to the general

knowledge of the surgical treatment of chronic constrictive pericarditis that we report our own experiences and our study of the literature. We shall omit further reference to the historical aspects of the subject which have been covered so ably by White.

Of the 9 patients with chronic constrictive pericarditis whom we have studied, 7 have been subjected to the operation of pericardiectomy. All the patients have recovered from operation. Three patients are cured in the sense that their symptoms and signs have disappeared and they are able to lead normal active lives, 3 patients are markedly improved and 1 patient is improved although sufficient time has not elapsed accurately to evaluate the results of operation.

PRE OPERATIVE TREATMENT

The pre operative medical treatment we have used is similar to that in the treatment of heart failure due to other causes. The patients are kept in bed, given a low salt diet (20 grams daily) and a limited amount of fluids (1200 cubic centimeters). A high protein diet has been given because it was indicated in 2 patients due to the low value of their serum proteins and because in the others, it seemed advisable to maintain the level of the serum proteins in order to hold fluids in the blood stream. Of the drugs used to mobilize fluids, mercupurin has been found to be the most satisfactory. It usually is given in 20 cubic centimeter doses intravenously at 3 day intervals. To some patients ammonium chloride 3 grams per day, was given at the same time to enhance the diuretic effect. Theocalcium 4.5 grams daily, urea, 30 cubic centimeters of a 50 per cent solution, twice daily and amino phyllin 0.1 gram three times per day were all tried but with less effect. From our observations the use of digitalis appears to be contra indicated in the medical treatment of these patients. Nevertheless, it seems necessary in those patients exhibiting auricular fibrillation to give this drug in adequate amounts to keep the ventricular rate slow. Abdominal and thoracic paracenteses were resorted to when fluid could not be removed by other measures. Patients were not subjected to operation until fluids accumulated in the

Fig 1 The skin incision used in the approach to the pericardium. A flap of the major pectoral muscle of equal size is reflected laterally with the skin flap.

Fig 3 Pericardium exposed. An incision is made through it over left ventricle, a cleavage plane between it and cardiac muscle is established. Mobilization of pericardium is carried out with knife, scissors, or blunt dissection.

Fig 2 Skin-muscle flap reflected laterally. The second to fifth costal cartilages, inclusive, with adjacent segment of rib are resected subperichondrially and subperiosteally. An incision is carried through intercostal muscles which are reflected laterally as an additional flap.

Fig 4 The resection of the pericardium completed.

death appear in 12, of the latter, in 23. It does not appear from these data that anesthesia was responsible for the deaths. These findings together with our own experience indicate that anesthesia, excepting by those in desperate condition, is well tolerated by patients with constrictive pericarditis.

APPROACH TO AND EXPOSURE OF HEART

A greater part of the ventral surface of the heart may be exposed by an approach upon the left side of the thorax, and at the primary operation a skin muscle flap is reflected upon this side. The position and extent of the flap may be determined by the position of the heart with reference to the overlying costal cartilages and ribs as shown in the r-ray film. We have found it desirable to expose the heart from its base to its apex, and to do so it may be necessary to resect inclusively the second to the fifth, the third to the sixth, or the second to the sixth costal cartilages and segments of the adjoining ribs. The skin muscle flap is formed by incisions which overlie respectively the uppermost and lowermost costal cartilages to be resected and which are connected by a vertical incision corresponding with the midsternal line (Fig. 1). The major pectoral muscle is freed from the sternum and ribs and reflected laterally with the skin flap. The costal cartilages and segments of the corresponding ribs are resected (Fig. 2). Thus far we have done a subperichondrial and subperiosteal resection and have preserved the intercostal muscles, which are divided at the left sternal border and together with the posterior perichondrium and periosteum are reflected laterally as an additional flap. The dissection is then carried down to the pericardium along the left sternal border and the fat and connective tissue overlying it are carefully freed and stripped laterally carrying with them the reflection of the left pleura. It is during the course of this maneuver that the left pleura may be torn and, therefore, it should be carried out slowly and carefully. The pericardium is freed to the left lateral border of the heart from the apex to the base in the course of which the left phrenic nerve may be brought into view. Having exposed the left pericardium, a similar procedure is

carried out over the right heart and to its right border. In doing so the heart is depressed so as to create a space between it and the sternum, sufficient to allow the subsequent resection of the pericardium. In 6 of the 7 patients subjected to pericardiectomy, it was possible to resect the pericardium over the right heart without resecting any portion of the sternum, in 1 case (Case 7) the resection of the left half of the sternum seemed necessary to obtain sufficient exposure.

A review of the literature shows that surgeons interested in the treatment of this disease are in agreement that the primary approach to the heart should be upon the left side, and that a right-sided approach should be reserved for cases in which at the primary operation the pericardium over the right ventricle cannot satisfactorily be mobilized. Schmieden and Churchill favor the complete resection of the bony thoracic wall over the heart rather than a subperiosteal and subperichondrial resection, believing it desirable that a mobile thoracic wall over the heart should be maintained. In our own cases, the ribs and costal cartilages have been reformed with the restoration of the normal thoracic wall, a condition which thus far in our experience has seemed consistent with satisfactory late results. Churchill and others proceed at once to the resection of the left half of the sternum finding that the additional trauma involved is compensated for by the greater ease in exposure of the right heart.

RESECTION OF THE PERICARDIUM

It has been our practice after fully exposing the pericardium, to incise it over the left ventricle and devote such time as may be necessary in establishing the most satisfactory cleavage plane between it and the heart muscle (Fig. 3). In some cases a satisfactory cleavage plane is at once evident and the mobilization of the pericardium may be proceeded with at once. Again there may appear to be complete fusion between pericardium and myocardium making the dissection of the pericardium a time-consuming matter. In some cases the pericardium is thickened and fibrous but not calcified; in other cases almost a complete bony shell, in still others a fibrous

Fig 6 Case 1 Infra-red photographs showing the gradual disappearance of the venous congestion a, left, December 9, 1936, taken about 10 months after operation, b, November 30, 1937, taken about 22 months after operation. Improvement in this patient was slow but she is now "cured"

tion between pericardium and myocardium well ahead of the cut edge of the pericardium so as to maintain a flap of this structure which we could bring against, and suture to, the heart muscle if it was inadvertently torn. We have also at times abandoned the attempt to separate a plaque of calcification or a particularly adherent piece of pericardium from the heart, thinking it better to leave it as a patch on the muscle than to risk injury to the heart muscle in an attempt to remove it (Fig 4).

How much of the pericardium it is necessary to remove in order to achieve satisfactory results is a difficult question. We have removed

as completely as possible the pericardium over the left and right ventricles, but have not attempted to remove the adherent pericardium over the auricles. An effort has been made to free the apex, and if possible the dissection is carried well down on the diaphragmatic portion of the pericardium. No attempt has been made to go beyond the right auriculo-ventricular groove, nor have we attempted to free the great vessels at the base. Schmieden first removes the pericardium over the left ventricle and believes the primary removal of the pericardium over the right ventricle is dangerous, for the sudden release of the thin-

Fig 5 Case 1 Studies of the circulation before and after operation. These include observations on the circulation time cardiac output and venous pressure. Certain clinical observations before and after operation also are noted.

membrane containing areas or plaques of calcification of various size and distribution. Calcified areas may be present over the right ventricle but not over the left may occur chiefly over the apex and diaphragmatic border of the heart or surround the great vessels at the base. They may be separated easily from the heart muscle or may extend into and involve the heart muscle. It is evident from these considerations that the resection of the pericardium may not be too difficult, or it may be extremely difficult and dangerous.

It has seemed best to us to dissect the pericardium off of the left ventricle first and for the reason that there is less likelihood of tearing into the left than the right ventricle in starting the mobilization of the pericardium. There is also less danger of overdistention of the left than the right heart. The mobilization is carried lateralward so as to free the

apex and left border of the heart, upward to the base of the heart, and downward to the diaphragm. A region where particular care is desirable is the interventricular groove containing the descending branch of the left coronary artery. It is here that adhesions between pericardium and myocardium may be particularly dense and it is possible as in one case in our experience that a part of the artery may be dissected out of its bed with the pericardium, the division of which might seriously interfere with the circulation of the heart. Having safely crossed the interventricular groove the mobilization of the pericardium is carried out over the right heart to the right, if possible to the right auriculoventricular groove, upward to the base of the heart and downward to the diaphragm. It has seemed easiest to resect the pericardium in fragments but we have always carried the line of separa-

Fig 8 Case 2 Studies of the circulation and notation of the prominent physical signs before and after operation

the heart occurred not infrequently, and in the majority of cases the dilatation of the right ventricle and its herniation through the pericardial defect added to the difficulties of the procedure. The manipulations necessary in the mobilization and removal of the pericardium certainly play a rôle in the irregularity of cardiac action. All the circumstances tend to urge the operator to hurry and finish the operation—but it is a tendency to be resisted. It has seemed to us wise to pause periodically in the course of the operation in some cases, in order to allow the heart to regain a more normal rhythm.

That great care in the operative procedure is of importance in the success of the surgical treatment of chronic constrictive pericarditis is evident from a survey of the literature. A study of the records of 19 patients who died

upon the operating table shows that in 7 no data referable to death are given while in 12 some data appear which might suggest the cause of death. Of these 12 deaths, 4 were the result of injury to the auricle (1) or ventricle (3), in 3 it was the result of, or at least associated with, the overdilatation of the right ventricle, in 2 it was ascribed to "cardiac failure" and "ventricular fibrillation" and 1 was the result of pressure pneumothorax. The 2 remaining patients are described as "extremely weak and cyanosed" and in "critical condition" when subjected to operation. Of the 28 patients who died after operation, data regarding the cause of death are lacking in 5. Of the 23 cases in which some data are available, death was due to injury to the ventricle during operation in 2, to wound complications (infection, empyema)

Fig. 7 Case 1. Roentgenograms of chest before and after operation. a left January 27, 1936 taken the day before operation showing the cardiac shadow and pleural effusion. b December 16, 1937 taken 22 months after operation when described as "cured." The earlier x-ray pictures taken before operation are not reproduced because the pleural effusion obscured the cardiac outline.

walled right ventricle at a time when the left ventricle is still supported, may lead to its sudden dilatation and even rupture. He attributes a death on the operating table to such an overdistention. Churchill, Cutler, and Beck are in agreement with Schmieden. Burwell and Blalock, although admitting the theoretical possibilities, have failed to observe any harmful effects in cases in which the right ventricle was first subjected to decortication.

With regard to the extent of the decortication, Schmieden states that it is more important to consider what parts of the thickened pericardium should be allowed to remain to support the weakened heart than how much should be removed. Because of the danger of acute tricuspid insufficiency and to avoid a deficiency of the auriculoventricular valves leading to inflow venous congestion, Schmieden states that the decortication should not be carried beyond the coronary sulcus. He emphasizes also the liberation of the apex of the heart which may be firmly fixed to the diaphragm, a condition which prevents normal systolic contraction. If the apex cannot be liberated, he advocates a left phrenicectomy. Churchill points out that the sulcus formed by the descending branch of the left coronary artery is apt to be the site of unusually dense adhesions and that great care should be ex-

ercised in this region to prevent injury to this important artery. He is of the opinion that the mobilization of the right auricular groove is an important step in the operation, indeed a "crucial" step in relieving obstruction to right ventricular filling. Several authors have referred to the importance of removing the scar about the vena cava, but Burwell and Blalock have made no attempt to remove it and have observed improvement in most of their cases.

Not only may the decortication of the heart be of itself a tedious and dangerous procedure, but it is made more so because of the necessity of operating upon an organ in constant motion and one very sensitive to external stimuli. In the 7 patients subjected to operation the heart beat as counted at the wrist, varied between 100 and 160 and in all cases was over 130 during the greater period of the operation. In 2 cases the heart action was fairly regular, in 5 markedly irregular. In some cases there were periods of paroxysmal tachycardia, in others transient ventricular fibrillation, in still others such complete loss of rhythm that the cardiac action could be described only as complete arrhythmia. Periods of transient stoppage of

In the replication of page 100, the heart was described by Beck had effect upon cardiac action.

in 5, to acute cardiac failure (variously designated "acute failure", "myocardial weakness", "acute dilatation") within 48 hours of operation in 6, to late cardiac failure (18 days to 2 months) in 4; to tuberculosis in 2; and to a variety of causes ("angina," "cachexia," "exhaustion," "sudden no data") in 4. A summary of these findings shows that of 35 patients in whom data regarding death are available, 26 died upon the operating table or within 48 hours of operation, and of these 6 died as a result of injury to the heart during operation, 6 died of wound complications (infection, 5, pressure pneumothorax, 1), 11 died from acute cardiac failure, and 3 died without explanation other than that they were desperate surgical risks when subjected to operation. Almost one-half the deaths, then, were purely surgical and possibly avoidable, one-half were due to acute cardiac failure which immediately followed and well may have been the result of the surgical procedure. Whether some of these deaths might not have been averted by gentler manipulations at the time of operation is problematical.

CLOSURE

In the 7 patients whom we have subjected to operation, bleeding has been controlled as perfectly as possible and closure of the large wound has been with silk and without drainage. In 6 cases, healing of the wound has been *per primam*; in 1 case a hematoma developed in the lower part of the wound followed by a localized, superficial infection which did not jeopardize the wound as a whole. In this case there also developed a moderate sized left hemothorax complications the result of imperfect hemostasis. In the closure of the wound we have retained all the layers reflected, first resuturing the intercostal muscles and posterior perichondrium at the sternal border, then the major pectoral muscle, and finally the subcutaneous layer and skin. Schmieden not only resects completely the bony thoracic wall but excises the major pectoral muscle, using only the skin and subcutaneous tissue to cover the heart. Churchill resects the bony thoracic wall but retains the pectoral muscle. Both surgeons think a mobile thoracic wall over the decorticated

Fig 11 Case 2 October 20, 1936 Photograph taken about 5 months after operation showing the scar of operation

heart is desirable. Our experience thus far in cases followed over 2 years indicates that the reformation of a rigid thoracic wall is not incompatible with satisfactory results.

POSTOPERATIVE TREATMENT

Five of our 7 cases had a surprisingly smooth postoperative convalescence and neither an oxygen tent nor any special form of postoperative therapy seemed indicated. Two patients were somewhat cyanotic soon after their return to the ward and were placed in an oxygen tent for a few hours. One patient, as previously noted, developed a hemothorax for which aspiration was performed. The same patient developed a local superficial wound infection which closed up under appropriate treatment. Subsequent to the immediate postoperative period the diet and salt and fluid intake prescribed before operation were continued for a time, as were diuretics when indicated. Three patients were found not to require them, 4 were given weekly injections of mercupurin, and 1, urea, after they had been ambulatory. Churchill

Fig 13 Case 2 Roentgenograms of chest before and after operation Comparison of b (September 22, 1938) taken 22 months after operation with a, left (November 11, 1936), taken before operation shows a decrease in the cardiac silhouette

was 4 months' pregnant, had a marked pallor and enlargement of the spleen. The cardiac rate was rapid but there were no signs of heart failure. Blood cultures taken on March 21 and again a week later were positive for *Streptococcus viridans* in small numbers. A roentgenogram of the chest failed to show evidence of pulmonary tuberculosis, the cardiac shadow was not remarkable except for a prominence along the left ventricular border. The urine contained albumin, red blood cells and a moderate number of granular and cellular casts.

Within 6 weeks of her admission certain changes in her physical condition had become manifest. There was increasing distention of the veins of the neck, the appearance of râles at the bases of both lungs, progressive enlargement of the liver, and soft pitting edema of the legs. The radial pulse had become paradoxical in quality. On May 12, 1935, the patient left the hospital against advice but returned in 2 weeks with cyanosis, swelling of the ankles, and weakness. Examination at this time showed dyspnea, cyanosis, distention of the veins of the neck and right pleural effusion. The heart was not remarkable, the pulse paradoxical. The liver was enlarged, the uterus corresponded with that of a 7 months' pregnancy, there was no ascites. The legs were edematous. At rest in bed the pulse remained rapid, the dyspnea and cyanosis persisted. She was digitalized rapidly over a period of 24 hours after which a maintenance dose was continued for 2 weeks. The drug had no effect either on the pulse rate or daily output of urine. On June 17, 1935, the patient went into labor spontaneously and after 8 hours was delivered of a living premature infant. The puerperium was uneventful.

On July 12, 1935, she again insisted on leaving the hospital. She remained in bed at home for 2 months, then got up and was moderately active. Her symptoms of dyspnea and weakness increased and a pro-

gressive enlargement of the abdomen occurred. She, therefore, reentered the hospital on December 3, 1935. On admission dyspnea, cyanosis, and orthopnea were noted, marked distention of the veins of the neck, signs of a large amount of fluid in the chest, moist râles over the bases of both lungs, marked ascites, marked enlargement of the liver and edema of the legs. The heart sounds were faint, the rhythm rapid and regular, the pulse markedly paradoxical. Special studies showed an increase in venous pressure, a diminished cardiac output, and a delayed circulation time (Fig 5).

The diagnosis of constrictive pericarditis in this case seemed positive, and operation was deemed advisable. The patient was given a diet containing 2 grams of salt, her fluid intake was restricted, ammonium chloride and mercupurin were administered. Abdominal paracentesis was performed on December 5, and 4000 cubic centimeters of fluid was withdrawn. Thoracentesis was performed on seven occasions and on each 1000 to 1300 cubic centimeters of fluid was withdrawn from the chest. The sediment from both abdominal and thoracic fluid was injected into guinea pigs with negative results for tuberculosis. As a result of all these measures the patient lost 14 kilograms in weight but later regained the weight.

Operation was performed on January 28, 1936, under ethylene anesthesia. A skin muscle flap was reflected upon the left side and the second, third, fourth, fifth, and sixth costal cartilages and the adjoining ribs were resected. The pericardium was exposed, was grayish white in color and appeared greatly thickened. When incised, the pericardium was found to be densely adherent to the heart but a line of cleavage was established. An area of pericardium 10 centimeters by 11.5 centimeters was removed. The excision extended to the left border of the left ventricle including the apex, to the right auriculoventricular sulcus, well up to the base of the

Fig 15 Case 4 Roentgenograms of chest Left, December 8, 1936, taken before operation. Right, January 29, 1938, taken 13 months after operation The shadow due to pleural effusion persists

the liver big and extending 8 centimeters below the right costal margin. There was no edema of the legs. The lungs appeared normal. The heart did not appear enlarged, the sounds were distant but otherwise normal. The rate was 126 per minute, the rhythm regular. The blood pressure was 88/52, the pulse definitely paradoxical. Fluoroscopy showed a small heart with marked diminution in the amplitude of cardiac contractions. X-ray films showed calcification of the pericardium over the right and the lower part of the left ventricle. Special studies of the circulation showed increased venous pressure, delayed circulation time, and diminished cardiac output. A positive diagnosis of chronic constrictive pericarditis was made and operation advised (Figs 8, 9, and 10).

The pre-operative treatment consisted in complete rest in bed, a diet containing 2 grams of salt, restricted fluid intake, and the administration of mercurpurn and aminophyllin. The drugs induced only slight diuresis and the result of pre-operative treatment was only slight decrease in the ascites. Operation was performed June 5, 1936, under ether anesthesia. A skin muscle flap was reflected over the left side and the second, third, fourth, and fifth costal cartilages and adjoining ribs were resected. The pericardium was exposed and appeared greyish white and on palpation greatly thickened. An incision was made through it and it was found that while the two layers of the pericardium were adherent, the adhesions were not particularly dense, a cleavage plane was therefore easily established and the mobilization and excision of the pericardium comparatively simple. Because of the extensive calcification of the pericardium, heavy instruments were occasionally necessary. The pericardium was removed over the left and right ventricles, an area 6 centimeters by 7 centimeters, as subsequently measured, being resected. The heart herniated markedly, but its rate and rhythm remained satisfactory. The wound was closed without drainage. Gross and microscopic examination of the excised pericardium showed a struc-

ture 3 millimeters in thickness with extensive calcification but no evidence of tuberculosis.

The postoperative course was remarkably smooth and uneventful. Within a month after operation the venous distention had decreased markedly, the pulse had ceased to be paradoxical, the liver had decreased in size, and the ascites had almost disappeared. The patient was discharged on the twenty-eighth post-operative day. She returned from time to time for re-examination. Her improvement continued, she developed physically in a remarkable way, and gained greatly in weight. At the present time (November 17, 1938) 2½ years after operation, she is a normal healthy girl leading an active life and able to engage in vigorous athletics. Careful examination reveals no symptoms or signs of heart failure (Fig 11).

CASE 3 W M, History No 103699, a male aged 36 years, was first admitted to the New York Hospital July 26, 1935, complaining of dyspnea on exertion and swelling of the ankles of 12 months' duration. With the exception of frequent colds and mild attacks of asthma his health had been good until 16 months before admission when he developed chills, fever and cough, productive of brown sputum. He entered the Morrisania Hospital where a diagnosis of bronchopneumonia was made. The report from this institution shows that he remained febrile for 2 months at the end of which time the temperature returned to normal. There developed, however, a bilateral pleural effusion, ascites, generalized dependent edema, enlargement of the liver, and distention of the veins of the neck. Except for a rapid rate the heart on examination was not remarkable. The patient was discharged from the Morrisania Hospital July 6, 1934. He remained short of breath on exertion, his ankles were swollen, he had a constant ache in the epigastrium, a cough with yellow expectoration and continuous mild wheezing. In the 12 months before admission to the New York Hospital, these symptoms increased and he developed orthopnea, precordial pain, and marked weakness.

Fig. 14 Case 4. Studies of circulation before and after operation.

heart and down to the diaphragmatic pericardium. During the operation the heart herniated through its pericardial covering in rather an alarming fashion but the cardiac rate and rhythm remained satisfactory. The wound was closed without drainage. The patient withstood the operation well. The postoperative course was uneventful. The study of the pericardium removed showed it to be a dense fibrous structure from 3 to 4 millimeters in thickness. Microscopic sections of which revealed typical tubercles and giant cells indicative of a tuberculous infection.

The postoperative story of this patient is as follows. The physical signs of heart failure did not immediately change and during her postoperative period in the hospital she was treated with ammonium chloride, mercupurin and thecalcin. She was discharged from the hospital a little over 2 months after operation with some but not sinking evidence that

the condition was greatly changed. But gradually her condition improved 3 months after operation the signs of cardiac failure were greatly diminished and 5 months after operation had disappeared. Re-admission to the hospital for re-examination approximately 1 year after operation showed that all signs of her previous condition had disappeared. The paradoxical pulse was no longer present, venous pressure had returned to normal, venous engorgement had disappeared and circulation time was normal. She was leading her usual active life without symptoms. Fourteen months after operation the patient was discovered again to be pregnant and it was thought advisable to terminate the pregnancy. A therapeutic abortion under ether anesthesia was well tolerated. Eight months later the patient again was pregnant. She was readmitted, the uterus emptied and the fallopian tubes ligated to affect sterilization (Fig. 6 and 7).

At the present time November 17, 1938, 2 years and 10 months after operation, she is in excellent health, does all her own work, and leads an active life with no symptoms or signs of heart failure.

The case is an example of slow recovery after operation, and, as an apparent cure of tuberculous pericarditis, is unique.

CASE 2. A. B. History No. 0323. Female aged 15 years was admitted to the New York Hospital May 14, 1936, complaining of swelling of the abdomen for 5½ years. There was no history of exposure to tuberculosis. She had had a single attack of polyarthritides at 6 years of age but no other manifestations of rheumatic infection. There was no evidence of cardiac disease until at the age of 10 years her parents observed that she had become listless and her abdomen began to swell. The size of the abdomen increased and 4 months after the onset of symptoms she was taken to Bellevue Hospital where 3 abdominal taps were performed in 7 weeks, a large amount of fluid being obtained on each occasion. This treatment had no effect and some time later jaundice was present for a short period. About 6 months after the onset of symptoms the abdomen still being greatly distended she was taken to the Broad Street Hospital where an exploratory laparotomy was performed. The liver was found to be greatly enlarged and its surface studded with small excrescences like tubercles. A diagnosis of tuberculosis was made. The swelling of the abdomen persisted but the child attended school regularly for about 4 years. At the end of this period the swelling of the abdomen increased still more and there appeared dyspnea on exertion, weakness, anorexia and progressive emaciation.

On admission to the New York Hospital the girl appeared markedly emaciated and chronically ill. There was cyanosis of the lips, marked engorgement of the veins of the neck and increase in the size and number of the superficial veins over the entire body. The abdomen was greatly distended and full of fluid.

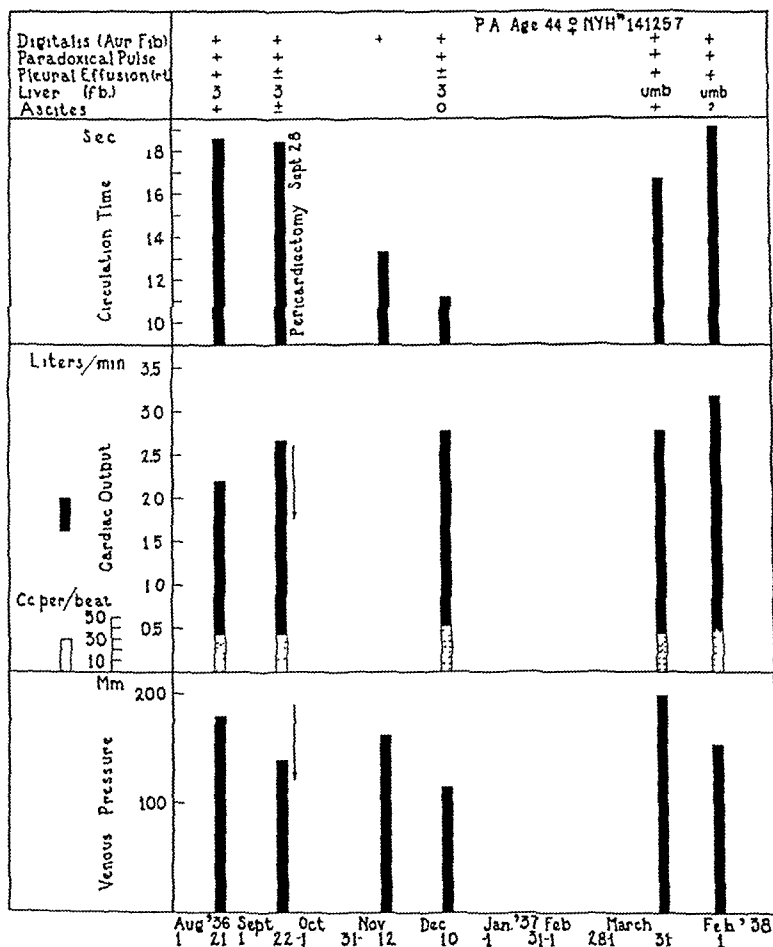

Fig 18 Case 6 Studies of circulation before and after operation

Fig 19 Case 6 Roentgenograms of chest before and after operation a and b, September 22, 1936, taken before operation show extensive calcification of the pericardium, c, December 10, 1936

Fig 16 Case 5 Infra red photographs taken before and after operation a May 26 1937 taken after medical treatment but before operation b November 19 1937 taken 4 months after operation c January 8 1938 taken 7 months after operation

Physical examination on July 26 1935 showed a man acutely ill with marked dyspnea cyanosis and orthopnea. The veins of the neck were markedly distended the pulse was paradoxical in quality the liver was enlarged the abdomen contained fluid and both legs were edematous. The heart was not remarkable the lungs showed moist râles over both bases and many sibilant wheezing sounds. The blood pressure was 122/90. During the first 24 hours in the hospital he was partly digitalized and perhaps as a consequence the distention of the veins of the

neck increased. A phlebotomy was performed with the removal of 650 cubic centimeters of blood a procedure which appeared to relieve his venous distention dyspnea and cyanosis. Both digitalis and phlebotomy were employed before the true nature of the condition was appreciated. Under rest in bed a low salt diet theocain and a maintenance dose of digitalis excellent diuresis was obtained. X-ray and fluoscopy examinations of the heart July 30 1935 showed marked diminution in the amplitude of cardiac pulsations no evidence of valvular heart dis-

Fig 17 Case 5 Roentgenograms of chest before and after operation Left June 15 1937 right November 19 1937 taken 5 months after operation

patient was given acetyl salicylic acid and coincidentally the temperature fell 1 to 2 degrees. Mercupurin and ammonium chloride were given without inducing diuresis, nevertheless, repeated fluoroscopic examinations showed a steady decrease in the pericardial and pleural effusions. Two months after admission these could no longer be demonstrated although the other signs of heart failure remained unchanged. The patient was discharged June 28, 1936. The dyspnea, swelling of the abdomen and ankles continued, and he was readmitted November 18, 1936. The fluid in his chest had reaccumulated, there was distention of the veins of the neck, enlargement of the liver and ascites. Roentgenograms of the heart showed some enlargement to the left and less enlargement to the right. Fluoroscopy of the heart showed only very slight pulsation. He was again discharged but readmitted December 7, 1936, for resection of pericardium. The usual pre-operative preparation resulted in some improvement and a loss of 2.5 kilograms in weight (Figs 14 and 15).

Operation was performed December 21, 1936. A skin muscle flap was reflected upon the left side and the third, fourth, fifth, and sixth costal cartilages and adjacent ribs were resected. The pericardium appeared opaque and thickened. It was incised over the left ventricle and found to be so densely fused with the heart that a cleavage plane was established and continued only with the greatest difficulty. The mobilization and resection of the pericardium was a difficult undertaking. An area 6.5 by 8.5 centimeters was resected. The heart bulged through the pericardial defect. Frequently during the dissection the heart became irregular, stopped beating temporarily, or exhibited periods of paroxysmal tachycardia. The wound was closed without drainage. The resected pericardium was 2 to 3 millimeters in thickness and on section showed a fibrous connective tissue, containing foci of polymorphonuclear leucocytes and lymphocytes suggesting an acute inflammatory process.

The patient withstood the operation well. A few hours after operation an increase in cyanosis was noted and he was placed in an oxygen tent. The morning after operation his condition was good and he was removed from the oxygen tent. Thereafter his convalescence was uneventful. His improvement was gradual but continuous. In his postoperative course ammonium chloride and mercupurin were given periodically. The signs of heart failure diminished but did not completely disappear. He was discharged from the hospital March 3, about 6 weeks after operation. Since then he has been re-examined from time to time. He has been up and about, has attended college regularly, is capable of moderate exercise, feels well, and is free from cardiac symptoms. Certain signs of his previous condition persist, as slight distention of his veins, engorgement of the liver, and a small amount of ascites. At the present (December 2, 1938) he is continuing his work at college. There are no symptoms of heart failure. There are signs of a small amount of fluid at the base of the right lung, enlargement of the liver to 2 fingers' breadth below right costal margin and minimal pitting edema of ankles. There is no longer distention of the cervical veins, nor signs of ascites. Mercupurin has not been required for 5 months.

CASE 5 J S, History No 169168, a female aged 38 years, was admitted to the New York Hospital May 24, 1937, complaining of swelling of the legs of 6 years' duration. There was no history of tuberculosis or rheumatic fever. Her health had been good until 6 years before admission when she had a bout of fever, cough, and stabbing pain in the left scapular region. This illness confined her to bed for 3 months. She then resumed her usual activities but began to suffer from dyspnea on exertion, orthopnea and swelling of the abdomen and legs. She consulted a number of physicians who prescribed a variety of treatments including the administration of digitalis, injections of mercupurin, and the operation of thyroidectomy, which was performed 5½ years prior to

Fig. 20. Case 1. Studies of the circulation before and after operation.

ease and no pleural effusion. Under this medical treatment he improved and on October 10 was up and about ward. Discharged November 5, 1935, with the diagnosis of chronic constrictive pericarditis.

Following his discharge he returned to the cardiac clinic monthly for observation. He secured a position as night watchman and indulged in moderate exercise. Eleven months after discharge he noted again increasing dyspnea, swelling of the ankles and a troublesome fullness in the head on exertion. He was readmitted to the hospital November 9, 1936, and on examination showed moderate dyspnea, cyanosis and distention of the veins of the neck. The examination of the heart again failed to show anything remarkable. The pulse was paradoxical, the blood pressure 115/90. The liver was enlarged. There was no edema of the extremities. X-ray films and fluoroscopic examination showed slight enlargement of the heart, absence of motion of the right side of the heart but slight motion of the left ventricle. Operation again advised and he was put on our usual pre-operative treatment (Fig. 12 and 13).

Operation was performed November 23, 1936, under ether anesthesia. A skin muscle flap was reflected upon the left side and the second, third, fourth, and fifth costal cartilages and adjacent ribs were resected. The pericardium appeared thickened and no cardiac pulsations were visible even with the pericardium exposed. An incision was made through the pericardium over the left ventricle and a cleavage plane was established. Without untoward event an area of pericardium 8 by 10 centimeters was resected. The wound was closed without drainage. The pericardium resected was 2 to 3 millimeters in thickness and had the consistency of cartilage. Microscopic examination showed a fibrous tissue which in many areas had undergone calcification. No tubercle or other characteristic findings were present.

The postoperative course was uneventful. On the day after operation the veins of the neck were definitely less distended and within a week the venous engorgement had almost disappeared. Fluoroscopic examination of the heart 3 weeks after operation showed good pulsation where previously it had been absent. Improvement in his condition was progressive and on December 30, 1936, 5 weeks after operation he was discharged. He was readmitted for examination March 31, 1937, and it was found that all symptoms previously noted practically had disappeared. Seen on January 11, 1938, he stated he felt as well as he ever had in his lifetime even though he was working hard every day and not restricting his activities. At present (November 1, 1938) 2 years after operation he seems to be entirely well, is doing heavy physical labor daily and is without any symptoms or signs of cardiac failure.

CASE 4. J. McC. History No. 1863, a male aged 20 years was admitted to the New York Hospital April 20, 1936, complaining of weakness of 1 week's duration. He had never had rheumatism or chorea. His health had been excellent until 7 months prior to admission when he had fever and pain in the chest and was told after x-ray examination that he had pericardial effusion. He was in bed 3 months, then went about and felt well until 7 weeks before admission when he began to suffer from dyspnea on exertion, orthopnea and swelling of the ankles. These symptoms persisted and 3 weeks before admission fever and pain in the lower posterior portion of his right chest recurred. He developed a non-productive cough and pain in his left shoulder.

On admission the patient appeared acutely ill and febrile. There was slight dyspnea and cyanosis. Examination of the heart and lungs suggested a large pericardial effusion and right pleural effusion. The heart was regular and there were no thrills or murmurs. The blood pressure was 106/60. The radial pulse was paradoxical in quality. The liver was enlarged, the abdominal cavity contained fluid. There was no edema of the legs. The red cells numbered 6.7 million, the white cells 11,200. Fluoroscopic examination showed a large pericardial and right pleural effusion. The temperature rose daily to 39 or 40 degrees C. On the eighth day of admission the

of the previous signs and symptoms. She was admitted to the hospital October 8, 1937. Under appropriate treatment her signs again improved and she was discharged on December 5, 1937. Since then she has been followed in the cardiac clinic of the out patient department. At the present time (November 4, 1938), 1 year and 4 months after operation, she is quite able to do her own work. Her symptoms are slight dyspnea and moderate fatigability. Her signs of heart failure are very slight venous distention, enlargement of the liver to four fingers' breadth below the right costal margin, and moderate edema of the ankles. The radial pulse still is paradoxical.

CASE 6 P. A., History No. 141257, a female aged 44 years, was admitted to the New York Hospital on August 12, 1936, complaining of swelling of the ankles and abdomen. She had never to her knowledge had tuberculosis. At the age of 20 years she had fever and cough for a week, diagnosed as pneumonia by the family physician. At the age of 30 she suffered from acute polyarthritis but never had a recurrence of the condition. She was in bed for 2 months but it is not known whether there was any cardiac involvement at this time. At the age of 34 years, 10 years before admission, she first observed swelling of the ankles. There were no other cardiac signs until 10 years later when 2 months before admission she observed progressive swelling of the abdomen and slight dyspnea on exertion. About 2 months before admission she began taking digitalis each day and continued to do so to the day of admission.

Examination showed a well developed woman with dyspnea and cyanosis. The veins of the neck were engorged, the abdomen distended with fluid, the liver enlarged, the legs and ankles markedly edematous. There were signs of a moderate amount of fluid at the base of the right lung. The heart appeared moderately enlarged to the left, the cardiac sounds were distant and poor in quality but no murmurs were heard. The blood pressure was 110/70. The pulse was definitely paradoxical. The electrocardiogram showed auricular fibrillation, roentgenograms of the heart showed it to be globular in shape and slightly enlarged. There was extensive calcification of the pericardium. The fluoroscopy of the heart showed marked diminution in cardiac motion. X-ray films confirmed presence of fluid in right pleural cavity.

Treatment consisting of bed rest, a low salt free diet, restricted fluids, digitalis, ammonium chloride, mercupurin and theocalcin, led to excellent diuresis and general improvement. She lost 14.7 kilograms in weight (Figs 18 and 19).

Operation was performed September 28, 1936, under ether anesthesia. A skin muscle flap was reflected on the left side and the second, third, fourth, and fifth costal cartilages and adjacent ribs were resected. The pericardium was opaque and showed extensive calcification. It was incised over the left ventricle and found to be adherent to the underlying myocardium. A cleavage plane, however, was established and the pericardium over the left and right ventricles mobilized and resected. The pericardium

was especially adherent along the sulcus between the left and right ventricles but was finally freed without misfortune. The wound was closed without drainage. The pericardium, which was removed, measured from 5 to 8 millimeters in thickness. It consisted largely of a hard bone-like tissue. On microscopic section it was found to be dense cellular tissue with masses of calcification. There was a marked tendency to true bone formation with the development of bony trabeculae.

The patient withstood the operation well and her condition continued excellent until the day after operation when she showed dyspnea, cyanosis, and on physical examination a moderate pneumothorax was found. She was placed in an oxygen tent; the treatment was effective and her temperature, pulse, dyspnea, and cyanosis were improved. Her further convalescence was uneventful. In her postoperative course, ammonium chloride and mercupurin were administered periodically. On discharge from the hospital December 19, 1936, the signs of heart failure were less evident but still present. Since discharge she has been followed in the cardiac clinic. Improvement has been slow but definite. At the present time (December 2, 1938), 2 1/6 years after operation, she does her own work. Her only complaint is occasional slight dyspnea. Her physical signs are a moderate amount of fluid at the base of the right lung, enlargement of the liver to 4 fingers' breadth below the right costal margin, questionable ascites, and moderate edema of ankles. Radial pulse still is paradoxical.

CASE 7 R. S., History No. 185223, a male aged 58 years, was admitted to the New York Hospital on January 17, 1938. He stated that his health had been good until 6 years before admission, and that he had passed an examination for life insurance 9 years before admission. Six years before admission he began to note dyspnea on exertion and swelling of the ankles. On examination in a cardiac clinic he was thought to be suffering from "hypertensive heart disease with heart failure." X-ray of the heart showed "marked dilatation of the left ventricle," and electrocardiogram revealed "low voltage of QRS in all leads, T₃ inverted, T₂ partly inverted." He was given digitalis but his symptoms did not improve. In the 6 years that ensued he visited a number of private physicians who treated him with digitalis and injections of mercurial diuretics but his symptoms persisted, and 3 years before admission to the New York Hospital dyspnea became so marked that he was forced to stop his work as a tinsmith. In the 2 month period immediately preceding admission he had been taking digitalis regularly and had been receiving an intravenous injection of mercupurin once a week in an attempt to control the swelling of the ankles. On admission to the New York Hospital January 17, 1938, there was slight cyanosis but no dyspnea or orthopnea. The veins of the neck were moderately distended when he sat erect. There were a few moist rales at the bases of both lungs, posteriorly. The heart showed enlargement to the left on percussion, and the rhythm appeared to be totally

Fig. 22. Summary of the circulation studies in the first 6 cases subjected to pericardectomy. Three cases in group A are cured; 3 cases in group B are improved.

admission. In spite of treatment her symptoms increased in severity and she entered the hospital.

Physical examination on admission showed a moderate dyspnea, orthopnea, and cyanosis. The veins of the neck were distended. The liver was enlarged; the abdomen contained a moderate amount of fluid; the legs exhibited a massive, pitting edema extending well up on the thighs. The lungs showed moist rales at both bases. The heart sounds were fairly well heard; there were no murmurs and the rhythm was regular. The radial pulse was markedly paradoxic. The blood pressure was 130/78. Fluoroscopic copy of the heart showed only faint pulsation of the right ventricle and only slight pulsation of the left ventricle. The heart was slightly enlarged. Roentgenograms failed to show calcification of the pericardium. Under complete rest in bed a diet containing 2 grams salt restriction of fluid, ammonium chloride, and injections of mercuripurin, there was some improvement. Thoracentesis was then administered which increased the urinary output moderately. Three weeks after admission the dyspnea, cyanosis, and orthopnea were no longer evident. The liver decreased in size; the ascites had diminished and the edema of the legs was less evident. She had lost 13.4 kilograms in weight (Figs. 16 and 17).

Operation was performed June 27, 1937, under ether anesthesia. A skin muscle flap was reflected on the left side and the second, third, fourth, and fifth costal cartilages and adjacent ribs ends were resected. The pericardium on exposure appeared opaque, hard, and thickened. It was incised over the left ventricle and found to be only loosely adherent to the heart. A cleavage plane was easily established and the mobilization and resection of the pericardium proceeded without difficulty. A large area of the pericardium was resected; the amount measuring 10.5 by 6 centimeters in diameter. The wound was closed without drainage. The pericardium removed was 3 millimeters in thickness, appeared fibrous and leathery, and on microscopic examination consisted of dense fibrous tissue with many foci of calcification. There were no tubercles or other significant findings.

The postoperative course was uneventful. At the end of 2 weeks the distention of the veins of the neck had diminished. Ammonium chloride and injections of mercuripurin were used in the postoperative period and produced excellent diuresis, which before operation they had failed to do. The patient was discharged 2 months after operation. Seen from time to time in the cardiac clinic it became evident that under moderate activity there was a reappearance

after the primary operation, he stated that he felt better than at any time since coming under our observation. His symptoms are minimal and consist of slight dyspnea. His physical signs are slight cyanosis, increased venous pressure, enlargement of the liver to 4 fingers' breadth below right costal margin, questionable signs of a small amount of ascites and moderate edema of the extremities. An evaluation of the results of operation is not yet possible.

SURVEY OF THE LITERATURE

We have found in the literature reports of 143 patients in whom the pericardium has been resected for chronic constrictive pericarditis. Of the 143 patients, 50, or 36.6 per cent, are reported as cured and 25, or 17.4 per cent as improved. Forty-seven, or 32.8 per cent of the patients died either upon the operating table (19) or in the immediate post-operative period (28). In addition to the 47 patients who died as a direct result of the operation, 13 are listed as having died at variable times after discharge from the hospital. An analysis of this group shows that 6 of the 13 patients lived more than 1 year, Schmieden's 2 cases lived 3 to 6 years, respectively; Beck's patient lived 6 years, L. Rehn's patient lived 1 year, and Lilienthal's patient lived "several" years. It is probable that these patients were improved, and they are so listed in our summary. Seven of the 13 patients died from 2 to 8 months after operation and presumably as a result of the continuation of the disease. Data regarding the results of surgical treatment are lacking in the reports of 8 patients. The final analysis, then, shows that of 135 patients in the reports of whom data are available, 50, or 37 per cent, are cured, 31, or 23 per cent, improved, and 54, or 40 per cent, died, either during or soon after operation.

The permanency of the cures reported in the literature has been questioned particularly by Paessler. The immediate effects of operation may be striking and dramatic, in a few months a water-logged, bedridden patient may be transformed into an individual capable of engaging in vigorous athletics. In other cases this return to normal is more gradual and may occupy a year. The information in the literature regarding the per-

manency of these favorable results often is lacking but certain data suggest that the results may continue over a period of years. Of Schmieden's 6 reported cures, 4 are well after 10, 12, 17, and 18 years; and of Churchill's reported cures 6 are well after 2 to 9 years, of which 5 are well more than 3 years. Five additional authors report patients well after from 5 to 11 years; 6 report cures of more than 2 years.

Paessler, however, after an investigation of 71 cases, is of the opinion that the late results have not been as favorable as the immediate results seemed to promise. He states that his studies have shown that the improvement after pericardiectomy has, in an appreciable number of cases, been followed after years by ill health with new and different manifestations which, however, cannot be interpreted as a recurrence of the constrictive pericarditis. He suggests that the chronic constrictive pericarditis is but one manifestation of a general disease process, the relief of which by decortication of the heart may not be sufficient to cure the patient; that it is necessary in addition to search for every possible focus of infection which, if found, is to be eradicated as a part of the treatment.

At first glance this record of surgical results may not appear to be impressive. But in judging the results it should be appreciated that the disease is incapacitating and invariably fatal, and to have improved or cured 60 per cent of the cases subjected to surgery is, after all, a real achievement. It should be realized also that the 150 cases represent the sum of the experience of 49 observers, 27 of whom have operated upon only a single case, 7 of whom have operated upon 2 cases, and 6 upon 3 cases. Only 8 surgeons, so far as can be determined from the literature, have operated upon 5 or more cases. It would appear certain that with more accurate diagnosis, a better selection of cases, more attention to pre-operative and postoperative management and greater perfection and experience in the operative technique, the results of this surgical treatment of chronic constrictive pericarditis will improve.

irregular. There were no thrills or murmurs. The blood pressure measured 135/100. The radial pulse was paradoxical in quality. The edge of the liver was felt 5 fingers breadth below the right costal margin in the midclavicular line. There were signs of a small amount of fluid in the peritoneal cavity. Both lower legs exhibited slight pitting edema. The hemoglobin amounted to 114 per cent. The count of the red blood cells was 5.4 million and that of the white blood cells 10,000. The blood Wassermann was negative. The total serum protein was 7.1 milligrams per cent. An electrocardiogram confirmed the diagnosis of auricular fibrillation. Roentgenograms of the heart showed the pericardium to contain extensive deposits of calcium, more marked on the right side of the heart than on the left. Both the right and the left ventricles were observed to be enlarged. Fluoroscopy of the heart showed fairly good pulsations in the region of the left ventricle and slight diminution of the pulsations on the right side of the heart. The patient was placed at bed rest. A diet low in salt was given, fluids were restricted to 1200 cubic centimeters daily and digitalis, mercupurin and ammonium chloride were used. These drugs were only moderately effective in producing diuresis during the first 4 weeks in the hospital, but during the latter part of the patient's stay marked diuresis was observed in response to mercupurin. On February 5, 1938, the weight had decreased from 80.0 to 74.6 kilograms. The only signs of heart failure on this date were slight cyanosis and enlargement of the liver to 4 fingers breadth below the right costal margin. The radial pulse still was paradoxical in quality. The patient remained in the hospital for 7 weeks longer. There was no further change in the signs of the heart failure and the weight did not change appreciably. He was discharged on February 7, 1938. Following discharge the patient indulged in only slight physical exertion. He returned to the cardiac clinic once each week and was given injections of mercupurin 2.0 cubic centimeters intravenously. He restricted his intake of salt and fluid. In spite of these measures he again began to suffer from dyspnea on slight exertion and swelling of the lower legs. The patient was readmitted to the hospital on April 15, 1938, and operation was performed April 26, 1938 (Figs. 20 and 21).

Under intratracheal ether anesthesia a skin muscle flap was reflected laterally upon the left side so as to expose inclusively the second to sixth costal cartilages and ribs. The third, fourth, fifth and sixth costal cartilages together with segment of the corresponding ribs were resected subperichondially and a second flap of tissue consisting of the intercostal muscles was reflected laterally. The extrapericardial fat and connective tissue were stripped from the pericardium together with the reflection of the left pleura. It was found in this case that the right heart could not be satisfactorily exposed and therefore the left half of the sternum immediately was resected. It was found after the pericardium was exposed that a cuff or cone of dense calcified tissue

surrounded the great vessels at the base of the heart that this cuff or cone was continuous with an area of calcification which covered the right heart but that the pericardium over the left ventricle was singularly free of calcification.

An incision was made through the thickened pericardium over the left ventricle and a cleavage plane between it and the heart muscle was established. Without great difficulty the left ventricle was uncovered well to the lateral border of the heart and the apex was completely freed. The separation of the pericardium from the right ventricle however was very difficult for here it was not only calcified but densely adherent to the wall of the ventricle. Nevertheless the right ventricle down to the diaphragmatic reflection of the pericardium was well exposed as it was as far to the right as the auriculo-ventricular groove. At the base of the heart however the calcified shell surrounding the heart and great vessels was so adherent that their exposure was not as satisfactory as in any of the 6 other cases. Throughout the operation moreover the heart was most sensitive to manipulations and was thrown into complete arrhythmia repeatedly. Application to the heart of novocain as suggested by Beck seemed to have no effect in improving the situation. Altogether the operation was most trying and from the viewpoint of freeing the base of the heart the most unsatisfactory of the 7 cases we have subjected to operation. The operative wound was closed in layers without drainage. The patient left the operating table in good condition.

The portion of the pericardium removed consisted of 2 pieces, one 7 by 4 centimeters the other 4 by 3 centimeters in size. In places it was but 1 millimeter in thickness in other places 4 millimeters in thickness. That over the right ventricle is largely calcified, the calcium deposit resembling thin bony plates as in an infant's skull. Microscopic sections failed to show any evidence of tuberculosis.

The postoperative course was entirely satisfactory for 3 days. Then he complained of some dyspnea at night. Eight days after operation the operative wound appeared puffy and there was dullness at the left base. A needle was inserted under the flap and 60 cubic centimeters of old blood with drawn. The left chest was aspirated and 523 cubic centimeters of bloody fluid obtained. He was placed in an oxygen tent for short periods for the next 2 days. He continued to take daily doses of digitalis and to receive injection of mercupurin. He was discharged from the hospital July 9, 1938.

The patient was readmitted September 19, 1938, for a revision of his wound which still continued to drain. The sinus tracts were excised. The upper sinus extended from the midline rather deeply to the left and contained a quantity of granulation tissue which was removed. Under the Carrel-Dakin treatment the wounds rapidly granulated and at the time of discharge October 26, 1938, were quite small. He continues to return to the clinic. On the last visit November 17, 1938, 7 months

years The longest duration was 15 years and the shortest 1 month. Four cases originated in warts, 3 on scars from previous burns which occurred 24 and 35 years before Three gave a history of itching followed by ulceration and 5 a history of trauma The others gave the origin from "sores," "pimples," or "growths" The treatment previous to admission varied from salves, repeated cutting with scissors, to "sprinklings of ground glass over the wound, and smoke of rooster's feathers" The blood Wassermann was negative in all cases Eighty-five per cent of the patients were not engaged in any industry, being "too old to work" Thirty-one patients were white, 1 was a negress

Volkman's observation in 1889 that epithelioma of the extremities is invariably of the squamous cell type still holds true Only 3 cases of the basal cell type were found at the Brooklyn Cancer Institute during the past 10 years These have been excluded

Clinically, squamous cell carcinoma of the extremities appears in two forms the ulcerative type characterized by indurated, irregular, rolled edges and necrotic base, and the cauliflower or solid form characterized by a fungating granulomatous or papillary appearance The ulcerative type, although the less malignant, has great destructive properties The indurated rolled edges become necrotic and break down, while the adjacent skin becomes infiltrated and assumes the characteristics of the former edge, thus spreading along the surface of the extremity The purulent secretion causes further destruction by undermining the edges of the ulcer and extending downward, penetrating the subjacent tissue attacking the periosteum, and finally resulting in necrosis and destruction of the underlying bone (Cases 22 and 25) The tumor then grows downward between the spicules of bone, where it meets no resistance (Fig 1), or finds its way between the fragments of a pathological fracture Although we may find carcinoma in the partially destroyed bone underlying the tumor, the carcinoma is part of the primary tumor and not of the bone Even histologically proved cancer cells in sections of destroyed bone do not alter these findings A similar case is illustrated by Kaufman in a man of 86 with an extensive carcinoma of the

leg and a pathological fracture of the tibia and fibula with carcinoma between fragments

The opinion that bone destruction is due largely to the admission of bacterial infection rather than to neoplastic invasion is shared by Willis He states that in the majority of closed non-infected tumors which have enveloped and adhered to contiguous bones or car-

SQUAMOUS CELL CARCINOMA OF THE EXTREMITIES

HERMAN CHARACHE, M D, Brooklyn New York

THE occurrence of squamous cell carcinoma of the extremities is comparatively rare. It comprises not more than 1 per cent of all the carcinoma in different parts of the body. (4) Volkmann was the first to call attention to this subject in 1889 when he analyzed 239 cases of carcinoma of the extremities. Thirty nine of these were from his own clinic during a period of 20 years. Heyman, in 1898, studied 20,544 cases of carcinoma and found only 207, or 1 per cent that affected the extremities. Broders found 44 cases in 2,000 admissions of general epithelioma, or 2 per cent, at The Mayo Clinic during the period of 1904 to 1915. De Asis, in 1926, found 17 cases of epithelioma of the extremities among 6,766 patients with carcinoma or 3 per cent, that were admitted to the Barnes Hospital and the Barnard Skin and Cancer Hospital of St. Louis. At St. Luke's Hospital in New York in 31 years only 9 cases were admitted to the wards and 6 to the dispensary, and at the New York Skin and Cancer Hospital only 26 cases were found among 35,000 admissions. (12) From January 1923 to January 1934 at the Stuyvesant Square Hospital only 60 patients with squamous cell epithelioma of the extremities were admitted. (5)

In the radiation therapy department of Bellevue Hospital New York, only 2 cases of squamous cell carcinoma of the fingers were found among 11,400 admissions. One case was reported by Rubinfeld in 1932, and the other by Siegel in 1937. Siegel found only 22 cases reported in the literature up to that time. At the Brooklyn Cancer Institute from 1928 to 1938 only 32 cases of squamous cell carcinoma of the extremities were found among 10,000 cases of carcinoma, or 3 per cent.

Von Brunn as well as other writers accept Volkmann's classification of carcinoma of the extremities (a) those that develop on chronic inflammatory tissue such as ulcers, scars,

fistulas, etc., (b) those that develop upon warts, moles, congenital or acquired, (c) those that develop on previously normal skin. In von Brunn's series of 320 cases, 227 occurred in the first group, 46 in the second, and 48 in the third. To bring Volkmann's classification up to date trauma should be added as a fourth group. Johnson stated that, "Epithelioma of the skin is induced almost exclusively by the chronic injury of previously normal or abnormal tissue." He reported 4 cases of carcinoma that originated on scar tissue following burns. He quoted Durand who reported 60 cases of degenerated scars, 70 of which were caused by old burns. In our own series, 3 cases occurred on old burn scars and 5 followed direct trauma. Fox described a case of epithelioma of the hand following the bite of a horse. He quoted a similar case of von Winnwarter and another case of Wurz of carcinoma of the forearm following the bite of a pig. Volkmann quoted a case that developed on the scar of a dog bite.

The age incidence of carcinoma of the extremities is higher than in any other malignancy. Males predominate over females in a ratio of 4 to 1. In our series of 32 cases the average age was 63, the oldest 86 and the youngest 33. Twenty occurred in males and 12 in females. The distribution of the lesion in order of frequency was dorsum of hand, wrist, leg, arm, forearm, foot, fingers, and thigh. The toes and the palmar surface of the hand are very rarely affected. The upper extremities are more often affected than the lower extremities. In our series 10 or 39 per cent occurred in the upper extremities: arm 5, forearm 2, dorsum of hand 9, finger, 3, and 13 or 41 per cent occurred in the lower extremities: foot, 4, leg, 7, thigh 2. Cases 5, 10, and 15 had multiple squamous cell carcinoma in other parts of the body. The average size of the lesion was $4\frac{1}{2}$ centimeters. The largest involved two thirds of the leg and the smallest was 2 centimeters. The duration of the disease before admission averaged $2\frac{1}{2}$

From the Brooklyn Cancer Institute. Dr. Ira I. Kaplan, Director, Division of Cancer, Department of Hospitals, New York City.

Among 334 cases of skeletal metastases from all types of malignancy reported by Geschickter 5 per cent metastasized from the skin. In Broders' series of 32 cases of metastatic squamous cell carcinoma, 1 metastasized to the upper and lower ends of the humerus, 1 to the rib, and 1 to the chest wall. In our series Case 1 had a tumor the size of an orange in the axilla with metastatic carcinoma in the corresponding lung. In our Case 29 autopsy revealed metastases to both lungs, heart, liver, spleen, kidneys, and pancreas (Fig 2). On roentgenographic examination Case 23 in our series showed metastasis to the third lumbar vertebra. No other primary lesion except the leg could be found. Case 4 had roentgenographic evidence of metastases to the pelvis and upper third of both femurs, but the patient died at home. This patient had an enlarged prostate, which, however, was not proved malignant.

Treatment of squamous cell carcinoma of the extremities is mainly surgical. Of 256 cases of squamous cell carcinoma of the skin at The Mayo Clinic reported by Broders, 236 or 92 per cent were treated surgically. DeBell and Stevenson, at Stuyvesant Square Hospital, state that all squamous cell carcinoma of the skin are treated by surgery in that institution. They believe that this method of cancer therapy is particularly adaptable to lesions on extremities. Perez, of the New York Skin and Cancer Hospital, in reporting 26 cases of epithelioma of the extremities concludes that adequate surgical removal is the treatment of choice. He states that radiation, either by radium or roentgen therapy, is not satisfactory. Johnson, of the Radium Department of the Steiner Clinic, reports that the treatment with radium therapy of a tumor with a scar tissue foundation is unwarranted, and that curative treatment is strictly surgical. Adair, at Memorial Hospital, New York, states that amputation of the hand for epithelioma should not be a very common procedure. He believes that, "If the ulcerating epithelioma is still confined to the integument, the best treatment is the application of radium plaques, 1 or 2 applications of 1000 millicurie hours each." If the lesion has infiltrated the tissues deeper than the integument, irradiation of whatever type

used is not effective. He concludes that if the lesion is large, deep, and painful, it often becomes necessary to amputate the hand.

In our own series of 32 cases, 16 received roentgen therapy alone, 7, x-ray therapy plus surgery, 6, surgery alone; 3, radium and surgery. Nine patients died, the youngest was 52 years, the oldest 82 years, the average age was 66 years. Four died from bronchopneumonia, 2 from cardiovalvular disease, 2 following amputation above the knee (24 hours and 1 week after operation), and 1 died from general metastases. Six patients could not be traced. When they were last seen they had no recurrence and were well for an average of 16.5 months following treatment. The average duration of cure in the 12 other patients was 2 years. The longest duration of cure was 8 years and 5 months. These patients are still being followed in our clinic.

One must agree with Adair that radiation has its use in the treatment of squamous cell carcinoma of the extremities, it also has its limitations. The ulcerative type, particularly, as pointed out by Adair, is too infected for conservative surgery, and one surely does not amputate for superficial ulcerated carcinoma. On the other hand, in the non-suppurative type there seems to be no logic in doing incomplete surgery for an adequate biopsy and not excising the whole lesion for curative purposes.

The deep-seated carcinoma and also the superficial ulcerating carcinoma that does not respond to radiation are exclusively surgical and amputation is the treatment of choice. We agree with Montgomery and Culver that these tumors are more resistant to radiation than those on the face, possibly because squamous cell carcinoma of the face is not associated with such predominant infection. A pre-radiation treatment consisting of thoroughly cleansing the ulcer several times a day for a number of days might stimulate better healing. We often find that following radiation therapy the healed ulcer will break down, not as a malignant recurrence, but because of the accumulation of purulent secretion beneath the healed layer. When this occurred in our Case 19 a number of biopsies were taken from the edge of the ulcer. They all

Fig. 2 Case 29. Healed squamous cell carcinoma of the foot with visceral metastases. A, primary lesion. B, photomicrograph showing squamous cell carcinoma of primary lesion.

tilages, the periosteum or perichondrium constitutes an effective barrier which excludes the growths from the bone or cartilage for long periods.

Roentgenologically, there is a variety of bone changes varying from periostitis (radiation and infectious), osteoporosis and osteomyelitis to areas of bone destruction and increased bone density. Eleven such cases, or 34 per cent, were found in our series: humerus 3, metacarpal 1, digit 1, femur 1, tibia 3, and metatarsal 2. In the presence of a carcinoma overlying the affected bone one does not wonder that some of these cases are interpreted as bony metastasis by the roentgenologist, the surgeon or both, resulting in amputation which is not always indicated. This is well illustrated by our Case 20. Amputation was advised because of bony metastasis. The patient refused operation and was not seen for 3 years. We considered her among the deceased. However, she was seen recently and proudly displayed her leg, stating, "I got

cured without youse doctors. I still have my leg without doin' nothin'." Case 3 in our series had his arm amputated in 1929. The roentgenological report was "metastasis to the underlying bone." The treatment was undoubtedly indicated because of the extensive ulceration of the arm. The patient is still working, but one wonders how much the surgeon was influenced by the roentgenological report before he decided on amputation.

The cauliflower type is less destructive but has greater malignant tendencies, subject to recurrence and metastasis. However, metastasis in carcinoma of the extremities is extremely rare. If at all it occurs late in the disease. De Asis explains this slow or late metastasis by the fact that the edges of the ulcer undergo thickening and induration, which are believed to squeeze the lumina of the lymphatic vessels, thus preventing the flow of the lymph which ordinarily carries the cancer cells. This explanation might be very consistent with the relatively benign course of the ulcerative type of carcinoma in which the edges of the ulcer are thickened and indurated. It also explains the relatively malignant course of the cauliflower type in which these factors are lacking in the majority of cases.

The regional lymph nodes are the first to be invaded, although the majority of the enlarged nodes are secondarily involved from the infection of the primary lesion and are not malignant. A great number of these enlarged nodes disappear when the primary lesion is removed. In our own series 7 patients had palpable nodes, the smallest the size of a pea and the largest the size of an orange. Internal and osseous metastases, although rare, have been reported in some instances. Mohr's case (quoted by Johnson) metastasized to the lungs, pleura, heart, and kidneys. He also quoted a case of Durand that metastasized to the iliac pelvic and lumbar lymph nodes and produced a metastatic tumor in the liver as large as an orange. One of De Asis's cases of carcinoma of the leg metastasized to both inguinal regions and to the liver, as evidenced clinically by an enlarged liver with multiple nodules. One of the cases cited by Perez revealed general internal metastasis which was proved by autopsy.

THE PRESENT STATUS OF CHRONIC OSTEOMYELITIS

H. R. McCARROLL, M.D., and J. ALBERT KEY, M.D., F.A.C.S.,
St. Louis, Missouri

BECAUSE it is relatively frequent and because it tends especially to affect the children of the poor who cannot pay for prolonged and often repeated hospitalization and the services of a private physician, chronic osteomyelitis is one of the most difficult problems encountered in the care of crippled children. Not only do these patients require prolonged hospitalization, but many of them need frequent dressings after they leave the hospital and, as will be shown, a considerable percentage of them are practically incurable.

We have reviewed 200 consecutive cases of chronic osteomyelitis which were admitted to the St. Louis unit of the Shriners' Hospital for Crippled Children, between the years 1924 and 1938 (6 per cent of 3,330 total admissions during this period). All of these patients gave histories of acute onset with fever and apparently their condition had resulted from an acute hematogenous osteomyelitis. No patients were admitted with chronic infection of the bone in whom the disease had resulted from a compound fracture or from the extension of an infection from neighboring soft tissues, except possibly extension into the bone from pyogenic joints. As we have not been able to separate these from the patients in whom the disease began in the bone, we have classed them all under the heading of chronic osteomyelitis. However, patients who had a primary pyogenic arthritis and who entered the hospital without chronic osteomyelitis were not included in this study. The series comprised 128 boys (64 per cent) and 72 girls (36 per cent). On admission their ages ranged from 10 months to 14 years and averaged 7.7 years. When admitted to the hospital the disease had been present from 12 days to 12 years and the average duration of the disease was 27 months.

From the Shriners' Hospital for Crippled Children and the Department of Surgery, Washington University School of Medicine.

This hospital usually has a relatively large waiting list and patients are not admitted until they have been recommended by their physician and investigation has been completed to show that the parents of these children are not in a position to pay for private medical care. This precludes us from receiving patients with acute osteomyelitis.

In reviewing the histories of these patients we were interested in determining why they developed the disease. As to the cause of the acute osteomyelitis, nothing of importance was learned except that 25 per cent of the patients gave a history of a definite injury during the preceding week, and 40 per cent during the month preceding the development of the disease. With due allowance for the frequency of minor injuries in children, it seems probable that in a considerable percentage of the cases trauma plays a part in inaugurating the disease, or at least in determining the site of the primary focus. Preceding illness and foci of infection were not mentioned with sufficient frequency to be of etiological significance. It is our opinion that most of these patients were apparently normal, healthy children in whom the disease developed suddenly and for some unknown reason.

Fig. 1. A small localized osteomyelitis of the humerus, typical of a + lesion. There is no involvement of epiphyseal cartilage or neighboring joint. Acute onset with drainage of abscess 3 months later and sequestrectomy 5 months later. Small sinus still draining when last seen after 1 year.

showed chronic inflammatory changes but no malignancy. Similar findings were present when the entire ulcer was excised and examined. No amount of cleansing will make an infected malignant ulcer suitable for conservative surgery, but it might improve the effect of radiation therapy.

If we find that an ulcerative carcinoma does not respond to radiation it becomes a surgical problem. Further delay would only transform a superficial carcinoma to a deep seated one, cause further destruction of the underlying tissue from the chronic infection, and increase the surgical risk.

Age and physical status of the patient are other factors that determine whether the patient should be treated by radiation or surgery, regardless of size or type of lesion. One therefore, cannot make a hard and fast rule whether to treat squamous cell carcinoma of the extremities by surgery or radiation. Each patient must be treated individually.

The prognosis in squamous cell carcinoma of the extremities is very favorable. This disease runs a slow course and metastasizes late if at all. Though histologically malignant clinically it is a relatively benign cancer. Recurrence is less common than squamous cell carcinoma of any other part of the body.

SUMMARY

1 Squamous cell carcinoma of the extremities is comparatively rare. It comprises not more than 1 per cent of all carcinoma in different parts of the body.

2 It is more common in males than in females and the age incidence is higher than in any other malignancy.

3 Trauma is a contributing factor in a number of cases.

4 Metastasis is rare and late in the disease if it occurs at all.

5 The non ulcerating type is comparatively more malignant.

6 The ulcerating type causes a great deal of destruction of the underlying tissues resulting in various pathological changes in the bone which are often interpreted as "metastasis".

7 The treatment in the majority of cases is surgical. Radiation therapy is indicated in the superficial ulcerating types not amenable to conservative surgery because of the infection and the poor surgical risk.

8 The prognosis is very favorable. Though histologically malignant clinically it runs a relatively benign course.

9 Thirty two cases of squamous cell carcinoma of the extremities have been studied and the findings summarized.

Fig 4 Massive destruction of the tibia demonstrating +++++ lesion There is involvement of the entire shaft, the epiphyseal cartilage at the 2 ends, as well as involvement of the knee and ankle joint Acute onset with drainage of abscess 6 days later Additional surgery has not been performed because of poor general condition and multiple involvement Drainage persists after 2 years

diagnosis It is thus apparent that acute hematogenous osteomyelitis is frequently treated for some time as some other disease, especially rheumatism, and that the physicians in general practice who are the first to see these cases are not osteomyelitis conscious This is true even today as 6 of these 41 cases have occurred during the past 2 years It is also in order to reiterate that in the early stages of acute osteomyelitis, the affected bones cast normal shadows on the x-ray film and abnormalities of the bones are not dis-

Fig 5 Extensive destruction in the femur demonstrating a +++++ lesion There is involvement of the entire shaft, epiphyseal cartilage at the 2 ends, and involvement of the hip joint Acute onset with drainage of abscess after 10 days Admitted to this hospital 3 months later Operation deferred because of poor general condition Several sequestra extruded and after 15 months all sinuses closed and have now been healed for 1 year

closed by the roentgenogram until sufficient time has elapsed for the bone to be eroded or for new bone to be formed (from about 10 days to 2 weeks)

The site of the primary lesion is shown in Table I It is to be noted that the large bones of the lower extremities (femora 95 and tibiae 72) account for 83.5 per cent of the total and that there were no instances in which the primary focus was in the spine or cranium. From a study of the x-ray pictures on admission it was not always possible to determine whether the disease began in the diaphysis or in the metaphysis, but in the great majority of instances the disease appeared to have begun in the metaphysis near the epiphyseal line In other words, the predominance of this disease is found in the large bones of the lower extremities which are most subjected to epiphyseal strains, and it suggests that this

Fig 2 A more extensive process in the metaphyseal region of the femur demonstrating a +++ lesion. No involvement of epiphyseal cartilage or adjacent joint. There was an acute onset and treatment for inflammatory rheumatism was carried out for 4 months at which time the abscess was drained. Sequestrum extruded spontaneously after which the sinus healed and has remained healed for 18 months.

Fig 3 An extensive involvement of the tibia demonstrating a +++ lesion. Most of the shaft has been destroyed but the process stops short of the upper and lower epiphyseal cartilages without any impairment in growth or adjacent joint function. Acute onset with drainage of abscess on fifth day. Sequestrectomy and saucerization 6 months later. Healed completely in 3 months and has remained healed for 3 years.

It was not possible in every case to determine how early the acute osteomyelitis was recognized but in 41 instances (20.5 per cent) it was stated that the patients were treated over periods of from 1 to 12 weeks for other conditions before a correct diagnosis was made. The false diagnoses and the number of times each was made are as follows: Rheumatism 15, typhoid fever 4, acute rheumatic fever 3, phlebitis 3, joint sprain 3, malaria 2, influenza 2, pneumonia 2, appendicitis (both operated) 2, fracture (without x ray) 2, blood poisoning 1, arthritis 1, tuberculosis 1.

In the majority of these a correct diagnosis was not made until large subcutaneous ab-

scesses had developed and in many instances not until these had ruptured and drained spontaneously. In others osteomyelitis was ruled out because of an early negative x ray and the erroneous diagnosis was adhered to until the x ray picture showed changes in the bone. In the 2 instances with a diagnosis of fracture x ray pictures were not taken. The 2 patients who were diagnosed as appendicitis cases were subjected to emergency appendectomies and normal appendices were said to have been removed. Both of these patients had osteomyelitis of the shaft of the right femur and it is probable that inflammation of the retroperitoneal lymph nodes caused abdominal symptoms which led to the erroneous

TABLE I—BONES INVOLVED PRIMARILY AND SECONDARILY AND LOCATION OF SECONDARY FOCI WITHIN THE BONE

Primary Foci			Secondary Foci

tation of movement and loss of function. These complications were present on admission and practically all of them developed during, or shortly after, the acute stage of the disease. It is recognized that metastatic foci may develop late in chronic osteomyelitis, but these are relatively rare when compared with the number which develop early in the process.

We believe that in acute osteomyelitis the bone should be drained as soon as possible after the onset of the disease provided the patient is in condition to stand the operation, and we believe that early and adequate drainage of the bone tends to prevent or limit the extent of the chronic bone infection and to decrease the number of instances in which joints or other bones will be involved (4, 5). This study was undertaken with the hope of furnishing evidence for or against the above beliefs. We have arbitrarily fixed the first week of the disease as the period during which we consider operative intervention as being early, but we by no means consider operation at from 6 to 7 days as really early enough. Unfortunately for our study, the bone was

opened during the first week of the disease in only 9 patients in the entire series (4.5 per cent, Table III). Among these 9 patients (femur 3, tibia 3, humerus 2, and foot 1), the adjacent joint was involved in only 1 instance and there was only 1 secondary focus in another bone (11.1 per cent as compared with 50 per cent and 25 per cent for the entire series). However, the number of patients so treated is too small to warrant definite conclusions as to the efficacy of this form of treatment.

It is further to be noted from Table III that soft tissue drainage, which was done in 42 patients during the first week, did not greatly decrease the number of complications, while drainage of the bone after the first week did not increase the number of complications. In the patients who had soft tissue drainage after the first week or in whom the abscesses

Fig. 6 A Broad adherent scar covering upper two thirds of tibia resulting from healed osteomyelitis B Hair line scar following excision of the original scar and shifting of pedicle flap to cover the defect C Double pedicle flap approximately 2 inches in width outlined with dye to show type of flap which is used D Split thickness graft on posteromedial aspect of leg outlined with dye which is used to fill the defect remaining after the flap is shifted

may be an important factor in creating a point of lowered resistance where casual organisms in the blood stream may settle and find conditions favorable for growth.

However 40 of 51 secondary foci developed in the metaphyseal regions of the femora and tibia and most of these occurred while the patients were ill in bed and trauma was not a factor. This inclines us to accept the theory of Hobo who demonstrated dilated capillary loops in the metaphysis adjacent to the epiphyseal cartilage plate. He found that bacteria and carbon particles injected into the blood of experimental animals tended to localize in these loops where the blood stream was slowed. Yet the volume of the metaphyseal regions of these 4 bones is hardly sufficient to explain the marked predilection of the disease for these areas. Likewise, we recall the large sinusoids of the spleen and red bone marrow where the blood current practically ceases at times and wonder why

these areas are not affected if the localization is due to a slowing of the blood stream. There were no patients with osteomyelitis of the vertebra in this series and only 7 in which the disease began in the pelvis. It is thus evident that we have no satisfactory explanation for the fact that in 83.5 per cent the disease began in the metaphyses of the femora and tibia.

We were interested in determining the type of treatment which these patients had received during the stage of their acute illness and if possible correlating this with the amount of bone involvement with the number of instances in which joints were involved and with those in which foci developed in other bones. It is to be noted from Table II, that in 50 per cent of the patients there was involvement of the joint adjacent to the focus in the bone and in 25 per cent of the patients secondary foci developed in other bones. Many of the joints were destroyed and others showed a variable amount of lim-

The operations have been performed by or under the direct supervision of the various orthopedic surgeons on the staff of the Shriners' Hospital during this period and always, we believe, by men competent to do as adequate a saucerization as could reasonably be expected on the various patients assigned to them. Consequently we have no quarrel with the quality of the surgery which these patients have received. This is important because, as will be mentioned later, we have not cured all our patients. We believe that most of the failures have been due to incomplete removal of infected bone. This occurred because in some cases it is absolutely impossible to remove all of the infected bone without the grave danger of producing greater and permanent disability in the extremity.

At present the procedure at the Shriners' Hospital is as follows. The operation is performed under a tourniquet when one can be used. After the wide saucerization is completed, the wound is packed with dry, fine mesh gauze in order to control the bleeding, and a dry dressing is applied. A cast is not applied unless there is danger of a fracture of the residual shaft or involucrum from slight violence. On the third postoperative day, the gauze pack is removed under gas anesthesia and a vaseline gauze pack is inserted. This is changed at intervals of from 2 to 4 days. After the first 2 or 3 dressings the wounds are lined by granulation tissue and little pain is experienced by the patients. If at any time the granulations do not appear healthy, wet dressings are used and the wounds are irrigated with normal salt solution for a few days. Vaseline gauze then is again substituted. This method is continued until the wound is healed or the patient leaves the hospital. It seems to be just as efficient as the Orr method and eliminates the odor which is so objectionable when the latter method is used.

One of us (J. A. K.)—most of whose work is carried on in other hospitals where it is necessary that the hospital stay be as short as possible—routinely uses the vaseline pack and plaster cast immobilization as advocated by Winnett Orr. The procedure which has been described by him (6) has been followed with a

reasonable degree of accuracy. Three slight modifications have been introduced and it is believed that they have been of some value. (1) The surrounding skin is covered with heavy zinc oxide ointment to protect it from the scalds and small furuncles which are so common when pus remains in contact with the skin under a cast. (2) In unusually foul and odoriferous infections, iodoform gauze is mixed with the vaseline gauze in an attempt at least to change the odor. (3) Where a reasonably satisfactory operation has been performed, large deep wounds are closed with a single layer of through-and-through sutures of silkworm gut, leaving wicks of vaseline gauze extending down to the bone and projecting at intervals between the sutures. The sutures and the vaseline gauze wicks are removed after the usual interval of 2 to 4 weeks and the small cavities remaining are repacked with vaseline gauze and a new cast is applied. By this method it is frequently possible to invaginate the soft tissues into deep cavities in the bone, and not only to shorten the time of healing and to limit the width of the scar but also to render healing more certain.

In addition to the above, we have used the Carrel-Dakin method and various types of wet dressings and other chlorine antiseptics. A few years ago when the newer mercurial antiseptics appeared we packed our wounds with gauze impregnated with merthiolate ointment, but we could not persuade ourselves that the wounds healed any more rapidly or more surely than did similar ones in which ordinary vaseline gauze had been used. We have even used gauze impregnated with ordinary hog lard and it seems to work just as well as any of the other preparations. We tried this in order to find some substance which would always be available to those patients who live in inaccessible places and who are required to do their own dressings. We have not used maggots because they are expensive, and we have not believed that they have any especial advantage unless the wound contains necrotic tissue. Our postoperative wounds contain no loose fragments of dead bone which the larvæ can bring up and deposit on the surface and relatively little necrotic soft tissue. The infected bone which

TABLE IV.—DEGREE OF PRIMARY DESTRUCTION AND END-RESULT IN RELATION TO TYPE OF PRIMARY TREATMENT

ruptured spontaneously the incidence of complications was relatively high.

In 47 patients no abscesses had been drained or had ruptured spontaneously, before admission and in these the number of secondary foci was relatively low (17 per cent) while the joint involvement was relatively high (55 per cent). It is believed that in many of this group the primary infection was one of rather low virulence.

In the 50 patients who developed secondary foci there were 81 metastatic lesions (Table I) an average of 1.62 lesions per patient. Thus a patient who develops one secondary focus is liable to develop others. Thirty-eight of the 50 patients with secondary foci were among the 100 patients in whom the adjacent joint was involved. This may be interpreted as evidence that secondary foci are more frequent among patients in whom (1) the adjacent joint is involved, (2) in whom the infection has broken through the epiphyseal cartilage plate to involve the epiphysis, or (3) in whom the primary disease is relatively extensive.

We have also divided these patients into 4 groups, depending upon the extent of the pathology in the bone where the primary focus occurred as shown by the x rays made on admission. These are classed as +, ++,

+++ +++++ pathology in the bone and naturally the groups are not sharply demarcated. Figures 1, 2, 3, 4 and 5 illustrate lesions which we regard as being typical of each group. We have attempted to correlate the extent of the bone pathology present on admission with the type of treatment which these patients received during their acute illness (Table IV). A study of this table, however, does not permit the drawing of any definite conclusions and it appears that the degree of bone destruction was not definitely influenced by the early treatment which was given in this series. Apparently the disease tends to be self limited, the bone is invaded very rapidly, and the amount of bone destroyed varies directly with the virulence of the invading organism and inversely with the resistance of the individual. If drainage is to be effective in limiting the spread of the primary focus it must be done very early in the disease.

As most of these patients came from the country or small towns, cultures of the loci or of the blood were rarely made during the acute illness, and we have no data regarding the organisms responsible for the disease. Neither have we any information regarding the frequency of septicemia, except that 3 of the patients were said to have had positive blood cultures.

TREATMENT

The treatment which these patients have received has been fairly uniform throughout the 14 year period. Most of the patients have been operated upon and the operation which we perform consists of the removal of any sequestra encountered and a wide saucerization of the cavity. As much as possible of the chronically infected bone is removed without the amputation or resection of bone. Care is taken not to curtail the main joints or to destroy epiphyseal cartilages and we avoid the leaving of deep bone cavities with overhanging edges or tunnels through the bone. These can be filled with muscle flaps and may heal, but experience has shown that in the majority of these in which healing occurs the disease recurs and the operations fail to give satisfactory results.

accomplish the purpose for which they were devised, namely, removal of all of the infected bone and the creation of a wound which can heal from within outward without leaving a dead space which will harbor chronic infection. Fortunately, in 61.3 per cent of our patients followed for 3 years or longer, the wounds healed and remained healed for 3 years or more in spite of incomplete removal of infected bone. In 38.7 per cent of this same group it was not practicable to create sufficiently favorable conditions by operative procedures to arrest the disease over the 3 year period.

Our observations lead us to believe that in any extensive series of patients with chronic osteomyelitis there is a considerable number (probably one-third) in whom, because of the extent of the involvement, permanent cure is impossible without complete, or almost complete, removal of the entire bone which is involved. We look with grave suspicion upon the various series of such cases in the literature in which all, or nearly all, of a given series were cured by one means or another (1). We believe that it is time the medical profession admitted this and realized that in the treatment of acute osteomyelitis the prevention of widespread destruction of bone is almost as important as is the saving of the life of the patient.

In addition to checking our patients as to whether or not the disease appeared to have been arrested, we have also evaluated them on a functional basis (Table IV) and endeavored to correlate the result with the treatment which the patients received during the acute stage of the disease. Poor results are those with a marked deformity, complete loss of function in the adjacent joint, complete destruction of an epiphyseal line, or persistent drainage, and these comprised 35.5 per cent of the 200 patients. Fair results are patients showing a slight or moderate deformity, as some impairment of joint function, slight disturbance of growth, or a slight amount of drainage, and these comprised 28 per cent of the series. Good results represent those patients in whom the disease appeared to have been arrested without residual deformity or important disturbance in growth

and without significant loss of function in the adjacent joints. This result was obtained by us in only 25.5 per cent of the 200 patients.

In some patients extensive scars cover the bone after healing is complete. These scars are attached to the bone, are poorly supplied with blood, and are covered by a thin layer of epithelium. They tend to break down with superficial ulcerations following relatively slight trauma. They heal very slowly and because of their persistent character, are often mistaken by the patient for a flare-up in the bone infection itself. Because of these characteristics and because these scars are unsightly, we feel that they should be excised and replaced by a hair line scar if possible. The defect remaining after excision of the scar is sometimes small enough so that the neighboring skin and subcutaneous tissue can be undermined and closed over the defect without undue tension. Sometimes, however, especially in the tibia, the defect is so large that this is impossible without increasing the tension on the skin edges to such an extent that a slough may occur. It is important to procure a healthy soft tissue covering for the bone. In order to obtain this result it may be necessary to raise a double pedicle flap on the medial aspect of the leg and shift it laterally to cover the exposed portion of the bone completely. The defect on the medial aspect resulting from the shifting of the double pedicle flap is then covered with a split thickness graft. The result in such a case is shown in Figure 6.

SUMMARY

Of 200 consecutive patients with chronic osteomyelitis, 41 had been treated for more than 1 week with an erroneous diagnosis during the acute stage of the process and in only 9 was the bone drained during the first week of the disease.

Consequently, at least 191 of these patients had been treated conservatively or by delayed operation. In this entire series the incidence of secondary bone foci was 25 per cent and the involvement of the neighboring joint was 50 per cent.

By means of the standard surgical procedures and prolonged hospitalization with

is left is beyond the reach of maggots or of any chemical or other agent which can be applied to the surface of the wound. Hence, we do not use bacteriophage. It has been amply demonstrated that this agent is inhibited by the body fluids and that bacteria in chronic infections quickly become immune to a bacteriophage.

Observations upon these and other patients with chronic osteomyelitis convince us that the permanent cure of chronic osteomyelitis in children over 3 years of age depends upon the thoroughness of the operation and not upon the after treatment. If all of the infected bone can be removed, the wound will heal and stay healed if it is kept open so that it heals from within out and it matters little what type of dressing is used as long as it is not actually harmful. It should also be remembered that the smaller the opening, the more rapid the healing as long as drainage is assured. Hence, our method of partial closure at the operation for saucerization.

If all of the infected bone is not removed, the wound may heal or may continue to drain indefinitely depending upon the activity of the infection and the geography of the wound, but even if it heals, the wound remains a potential source of trouble because the infection may become active again and cause a flare up of the old disease. This is because human beings do not tend to develop an effective degree of immunity to the staphylococcus or to the streptococcus regardless of the period of contact with the organisms, nor has any means been found as yet which will confer such an immunity. (2)

RESULTS OF TREATMENT

Of the 200 patients in this series it has been possible to follow 98 of them over a period of 3 years or longer. Of these, 60 were apparently cured and had shown no evidence of active disease during the 3 year or longer period while 38 had evidence of active disease during that time. Of these 38 failures 24 had been healed and apparently cured during part of the 3 year or longer period, but the disease had recurred and abscesses had formed. In the remaining 14 patients the disease had remained clinically active during the entire

period of observation. In these 14 cases of persistent drainage, there was involvement of epiphyseal plates or of neighboring joints.

Of the remaining 102 patients it was possible to follow 38 of them over a period of from 2 to 3 years. Of these, 16 had remained clinically healed for at least 2 years while the remaining 22 revealed evidence of some activity during this time.

Thirty seven of the 64 remaining patients were followed for a period of from 1 to 2 years. Of these, 22 were clinically well and the 15 remaining still had evidence of active disease. There remain 27 patients who failed to return for additional observation or were followed for less than 1 year. There were 2 amputations and 1 death in the series of 200 patients. The death resulted from an attempt to do an adequate sequestrectomy on an involved hip joint. Only 1 resection was performed and this was for removal of a portion of 1 rib.

Our failure to cure 38.7 per cent of the 98 patients who were followed for 3 years or more is not entirely due to the extent of the bone pathology present on admission because they were graded as follows: 4, ++, 18, +, 9, +++ and 7, ++++, while the 3 year cures consisted of 7, +, 24, ++, 18, +, +, and 11, ++++ involvement. In regard to the bones affected, the 3 year cures were femur, 33, tibia 14, humerus 1 and other bones, 10. Our failures were due to our inability to arrest the activity of the disease. This is due to the fact that in a bone which is chronically infected the infection is by no means limited to the abscess cavity or to the adjacent bone, but eburnation of bone extends for a considerable distance up the shaft and this contains minute temporarily walled-off nests of infected granulation tissue which may give rise to an active infection in the future. Furthermore it is the rule rather than the exception for a bone which is extensively involved to show pathology throughout the entire extent of the bone in the involved area. At the saucerization operation a part of the area is always left to preserve the integrity of the shaft, and this so called pencil of bone is always infected bone. It is thus evident that relatively few of our saucerization operations

accomplish the purpose for which they were devised, namely, removal of all of the infected bone and the creation of a wound which can heal from within outward without leaving a dead space which will harbor chronic infection. Fortunately, in 61.3 per cent of our patients followed for 3 years or longer, the wounds healed and remained healed for 3 years or more in spite of incomplete removal of infected bone. In 38.7 per cent of this same group it was not practicable to create sufficiently favorable conditions by operative procedures to arrest the disease over the 3 year period.

Our observations lead us to believe that in any extensive series of patients with chronic osteomyelitis there is a considerable number (probably one-third) in whom, because of the extent of the involvement, permanent cure is impossible without complete, or almost complete, removal of the entire bone which is involved. We look with grave suspicion upon the various series of such cases in the literature in which all, or nearly all, of a given series were cured by one means or another (1). We believe that it is time the medical profession admitted this and realized that in the treatment of acute osteomyelitis the prevention of widespread destruction of bone is almost as important as is the saving of the life of the patient.

In addition to checking our patients as to whether or not the disease appeared to have been arrested, we have also evaluated them on a functional basis (Table IV) and endeavored to correlate the result with the treatment which the patients received during the acute stage of the disease. Poor results are those with a marked deformity, complete loss of function in the adjacent joint, complete destruction of an epiphyseal line, or persistent drainage, and these comprised 35.5 per cent of the 200 patients. Fair results are patients showing a slight or moderate deformity, as some impairment of joint function, slight disturbance of growth, or a slight amount of drainage, and these comprised 28 per cent of the series. Good results represent those patients in whom the disease appeared to have been arrested without residual deformity or important disturbance in growth

and without significant loss of function in the adjacent joints. This result was obtained by us in only 25.5 per cent of the 200 patients.

In some patients extensive scars cover the bone after healing is complete. These scars are attached to the bone, are poorly supplied with blood, and are covered by a thin layer of epithelium. They tend to break down with superficial ulcerations following relatively slight trauma. They heal very slowly and because of their persistent character, are often mistaken by the patient for a flare-up in the bone infection itself. Because of these characteristics and because these scars are unsightly, we feel that they should be excised and replaced by a hair line scar if possible. The defect remaining after excision of the scar is sometimes small enough so that the neighboring skin and subcutaneous tissue can be undermined and closed over the defect without undue tension. Sometimes, however, especially in the tibia, the defect is so large that this is impossible without increasing the tension on the skin edges to such an extent that a slough may occur. It is important to procure a healthy soft tissue covering for the bone. In order to obtain this result it may be necessary to raise a double pedicle flap on the medial aspect of the leg and shift it laterally to cover the exposed portion of the bone completely. The defect on the medial aspect resulting from the shifting of the double pedicle flap is then covered with a split thickness graft. The result in such a case is shown in Figure 6.

Consequently, at least 191 of these patients had been treated conservatively or by delayed operation. In this entire series the incidence of secondary bone foci was 25 per cent and the involvement of the neighboring joint was 50 per cent.

By means of the standard surgical procedures and prolonged hospitalization with

is left is beyond the reach of maggots or of any chemical or other agent which can be applied to the surface of the wound. Hence, we do not use bacteriophage. It has been amply demonstrated that this agent is inhibited by the body fluids and that bacteria in chronic infections quickly become immune to a bacteriophage.

Observations upon these and other patients with chronic osteomyelitis convince us that the permanent cure of chronic osteomyelitis in children over 3 years of age depends upon the thoroughness of the operation and not upon the after treatment. If all of the infected bone can be removed, the wound will heal and stay healed if it is kept open so that it heals from within out, and it matters little what type of dressing is used as long as it is not actually harmful. It should also be remembered that the smaller the opening, the more rapid the healing, as long as drainage is assured. Hence, our method of partial closure at the operation for saucerization.

If all of the infected bone is not removed, the wound may heal or may continue to drain indefinitely depending upon the activity of the infection and the geography of the wound, but even if it heals, the wound remains a potential source of trouble because the infection may become active again and cause a flare up of the old disease. This is because human beings do not tend to develop an effective degree of immunity to the staphylococcus or to the streptococcus regardless of the period of contact with the organisms, nor has any means been found as yet which will confer such an immunity. (2)

RESULTS OF TREATMENT

Of the 200 patients in this series it has been possible to follow 98 of them over a period of 3 years or longer. Of these, 60 were apparently cured and had shown no evidence of active disease during the 3 year or longer period, while 38 had evidence of active disease during that time. Of these 38 failures, 24 had been healed and apparently cured during part of the 3 year or longer period, but the disease had recurred and abscesses had formed. In the remaining 14 patients the disease had remained clinically active during the entire

period of observation. In these 14 cases of persistent drainage, there was involvement of epiphyseal plates or of neighboring joints.

Of the remaining 102 patients it was possible to follow 38 of them over a period of from 2 to 3 years. Of these, 16 had remained clinically healed for at least 2 years while the remaining 22 revealed evidence of some activity during this time.

Thirty seven of the 64 remaining patients were followed for a period of from 1 to 2 years. Of these, 22 were clinically well and the 15 remaining still had evidence of active disease. There remain 27 patients who failed to return for additional observation or were followed for less than 1 year. There were 2 amputations and 1 death in the series of 200 patients. The death resulted from an attempt to do an adequate sequestrectomy on an involved hip joint. Only 1 resection was performed and this was for removal of a portion of 1 rib.

Our failure to cure 38.7 per cent of the 98 patients who were followed for 3 years or more is not entirely due to the extent of the bone pathology present on admission because they were graded as follows: 4, +, 18, ++, 9, +++, and 7, +++++ while the 3 year cures consisted of 7, +, 24, ++, 18, +++, and 11, +++++ involvement. In regard to the bones affected the 3 year cures were femur, 35, tibia 14, humerus 1, and other bones 10. Our failures were due to our inability to arrest the activity of the disease. This is due to the fact that in a bone which is chronically infected, the infection is by no means limited to the abscess cavity or to the adjacent bone, but eburnation of bone extends for a considerable distance up the shaft and this contains minute, temporarily walled-off islets of infected granulation tissue which may give rise to an active infection in the future. Furthermore, it is the rule rather than the exception for a bone which is extensively involved to show pathology throughout the entire extent of the bone in the involved area. At the saucerization operation a part of this area is always left to preserve the integrity of the shaft and thus so called pencil of bone is always infected bone. It is thus evident that relatively few of our saucerization operations

A BACTERIOLOGICAL STUDY OF THE PERITONEAL FLUID IN PERFORATED PEPTIC ULCERS

MARSHALL DAVISON, B.S., M.D., F.A.C.S., LEON J. ARIES, M.S., M.D., and
ISADORE PILOT, B.S., M.D., Chicago, Illinois

PERFORATION of a peptic ulcer with an immediate diffuse contamination of the peritoneal cavity has long been known to be a condition demanding immediate surgical intervention. It has been empirically recognized that the morbidity and mortality in such patients is determined to a large extent not so much by the character of the material which has already accumulated in the peritoneum as by the length of time that this contamination has been present. The recognition of the difference between early chemical peritonitis and the succeeding bacterial peritonitis is not new, but little study has been made of the type of bacterial peritonitis once this complication has occurred.

The literature on the subject is rather brief. Published monographs lead one to believe that such exudates are innocuous in the first hours. Ulrich, Moynihan, and Alexander state that there is no growth in the peritoneal fluid up to 12 and 18 hours, conversely Bruett reports 74 per cent positive cultures following perforations between the sixth and twelfth hours, and 93 per cent positive cultures in patients coming to operation 12 hours or more after perforation.

In a series of collected cases in which the peritoneal fluid following perforated ulcers has been cultured, Judine obtained 89.3 per cent positive cultures in the first 12 hours, and 100 per cent positive cultures in the second 12 hours. He also showed that those patients with sterile cultures had a smooth postoperative course with no complications. The bacterial flora found in his series consisted mostly of streptococci and staphylococci.

Vendt demonstrated bacteria in 77 per cent of his cultures of 16 cases but found few bacteria in each instance. The non-hemolytic

streptococcus dominated the picture, occurring in 90 per cent of the positive cases.

Dudgeon and Maybury report a series of 23 cases. Ten of these peritoneal fluids contained diplococci or streptococci. The authors believe that the streptococci found in the peritoneum in cases of gastric and duodenal perforations are derived from the food and have caused infection at the base of the ulcer and in the peritoneum.

In our own experience and that of other clinics (5), the greatest number of casualties and complications are due to a bacterial peritonitis. It has been our belief that a relative prognosis may be made if we could know whether or not organisms are present at the time of operation and, if present, what types.

Before considering our series of perforated peptic ulcers that were studied bacteriologically, a review of the cases of perforated ulcers for the year 1937 at the Cook County Hospital is desirable. Of 652 patients who were treated for peptic ulcer or one of its complications, 76 patients had perforations, of which 43 (56.5 per cent) were duodenal, 26 (34.2 per cent) were gastric, and 2 (2.6 per cent) were gastrojejunal. Five cases of this group were not operated upon.

Patients entering the Cook County Hospital with the diagnosis of perforated peptic ulcer were brought to surgery as soon as they could be adequately prepared. Such preparation consisted of aspiration of the stomach contents by the aid of a Levine tube and continuous suction, the intravenous administration of saline and glucose solution, and morphine and atropine. Thirty-four patients with perforated ulcers that came to operation had cultures made of the peritoneum.

adequate after treatment, it was possible to obtain healing in only 61.3 per cent of 98 cases which we followed for 3 years or longer. In 38.7 per cent of these the sinuses continued to drain or the disease healed and recurred during the period of observation.

In the series of 200 cases we consider our end results as poor in 35.5 per cent, fair in 28 per cent, good in 25.5 per cent, and unknown in 11 per cent.

We believe that the cure of the disease depends upon the ability of the surgeon to perform an adequate operation and remove all of the infected bone and that the type of after treatment is relatively unimportant, provided adequate drainage is maintained.

In about 40 per cent of the patients, adequate surgery is not feasible and such patients are practically incurable.

We believe that early diagnosis of acute hematogenous osteomyelitis and prompt drainage of the focus in the bone is the most important factor in the prevention of chronic osteomyelitis with its attendant economic waste and crippling.

a sterile syringe placed in a sterile test tube, and transferred to the bacteriology laboratory. Numerous specimens collected were discarded as they had been allowed to stand at room temperature for a length of time sufficient to allow bacteria to be destroyed before they could be placed on a media conducive to growth. Direct smears were not made routinely, as the presence of alimentary debris too frequently made it difficult to identify organisms. The samples were then cultured in the following manner:

Ascitic blood agar media was used to isolate streptococci. This is a 20 per cent ascitic fluid with one half cubic centimeter of blood added to 8 cubic centimeters of meat infusion agar. Several loops of the material to be cul-

TABLE IV — COURSE IN 6 POSITIVE CULTURE CASES

Case number	Hours elapsed	Location	Organisms	Course
14	8	Duodenum	Bacilli + cocci	Fatal in 3 days after surgery
16	12	Pylorus	Bacilli pyocyanus	Mild course
18	12	Pylorus	Saccharomyces cerevisiae	Mild
27	20	Pylorus	Streptococcus viridans (colonies few)	Wound infection
28	22	Duodenum	Staphylococcus aureus	Wound infection
34	7 days	Pylorus	Hemolytic bacillus coli	Perforation in ileum, fatal 15 days after

tured were added to this media and pour plates were made. These were examined in 24, 48 and 72 hours. The colonies obtained were then stained by Gram's method, and the gram negative colonies were replated on Endos' media. Organisms which were still unidentified were then placed on the various sugar media and a final diagnosis made by their fermentative properties. Anaerobic organisms were sought by making cultures from the original fluid on the ascitic blood agar slants from which oxygen had been absorbed by pyrogallic acid alkali mixture.

Thirty four cases with perforations were cultured. Twenty perforations were located in the stomach and 14 in the duodenum. Three (8.8 per cent) of the 34 perforations occurred in women, 2 were located in the duodenum.

The most frequent organisms found were the *Bacillus coli* and the hemolytic *Bacillus coli*. Second in frequency was the *Streptococcus hemolyticus* of both alpha and beta types. Next most frequent was the *Staphylococcus*, and in 3 instances anaerobic bacteria were isolated, one of which was of a hemolytic variety. In addition to these 1 *Bacillus pyocyanus* and 1 yeast fungus were isolated. Eighteen or 53 per cent, of the 34 cases had positive cultures. There were 16 deaths among the 34 cases (Table III). Twelve of the 16 deaths were associated with bacteria of a marked pathogenic nature. Six patients with positive cultures recovered as shown in Table IV.

TABLE V.

Case number	Hours from perforation	Location	Hours post-operative to death	Age	Cause of death
5	5	Stomach	18	60	Shock
9	6	Stomach	2	34	Shock
25	18	Duodenum	6	45	Shock
30	28	Duodenum	24	72	Age-shock

All the cases with *Bacillus pyocyaneus*, yeast infection, and *Staphylococcus albus* had mild postoperative reactions in spite of wound infections. Of those infected with *Bacillus coli*, 1 had a 7 day history with perforation into the lesser omental bursa which was well walled off as an abscess and did not contaminate the general peritoneal cavity. The second had *Bacillus coli* in the free peritoneal cavity and ran a stormy postoperative course with generalized peritonitis, resulting in many weeks' stay in the hospital.

There were 4 deaths in 34 cases in which the patients had sterile cultures. In spite of this fact, the death in each case was prior to 24 hours following operation (Table I).

The majority of positive cultures occurred after the sixth hour of perforation, cultures of *Bacillus coli* were present in only 2 instances before the twelfth hour. Anaerobic bacteria were found only after the eighteenth hour. Lohr and Clavel believe that the presence of anaerobic organisms are encountered only as secondary invaders. They are usually found in localized abscesses and may arise from neighboring intestinal loops. All patients having cultures containing both streptococci and *Bacillus coli* died of diffuse peritonitis. The 2 patients with subphrenic abscess who came to postmortem examination had pure cultures of *Bacillus coli* in great quantities. All the positive cultures of streptococci were found in cases of perforation of the stomach, while *Bacilli coli* were found in the stomach or in the duodenum, either alone or in combination with staphylococci, streptococci, and anaerobes.

It is interesting to note the marked change in the bacterial flora in the second 6 hours following perforation. The presence of streptococci and *Bacillus coli* then appear in the peritoneal cavity, and their presence may be

explained on the theory of invasion of the upper bowel by organisms normally found only in the lower intestinal tract. The presence of an early "chemical peritonitis" causes a cessation of peristalsis with a concomitant cessation of secretion of hydrochloric acid, thus allowing for a proximal migration of bacteria from the lower bowel. The quantitative acid secretion in the stomach, therefore, may be responsible for the type of organism found. Streptococci and staphylococci are the organisms most sensitive to the presence of acid. The fact that organisms are infrequent in the early hours following perforation accounts for the fact that few of these patients develop a bacterial peritonitis, the more time elapsing following the perforation the more pathogenic the type of organism. Thus, patients having sterile cultures follow an uneventful postoperative course and do not develop complications.

The clinical course and prognosis in perforated ulcer may be determined by the bacteriological flora as is evidenced by the following case.

The patient, a laborer, aged 27 years, entered the hospital with diffuse abdominal pain present for 5 hours. The onset of the pain was sudden and severe in the upper abdomen spreading rapidly to the lower abdomen. There was no previous gastro-intestinal complaint. Physical examination revealed a well nourished young man lying quietly in bed with a rigid abdominal wall, absence of peristaltic sounds and obliteration of liver dullness. Fluoroscopy revealed a large air bubble beneath the diaphragm confirming the diagnosis of perforated peptic ulcer. Operation was performed within 6 hours after the onset of symptoms. A culture was taken upon opening the peritoneal cavity and 1200 cubic centimeters of a turbid fluid was aspirated from the peritoneal cavity and pelvis. The ulcer one half centimeter in diameter with a soft friable margin was closed with linen suture, and the abdomen was closed without drainage. Continuous gastric suction and supportive treatment were instituted after operation. The abdomen began to distend after the twenty-eighth hour in spite of the gastric decompression, temperature rose to 103 degrees. Transfusion of 350 cubic centimeters of blood was given on the second and third postoperative days because of the patient's poor condition. There were no intestinal sounds at any time and the patient became progressively worse in spite of all therapy and died on the fifth postoperative day from a diffuse peritonitis. The bacteriologist reported the presence of streptococci, *Bacilli coli* and proteus. The diffuse contami-

nation of the peritoneal cavity by such pathogenic organisms in the early hours following perforation offers a poor prognosis and we were cognizant of this fact within 40 hours.

There is no indication for draining those patients who have sterile material in their peritoneal cavities. The significance of a lower mortality rate (22.3 per cent) in the past year at the Cook County Hospital is due to the fact that the majority of patients, namely 57 of the 76 cases, were operated upon in the first 12 hours after perforation and in no patient operated upon was there a drain introduced into the peritoneal cavity.

CONCLUSIONS

1. Certain positive cultures from the peritoneal fluid in perforated peptic ulcers offer a prognostic significance as to the clinical course.

2. Cultures taken in the first 6 hours are usually sterile but when positive offer a poor prognosis.

3. The most frequent organisms found are the *Bacillus coli* and the streptococcus.

4. When cultures are sterile the postoperative course is smooth and the mortality is low.

5. The presence of pathogenic organisms in the cultures is associated clinically with complications and are directly responsible for the mortality and morbidity.

6. Drainage is indicated only in patients operated upon many hours following perforation, and then this can be construed only as an heroic treatment.

We wish to thank Miss Silka Stocker and Miss Kathryn E. Buck for their technical assistance.

THE USE OF NEOSYNEPHRINE IN SPINAL ANESTHESIA

ROBBIE S. BRUNNER, M D, and GÉZA de TAKATS, M D, F A C S,
Chicago, Illinois

ONE of the difficulties encountered during the administration of spinal anesthesia is the maintenance of a stable level of blood pressure. The drugs commonly used for this purpose are epinephrine and ephedrine. Both produce an increase in heart rate with a tendency to arrhythmia and are stimulants of the central nervous system. Epinephrine when given subcutaneously or preferably into the muscle produces only an evanescent and inconstant rise in blood pressure, administered intravenously the rise in blood pressure may be marked but is transient. Its action on the heart is marked, ventricular fibrillation has been reported after its intravenous use and pulmonary edema may be produced. Ephedrine has a more prolonged and less violent action on the cardiovascular apparatus but similar to epinephrine it increases the heart rate and nervous tension. The well premedicated conscious patient may become "jittery" after its use.

A brief series of spinal anesthetics has been reported by Tovell who used benzedrine for the control of blood pressure. Our interest in the use of neosynephrine as a peripheral vasoconstrictor was aroused by the work of Carl A. Johnson (2, 3) who showed in a series of animal and clinical experiments that the subcutaneous injection of this drug is followed by an increase in blood pressure, a slowing of the heart rate, and that therapeutic doses such as 5 to 10 milligrams did not produce nervousness and anxiety. The previous literature on the subject can be found in his two articles. Johnson did not find any abnormal cardiac mechanism following its repeated use and found it valuable in combating the hypotension in shock and hemorrhage following operations. It occurred to us that if the drug was so effective in raising a low blood pressure, it might be advantageously used in smaller

doses as a preventive against the fall in blood pressure following the induction of spinal anesthesia. A preliminary report on our first 50 cases was made in October, 1937 (1). In January, 1938, Lorhan and Oliverio reported a series of 30 cases and concluded that the drug could be repeated without losing its effect but without the toxic phenomena observed with ephedrine. They stated that the action of the drug was rapid and that blood pressure was maintained for at least 30 minutes following its injection. They were impressed with the rate, rhythm, and volume of the pulse after its use.

We are reporting a series of 163 cases of spinal anesthesia administered in conjunction with the use of neosynephrine. For a control series we selected 100 operations done under spinal anesthesia in which ephedrine was used for the control of blood pressure. The neosynephrine group has been subdivided into low and high spinal anesthetics. In 113 low spinal anesthetics the loss of sensation extended to the umbilicus or slightly above, in the 50 high anesthetics the level of the anesthesia was at the costal margin or above in 60 per cent, midway between umbilicus and xyphoid process in 14 per cent, and to the umbilicus in 26 per cent. Every effort was made to select as nearly as possible a similar control group in which we have 50 low and 50 high spinal anesthetics. The anesthetic drugs used and their dosage will be discussed later.

PROCEDURE

Blood pressure and pulse were determined while the patient was in the ward and then again after reaching the operating room. Following the injection of the vasoconstrictor, readings were made every 5 minutes until the operation was completed. Spinal anesthesia was induced within 5 minutes of the injection of neosynephrine or ephedrine, these were injected into the deltoid muscle and the site of injection was not massaged. Excluded from

From the Department of Surgery and the Division of Anesthesia, University of Illinois, College of Medicine

nation of the peritoneal cavity by such pathogenic organisms in the early hours following perforation offers a poor prognosis and we were cognizant of this fact within 40 hours.

There is no indication for draining those patients who have sterile material in their peritoneal cavities. The significance of a lower mortality rate (22.3 per cent) in the past year at the Cook County Hospital is due to the fact that the majority of patients, namely, 57 of the 76 cases, were operated upon in the first 12 hours after perforation, and in no patient operated upon was there a drain introduced into the peritoneal cavity.

Graph 4 Average curves of blood pressure and pulse in 50 cases under high spinal anesthesia using neosynephrine with pontocaine in 10 per cent glucose solution. The average duration of anesthesia was 2 hours and 15 minutes. The stability of the curves is impressive after the use of neosynephrine.

heart rate. Neosynephrine was given in doses of 0.5 cubic centimeter of a 1 per cent solution, in 15 cases it was repeated again and in 1 case 3 injections were given. It will be noted that the average systolic pressures did not vary over 12 points and the average diastolic pressures over 10 points. The average pulse rate was maintained below 80 but not lower than 70 beats a minute. One would get a false impression, however, by looking at only the average curves in regard to marked fluctuations of blood pressure under spinal anesthesia and the ability of neosynephrine to control them. In Graph 2 one can see the marked pressor response to the first dose of neosynephrine which, however, wore off in 30 minutes when the pulse pressure became small. The small pulse pressure is often the earliest sign of shock, but a small dose (0.25 cubic centimeter) of neosynephrine promptly restored the systolic blood pressure. Note also the marked bradycardia, the pulse rate ranging around 50 for at least 45 minutes. In such cases added to the hypotensive effect of the spinal anesthesia, one has to consider the effect of hemorrhage and shock, both of which may be compensated within limits by vasoconstriction (3).

Graph 5 Average curves of blood pressure and pulse in 50 cases under high spinal anesthesia using ephedrine with procaine hydrochloride. The average duration of anesthesia was 1 hour and 40 minutes. Both systolic and diastolic pressure gradually drop. The pulse rate is well stabilized. Since these records were obtained several years ago before pontocaine-glucose was available, they are not ideal as controls to compare with Graph 4. However, pontocaine-glucose produces a long anesthesia and thus constitutes a more severe test for neosynephrine.

Graph 1 Average curves of systolic and diastolic blood pressures and pulse rates in 113 cases under low spinal anesthesia with procaine hydrochloride. Five tenths cubic centimeter of 1 per cent solution of neosynephrine was given subcutaneously 5 minutes before the intraspinal injection. The level of all 3 curves is well maintained.

Graph 3 Average curves of blood pressure and pulse in 50 cases under low spinal anesthesia. Every effort was made to make this "control" series comparable to the one shown on the first graph. Three fourths grain of ephedrine was used instead of neosynephrine. Note that the blood pressure shows a gradual fall and the pulse rate rises.

Graph 2 Blood pressure and pulse record of a patient undergoing transurethral resection of the prostate. Circles indicate beginning and end of operation. Note the marked rise in systolic with the moderate rise in diastolic blood pressures together with a slowing of the pulse after injection of one half cubic centimeter neosynephrine. A second dose of a small amount of neosynephrine (0.4-cub. centimeter) is quite effective. Such large responses are sometimes seen; the pressor response here lasted 45 minutes.

our statistics were patients who had complications during operation such as hemorrhage in the presence of marked hypertension, neosynephrine was not administered except when a fall in blood pressure occurred. In order to stabilize blood pressure as much as possible a second dose of neosynephrine was given as soon as the blood pressure began to drop. The interval between 2 injections ranged from 10 minutes to 1 hour and 15 minutes, the majority of them being within 30 minutes after the first dose.

RESULTS

In the first group of 113 cases in which low spinal anesthesia was induced and neosynephrine was used to control the blood pressure, the average dose of procaine crystals was 97 milligrams in 2 cubic centimeters of spinal fluid. The maximum dose was 200 milligrams in 3.5 cubic centimeters and the minimum dose was 50 milligrams in 2 cubic centimeters of spinal fluid. Graph 1 shows the average systolic and diastolic blood pressures and the

Graph 9 Electrocardiogram (a, before injection, b, after) of a patient with a normal cardiovascular apparatus before and after the administration of 1 cubic centimeter of a 1 per cent solution of neosynephrine. The pulse rate dropped to 40 from 58, a simple bradycardia resulted from the injection

the level of the umbilicus or below it, the average dose of procaine was higher than in the first group, namely, 125 milligrams. The maximum dose, however, was lower, only 150 milligrams and the minimum dose given was 80 milligrams of crystalline procaine. Ephedrine sulphate was administered in a dose of 50 milligrams (three-fourths grain). It was repeated in 2 cases. Both systolic and diastolic pressures show a gradual fall, 22 points in the systolic and 20 points in the diastolic average pressures (Graph 3). The average pulse rate in contrast to the first series shows a definite rise; it ranged between 95 and 105 beats a minute during the course of operation.

In another series of 50 patients, high spinal anesthetics were studied with neosynephrine and compared with another 50 cases in which ephedrine was employed. These 2 groups are again not strictly comparable, as in the neosynephrine group pontocaine in 10 per cent glucose was the spinal anesthetic, whereas in the control group, which was selected from the material of previous years, crystalline

procaine was used. However, the level of anesthesia was just as high in the control series and it is permissible to assume that the fall in blood pressure is commensurate with the level of vasoconstrictor paralysis. In addition, the pontocaine-glucose anesthesia lasts so much longer than the procaine anesthesia that neosynephrine has been put to a more severe test in this group than it has been in the controls.

Graph 4 shows the average figures of 50 cases. The average dose of pontocaine was 17 milligrams, individual doses ranging from 20 milligrams in 3.5 cubic centimeters to 10 milligrams in 1 cubic centimeter of 10 per cent glucose. Readings were continued for 2 hours and 5 minutes, although individual cases had even longer operations under effective anesthesia. The curves show a satisfactory leveling of blood pressures and pulse rates within this period. Again the average pulse did not go above 73 nor drop below 60 beats per minute. The lowest average reading of blood pressure was 92/60.

Graph 6 Blood pressures and pulse rates of a patient during and for 5 hours after spinal anesthesia. Following the return of the patient to bed a bradycardia between 44 and 48 continued for over 2 hours. The pulse however was regular. When the blood pressure fell to 74/50 another 0.5 cubic centimeter of neosynephrine was given.

The rise in blood pressure occurred on the average within 10 minutes following the injection of neosynephrine. Within this limit 27 per cent of the cases showed a rise of 20 points or more of the systolic blood pressure while in some cases no rise occurred after the first dose. The lack of rise of course, does not indicate that the drug was ineffective, as it is really given to prevent a fall which so often accompanies spinal anesthesia.

Graph 7 This patient shows a good pressor response with a slight bradycardia which seems to last just as long as the hypertension. Such observations may be duplicated many times and would suggest that the bradycardia is a reflex response to the rise in blood pressure such as occurs when closing an arteriovenous fistula (Branham's sign).

which resulted in a prompt pressor response the pulse fell as low as to 30 and later varied between 38 and 60 beats per minute. There was an arrhythmia for 2 hours. While no electrocardiogram is available during this bradycardia with arrhythmia the probability of a partial heart block is high.

A control series of 50 patients had been given a low spinal anesthesia with ephedrine as the vasomotor stimulant. While every attempt was made to select a comparable series this is possible only within limits. Thus, while all these patients had an anesthesia at

Graph 8 This patient underwent a nephro tomy under general anesthesia. Severe bleeding occurred followed by a fall in blood pressure to 90/60. The pulse rose from an initial rate of 90 to 140. One cubic centimeter of neosynephrine failed to raise the blood pressure although it might have prevented a further fall and the pulse rate rose to 160. Restoration of blood volume with serum raised the blood pressure slightly. This graph is presented to illustrate that when hypotension is due to loss of circulating blood volume the drug is not as dependable as when a pure vasomotor palsy is present.

pulse rate became as low as 30 beats per minute and a marked arrhythmia developed and persisted for 2 hours. It is interesting to note that this patient had an arrhythmia on the floor before coming to the operating room. To illustrate, however, that this bradycardia is not always of as long duration, we show the curves obtained in a patient with an inguinal hernia (Graph 7). In this case the bradycardia, which was not pronounced, lasted exactly the length of time which the hypertension did. In case of profuse hemorrhage, however, neosynephrine may not raise blood pressure or produce a bradycardia. In Graph 8 a nephrostomy was done under general anesthesia. When severe bleeding occurred and the blood pressure fell, neosynephrine did not produce a rise although it may have prevented a further fall, the pulse kept climbing up. Restoration of blood volume with acacia effected a prompt rise in blood pressure.

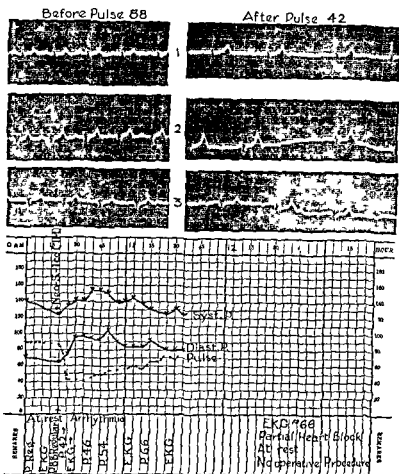

EVALUATION OF STUDY

Our experience with neosynephrine, as shown in the graphs presented, shows that it is capable of stabilizing blood pressure in spinal anesthesia in the majority of cases whether the anesthesia is low or high, or of short or long duration. As the acute hypotension during spinal anesthesia is of vasomotor origin, it is to be expected that a drug which has a marked peripheral vasoconstrictor action would be suitable for the maintenance of blood pressure. It definitely lacks the action of epinephrine and ephedrine on the central nervous system and does not increase the irritability of the patients who are in a conscious state under spinal anesthesia.

It can also be said that if the hypotension is due only to a vasomotor palsy but not to a sudden loss of circulating blood volume the drug can be depended on to restore blood pressure to a safe level. As a matter of fact the drug should really be given more for prevention of hypotension than for restoration of the blood pressure. It has been our custom to give the first dose just before the induction of spinal anesthesia and give the second dose when the blood pressure begins to drop, which is usually around 30 minutes following the induction of the spinal anesthetic.

Beside the hypertensive action of the drug a slowing of the heart occurred to 48 beats or below in 11 per cent of 163 cases. One might at first consider this as due to the pressor-receptors in the vascular system which respond with a vagal slowing of the heart whenever systemic or pulmonary pressure rises. This is a useful mechanism and has a sparing action on the heart. But as shown in Graph 6 the bradycardia outlasted the hypertension for several hours. The pulse rate dropped as low as 30 and varied mostly between 48 and 42. This and a few other observations prompted us to investigate this bradycardia more closely. Johnson has pointed out that this is a simple bradycardia and we found this to be so in a few experiments in which electrocardiographic tracings have been made before and after the use of the drug (Graph 9). That one can produce a partial heart block with neosynephrine is illustrated in the case of E. S., a patient with an atypical hyperthyroidism and a high unstable vegetative nervous system, whose electrocardiographic record would indicate that a partial heart block had been produced with 1 cubic centimeter of 1 per cent neosynephrine (Graph 10). This observation and the one recorded on Graph 6 would indicate (1) that, in patients with advanced age and slow pulse or evidence of myocardial damage, the drug be used with great caution, preferably with atropine, (2) that doses of 0.5 cubic centimeter be not exceeded for 1 injection, but repeated injections are permissible. However, we do not wish to create the impression that any untoward cardiac symptoms are to be expected from 0.5 cubic centimeter doses. To illustrate the tolerance of some patients to this drug the case of a patient who received 1 cubic centimeter of a 1 per cent solution of neosynephrine intravenously by mistake may be cited. Outside of a violent headache and palpitation no damage resulted from this error.

A further study of neosynephrine on the heart with electrocardiograms and measurements of cardiac output is now under way. As a persistent heart rate at rest below 50 is always suspicious of a heart block (4), we intend to exclude such patients from the use of neosynephrine until more is known about

Graph 10. Electrocardiogram blood pressure curve and pulse rate following the injection of 1 cubic centimeter of a 1 per cent solution of neosynephrine. The pulse dropped to 42 and 38. With a pulse rate of 42 a partial heart block developed which was present also in a subsequent tracing taken 45 minutes after the injection. A last tracing taken an hour after the injection showed a normal rhythm. There were no symptoms in the patient save his dry which would be indicative of myocardial disease.

Comparing these figures with the ones obtained in the control group, in which epinephrine was used for maintenance of blood pressure, one notes that the average duration of anesthesia is shorter and yet the tendency for both systolic and diastolic pressures to drop is more pronounced as is shown in Graph 5. The average dose of procaine was 202.5 milligrams in 2.4 cubic centimeters of spinal fluid ranging from a maximum of 300 milligrams in 5 cubic centimeters to a minimum dose of 150 milligrams in 1 cubic centimeter of spinal fluid. The dosage of epinephrine was 1.5 grains

in 10 cases, 1 grain in 1 case and three fourths grain in the remaining 30 cases.

The average pulse rate is again higher here than in the neosynephrine series. The bradycardia following the administration of neosynephrine is a striking phenomenon. It outlasts the temporary rise in blood pressure. In Graph 6 the bradycardia continued after the patient had been returned to his bed and varied between 44 and 48 for over 4 hours. Following a second dose of neosynephrine which was given because of a fall in blood pressure to 80 systolic and 55 diastolic, the

KNEE JOINT TUBERCULOSIS

Two Hundred Twenty-Two Patients Treated by Operative Fusion

JAMES W. TOUMEY, Jr., M.D., F.A.C.S., Med.Sc.D., New York, New York

FUSION of the knee joint has not yet been universally accepted, especially the use of this procedure in children.

It is, therefore, considered advisable to present this large series consisting of all the cases of knee joint tuberculosis operated upon at the New York Orthopedic Hospital from September, 1915, through December, 1936. Knee fusion was performed in 222 cases during this period. One hundred and ninety-nine cases have been followed 1 year or more, and these patients form the group for end-result study.

DIAGNOSIS

The diagnosis is not difficult in late cases which often have a suggestive appearance. Flexion deformity, synovial thickening, marked atrophy of the thigh and calf, with slight heat and tenderness at the joint, form a typical group of physical signs to which sinus formation is frequently added. In the early cases, the diagnosis is not so evident. Persistent, unilateral, synovial thickening or effusion at the knee, raises the question of tuberculosis, and it has been our experience at this hospital for many years that this question cannot be satisfactorily answered except by exploration of the joint, thereby verifying the diagnosis by laboratory methods. Tuberculosis may be present even though it is not found by aspiration and guinea pig inoculation.

The most usual history is one of chronic swelling of the knee with gradual onset. A history of injury was given in 60 of the entire series of 222 cases. It is difficult to evaluate this factor. Frequently trauma is slight and the symptoms do not appear until many months after the injury.

In 146 cases of the series the diagnosis was proved by the finding of tubercles in the sections of pathological material taken from the knee joint, by guinea pig inoculation of this

material, or by both. Thirty-two cases were negative. It is our practice to take from each joint opened, tissue for frozen sections, tissue for permanent sections, and tissue and joint fluid for culture. We advocate the inoculation of 2 guinea pigs in each case, as we have found that a number of pigs died of causes other than tuberculosis before the allotted 3 weeks prior to autopsy. The 32 unproved cases were included in the series because of the history, physical, and operative findings. It is sometimes difficult for the surgeon to select fragments of tissue which contain tubercles for examination, even when the process is active and extensive. Tubercles are more frequently found in the synovial layer than elsewhere in the joint. Many of the unproved cases are those of long duration in which patients have had years of conservative treatment prior to operation. Their course has been typical of tuberculosis, the majority having had sinuses in the past. At operation, there is found much fibrosis, marked destruction of cartilage, and usually erosion of bone.

SYMPTOMS AND SIGNS IN EARLY CASES

Seventy-nine cases entered the clinic for treatment 1 year or less following the onset of symptoms and form an interesting group of early cases. The most common presenting complaint among these individuals was swelling at the knee, the next was pain, and the next, stiffness. A limp, though it must have been present early, was not noted as a rule. The shortest period in which medical aid had been sought after the onset was 3 days.

In the dispensary examination of these early patients, physical signs were noted in the following frequency: swelling, 67; flexion deformity, 43; spasm, 37; effusion, 30; increased heat, 19; atrophy, 12; tenderness, 9; sinuses, 3. In every case one or more definite physical signs were present. In all these early cases the legs were of equal length.

the action of this drug on the heart. While a pre operative electrocardiogram often would be desirable, its routine use on large surgical services is not feasible at present, nor is the clinical significance of some abnormal electrocardiographic findings certain enough to deny some of these patients the benefit of surgical relief. This is especially true of the group suffering from prostatic obstruction.

SUMMARY AND CONCLUSIONS

In a series of 163 patients who were given a spinal anesthesia neosynephrine was used in a single or repeated dose to stabilize blood pressure. In a control series of 100 patients ephedrine was employed for the same purpose. It was found that neosynephrine could be depended upon to raise or maintain a falling blood pressure at least as effectively as ephedrine but it lacked the stimulating effect of ephedrine on the central nervous system which is a distinct advantage. Also instead of producing a tachycardia, as epinephrine and

ephedrine do, a bradycardia was quite apparent. The finding of this bradycardia has led to a warning in patients suffering from myocardial damage and especially those in whom partial heart block is suspected. In the group, however, which contained many bad risks no untoward reactions have been produced.

yses was often present. There was x-ray evidence of bone erosion in 5 cases.

In later stages progressive thinning of cartilage, bone erosion, and a transparent haziness of the bone shadow make the roentgenographic diagnosis less difficult. The most usual conditions to be confused with early tuberculosis are gonococcus arthritis, and arthritis of the rheumatoid type. Early acute suppurative arthritis may also give the x-ray appearance of tuberculosis though clinical differentiation should be easy.

PRE-OPERATIVE EXAMINATION

In this series there were 130 males and 92 females. The ages at the onset of symptoms were distributed from 6 months to 61 years and were grouped as shown in Table I.

TABLE I — AGE AT ONSET

Age in years	No. of cases
Under 10	127
10-19	44
20-29	27
30 and over	25

The ages at the time of fusion varied from 2½ to 62 years, and were grouped correspondingly as in Table II.

TABLE II — AGES AT TIME OF FUSION

Age in years	No. of cases
Under 10	60
10-19	73
20-29	43
30 and over	47

The usual findings before operation were swelling, limitation of motion, spasm, and atrophy of the thigh and calf. Increased heat and effusion were less commonly present. In several instances an effusion was noted which was found to consist of greatly thickened, soft, boggy, synovial lining at operation.

Measurements before fusion were recorded in 153 cases. There was shortening of the affected extremity in 62 cases, lengthening in 30 cases, and the legs were of equal length in 61 cases. Shortening was present up to 3 inches. The median was 1 inch. In the cases with lengthening of the involved extremity the maximum was 1 inch and the median one-half inch.

The position of maximum extension was noted in the pre-operative examination of 180 patients. The most severe flexion deformity was 55 degrees and the average was 20 degrees. In 21 cases complete extension was present.

Actively draining sinuses were present at the time of the fusion operation in 15 cases. In 25 other cases actively draining sinuses previously present had healed at the time of operation.

A record of tonsil examination was made in 159 cases. The tonsils appeared negative in 74 cases and inflamed or hypertrophied in 41 cases. In 41 additional cases tonsillectomy was done before operation and soon after fusion in 3 cases. Microscopic sections of tonsil tissue were examined in 15 of these cases. In 5 patients tuberculosis was found and in the 10 remaining the reactions were negative. In our opinion tonsils which do not appear normal should be removed before the fusion operation, thereby eliminating a possible focus of tuberculosis.

At examination before operation physical signs of active pulmonary tuberculosis were present in 14 cases and there were signs of inactive pulmonary tuberculosis in 4 cases. Fifty-one chest roentgenograms were taken before operation. Evidences of active pulmonary or hilus tuberculosis were present in 21, 10 had healed lesions, and 20 were negative. Other complications noted before operation are as follows:

TABLE III — COMPLICATIONS

Complication	No. of cases
Tuberculosis of hip	5
Tuberculosis of spine	9
Tuberculosis of ankle	2
Tuberculosis of wrist	1
Tuberculosis of tarsus	1
Multiple soft tissue tuberculous abscesses	1
Tuberculous cervical adenitis	1
Tuberculosis of kidney	3
Tuberculosis of sternum	1
Tuberculosis of testes	1
Syphilis	4
Gonorrhea	1

DECLINING INCIDENCE

The most encouraging aspect of knee joint tuberculosis, apart from the success of arthrodesis, is its declining incidence. This is also

PRE-OPERATIVE TREATMENT

Many of the patients in this series had been treated conservatively for years. In the entire series the average duration of symptoms before operation was $6\frac{1}{2}$ years, and there were 18 patients who had had symptoms for 15 to 48 years. There were 24 patients who were treated conservatively at the Country Branch of the New York Orthopedic Hospital at White Plains, New York, for a period of from 1 to 10 years (median 4 years), and in addition, 31 patients who had been under our treatment at the dispensary from 1 to 19 years (median 5 years). This forms a group of 54 cases, in which certainly a fair trial of conservative treatment had been made and yet the condition was not arrested by this treatment, or else, there was finally presented an inactive joint so deformed by disease that it was unfit for weight bearing. How much better it would have been had these patients with distorted useless joints come to operative fusion early instead of undergoing long years of disability meanwhile harboring a potentially dangerous focus of tuberculosis. At the Country Branch Hospital every effort was made to improve the general health of these patients. They were treated by rest and plaster when the condition was acute and in the chronic stage walking with a brace was allowed. A long leg brace was used with a steel upright on either side and leather backing behind the knee, and in some cases behind the entire leg which was snugly bandaged against the leather. The brace was attached to the shoe or to an inner foot plate and lateral joints permitted ankle motion.

It has become our practice to explore the knee by operation as soon as the diagnosis of tuberculosis is suspected either to rule out that disease by laboratory examination or to fuse the joint if the frozen section is positive. These cases are unselected except for a few in which fusion was not performed because the patient's condition obviously did not warrant the operation.

LABORATORY DIAGNOSIS

It cannot be said that frozen section is entirely reliable as there were 3 cases in which the frozen section was negative whereas the

additional permanent sections were positive thus necessitating arthrodesis at a second procedure. In 11 cases the sections were positive while the guinea pig inoculated with material from the same knee at the same time, was negative. In 2 cases the sections were negative while reaction in the pig was positive for tuberculosis. In 2 instances an inoculated pig developed tuberculosis, while a second pig inoculated with the same material from the same knee was negative.

A Mantoux or von Pirquet test was reported in 154 cases. In 2 of these cases the von Pirquet test was negative. One case was proved by section and pig while the sections in the other case, which was a chronic one of long duration were negative.

In 116 cases white blood and differential counts were taken shortly before fusion. In half the cases, which were children under 12 years of age, the lowest white count was 3,500 the highest 14,000 and the average 9,000. The other half were patients over 12 years old and among them the lowest white count was 4,600 the highest 17,000 and the average 9,500. In the younger group the polymorphonuclear leucocytes ranged from 15 to 83 per cent, the average 52 per cent. In the older group this varied from 44 to 87 per cent with an average of 69 per cent.

A Wassermann Kahn or Klein test was done on the blood of 146 patients. Four had plus 4 Wassermann reactions. Fusion occurred in all 4 syphilitic cases in from 8 to 17 months after operation.

Red blood counts and hemoglobin determinations were made in 93 cases before fusion. The lowest red count was 1,300,000 the highest 3,900,000 and the average 4,500,000. The percentage of hemoglobin varied from 50 to 100 per cent and the average was 77 per cent.

X-RAY FINDINGS

Forty three cases had x-ray films taken 1 year or less after the onset of symptoms and these form a group for the study of early x-ray changes in this condition. The most common finding was effusion or synovial thickening which was seen in 31 instances. Thin joint space and decalcification were each present in 18 cases and overdevelopment of the epiph-

Fig 2 Removal of articular cartilage from femur

Fig 3 Removal of articular cartilage from patella

costal margin. Adult knees are put up in 10 degrees' flexion as the gait is better in that position, while those of children are placed in 180 degrees' extension to prevent strain on the lower femoral epiphysis

Since 1928 ethylene has been the routine anesthetic for these cases, previously gas-ether was used. Ethylene has been employed

in 58 cases, gas-ether in 161, and spinal in 3. In no case has pulmonary tuberculosis flared up after operation whether gas-ether or ethylene was employed. A tourniquet is used during operation, the leg being first emptied of blood by a spiral Esmarch rubber bandage

Fig 4 Patella has been enucleated, and tibial articular cartilage has been removed. Slots have been made in femur and tibia to receive patella

Fig 5 Patella has been placed in prepared slots

Fig. 1. Incision for arthrodesis of knee joint

true of the general incidence of joint tuberculosis. In the 5 year period 1921 through 1925, an average of 15 knee fusions for tuberculosis were performed at this hospital each year. In comparison, during the 5 year period 1932 through 1936, the yearly average was but 5 knee fusion cases.

OPERATION ON KNEE PREVIOUS TO FUSION

Aspiration for diagnosis was done at this hospital on 16 knees and the fluid was used for guinea pig inoculation. The pigs were positive in 8 cases and negative in 8. Six of the 8 cases with negative aspirations were proved tuberculous at subsequent operation. A negative aspiration therefore does not rule out tuberculosis and this procedure should be reserved for cases in which operation must be delayed.

Exploratory arthrotomy was performed in 17 cases previous to fusion and the diagnosis of tuberculosis was verified by laboratory findings. In 4 other cases synovectomy was done because the frozen section was negative though the final report on the permanent sections was positive for tuberculosis. Three additional synovectomies were done with a preoperative diagnosis of chronic arthritis the final sections proving the condition to be tuberculosis. Incision and drainage and synovectomy were performed in 4 secondary in-

fect cases, and 2 cases had a tuberculous bone abscess close to the joint which was explored before fusion.

Twenty four additional operations were performed at other hospitals on 19 patients before fusion. These procedures included arthrotomy, resection synovectomy, incision and drainage, excision of meniscus, aspiration, and attempted arthrodesis.

FUSION OPERATION

Arthrodesis was performed in all cases essentially in the manner described by Russell A. Hibbs in 1911, who first used this procedure in cases of polyomyelitis. According to the present technique, the knee is widely exposed through a U shaped incision, from the medial aspect of the joint at the femoral condyle curving to bisect the ligamentum patellae to a corresponding point on the lateral aspect of the joint. The medial limb of the U is made first and the joint exposed through it for frozen section. The menisci are removed together with the articular cartilage from the femur and tibia to secure direct bone contact between them. The patella is denuded of cartilage and periosteum and it is placed in the slots prepared for it without changing its axis. In some cases a portion of the periosteum on the anterior surface of the patella is left attached.

Formerly the wound was closed with chromic suture for the skin though recently silk has been used in preference. In 2 cases the patella was diseased so extensively that it could not be employed in the mortice and in 2 children the bony portion of the patella consisted of a very minute fragment. In 7 cases the patella was found to be formed entirely of cartilage and in 2 of the cases the patella could not be used. In 5 cases the wound was drained because of secondary infection from open sinus tracts. The operations in this series were performed by 30 different surgeons.

Once the closure has been completed a dry dressing is placed on the wound. The joint is then surrounded with a layer of cotton gauze being taken to protect the peroneal nerve at the fibular head. Short wadding and paper are applied and then the single plaster spica extending from the toes to above the lower

material may become abundant in the joint. Thinning of the cartilage to the extent of perforation is a later change. The cartilage seems more resistant than the bone to destruction, as not uncommonly a small perforation through the cartilage becomes the mouth of a large cavity in the bone beneath. However, in 3 cases in the entire series the joint unquestionably became involved secondarily by direct extension from a tuberculous bone abscess. Areas of caseation are found only in advanced cases.

POSTOPERATIVE CARE

Two weeks after operation the plaster is fenestrated over the operative wound for inspection and suture removal. The case is then transferred by ambulance to the Country Branch Hospital at White Plains for convalescent care. Eight weeks after the fusion operation the spica is removed, an x-ray is taken, and a long leg plaster is applied from toes to groin in which the patient is allowed to walk. Following this the plaster is changed at 8 week intervals with an x-ray examination after each removal until the fusion is solid. Then the cast is left off and the patient is allowed to walk without protection. Children, however, at this stage are given a long leg brace to prevent slipping of the lower femoral epiphysis. Twenty-eight children wore braces after the plaster was removed for an average period of 8 months. Experience has shown that in some cases slipping of the lower femoral epiphysis has occurred which probably could have been prevented by the use of a brace. Epiphyseal slipping, a troublesome postoperative complication, occurred after operation in only 3 children over 10, and in each instance this was because the knee was not put up straight at the time of operation.

OCCURRENCE OF FUSION

Cases have been kept in plaster from 2 to 42 months postoperatively. The average time was 8 months. The plaster is left on in most cases until the arthrodesis is solid. Therefore, this is a measure of the time elapsed in securing fusion. A few cases with extremely active disease and many sinuses have been kept in bed longer than the 8 weeks' routine period of bed rest before weight bearing was allowed.

END-RESULTS

Of the 222 cases in which the knee fusion operation was performed, 5 died within 1 year after operation, and 18 patients were lost to the follow-up clinic within a year.

One hundred and ninety-nine cases thus remained which were followed for more than 1 year after operation and these form the group for end-result study. Every one of these 199 knees in the end-result group fused but 3; and these 3 had such hopeless sinuses both before and after the fusion operation that amputation of the leg was finally performed. These 3 patients were living and well at the last examination.

No patient with a follow-up period shorter than 1 year was retained in this series. The longest follow-up period after fusion was 17 years, the average $5\frac{1}{2}$ years. These end-result examinations were made by the staff of the New York Orthopedic Hospital.

Seven of the 199 patients, followed for more than 1 year, are dead, and successful fusion had taken place in each case. (The diagnoses at the time of death in these 7 cases were the following: pneumonia, carcinoma of the uterus, amyloidosis, pulmonary tuberculosis, renal tuberculosis, sarcoma, and unknown in 1 case.)

In the 196 cases which became fused, there was no evidence of either tuberculosis or secondary pyogenic infection remaining at the knee, except in 7 patients who had draining sinuses at the last examination. There are 3 cases now fused in which a refusion operation was performed.

The position in which the knee was arthrodesed at last examination was noted in 142 cases. Eighty-three of these were flexed, 49 were straight, and 10 were in recurvatum. In the flexed group the median amount was 10 degrees, and in the hyperextended cases the median was 10 degrees. Knock knee was present in 19 and the median was 5 degrees. Two cases had a genu varum deformity. Four cases were advised to have osteotomy because of the degree of flexion deformity.

In 93 cases measurements from the anterior superior iliac spine to the medial malleolus were recorded and 76 of these had shortening. The greatest amount of shortening was 5

Fig 6 Position of patella when arthrodesis has been completed. Bony contact has been secured between femur and tibia.

Five cases died within 1 year after operation. Three of these died of tuberculous meningitis, 1 of pulmonary tuberculosis, and 1 of renal tuberculosis.

PATHOLOGICAL FINDINGS

Thirty four patients were operated upon at the New York Orthopedic Hospital within 1

year after onset of symptoms and in 32 of these tuberculosis was proved by sections or inoculation of pigs. These cases were significant because of the early pathological changes. According to the operative findings, the synovial layer was involved in all these cases and was found to be thickened in 30 cases. The synovial membrane was red or gray in color, and in 7 cases was described as 'gelatinous'. An excess of turbid fluid was present in 5 cases and a serous effusion in 6. Three joints contained thick pus. The cartilage was eroded in 15 cases and usually was partially covered with pannus before erosion. Bone destruction was present in 7 cases. In every case but 1 it appeared that the synovial layer was the primary site of the disease.

Thus in the earliest cases a moderate thickening and reddening of the synovial layer are all that is seen. There may or may not be a serous effusion. In these cases there is often pannus formation on the joint cartilage where it does not directly articulate. Later this may extend over the articular portions. As the synovial lining becomes more necrotic the color changes to gray and its appearance has been described frequently by surgeons as 'edematous'. This edematous or gelatinous

Fig 7 W. J. Proved tuberculosis of knee joint. Fusion was performed at age of 5-6 years before this roentgenogram was taken.

Fig 8 J. F. Proved tuberculosis of knee joint. Fusion was performed at age of 12 years, 7 years before this roentgenogram was taken.

CASE E. M. No. 127438, male Fusion operation was performed at the age of 4 years when tuberculosis was proved. Symptoms had been present for less than 1 year. The last examination took place 8 years after fusion. The knee was solidly fused with 20 degrees' flexion and $1\frac{3}{4}$ inches' shortening.

CASE E. D. No. 131477, female Fusion operation at the age of 4 years proved tuberculosis. Symptoms were present for $1\frac{1}{2}$ years. The last examination took place 6 years after operation at which time shortening was $1\frac{3}{4}$ inches because the lower femoral epiphysis was implicated by disease.

CASE W. J. No. 141612, male Fusion operation at the age of 5 years proved tuberculosis. Symptoms were present for 1 year. Seven years after operation the knee was fused in straight alignment with $1\frac{1}{4}$ inches of shortening.

CASE B. R. No. 143464, female Fusion operation at the age of 2 years (the youngest case in the entire series) proved tuberculosis. Symptoms were present for 6 months. The patient was last seen 6 years after operation with the knee fused in 5 degrees' flexion and shortened $\frac{1}{2}$ inch.

CASE H. B. No. 152587, male Fusion operation at the age of 4 years proved tuberculosis. Symptoms were present for $1\frac{1}{2}$ years. The patient was last seen 2 years after operation with $\frac{3}{4}$ inch shortening. Fusion took place in full extension with slight knock knee.

CASE R. S. No. 184967, male Fusion operation at the age of 5 years proved tuberculosis. Symptoms were present 7 months. The knee was solidly fused in straight alignment with $\frac{3}{4}$ inch shortening $2\frac{1}{2}$ years after fusion. The lower femoral epiphyseal line had been destroyed by cavitation before operation.

SUMMARY AND CONCLUSIONS

1. In the period, September, 1915, to December, 1936, knee fusion was performed in 222 cases of knee joint tuberculosis at the New York Orthopedic Dispensary and Hospital.

2. One hundred and ninety-nine of these cases have been followed from 1 to 17 years after operation with an average follow-up period of $5\frac{1}{2}$ years.

3. Fusion occurred in 196, or 98 per cent, of these cases. Fusion took place and plaster was left off at an average period of 8 months after operation. The disease subsided in all but 7 in whom sinuses persisted. In no fused knee did tuberculosis recur.

4. Fifty-nine patients were 10 years of age or less at the time of operation, and 14 were 5 years old or less.

5. Diagnosis, operative technique, and after care are described.

6. The results of arthrodesis in very young children are discussed.

7. On the basis of our 21 year experience with operative arthrodesis of the knee joint for tuberculosis in 222 cases, this procedure is recommended both for children and for adults. In no other joint in the body has such a high percentage of successful fusions been obtained.

inches in a patient who had had a resection elsewhere previous to fusion. The average shortening of the 90 cases was 1 inch. In 1 case, the fused leg was one fourth inch longer than the other.

Slipping lower femoral epiphysis. The most troublesome postoperative complication is the tendency of the lower femoral epiphysis to slip in children up to the age of 14 after fusion has taken place. In 19 children slipping, requiring either closed or open correction, took place between the ages of 3 and 14. Closed stretching under anesthesia was done in 17 cases and repeated in 2 of them. Supracondylar femoral osteotomy was done in 7 cases and osteotomy at the fusion site in 4. Only 1 slipping occurred at the upper tibial epiphysis. At present we believe that this slipping has been overcome by putting up the child's knee in full extension and by the use of a long leg brace in younger children.

Wound healing. Of 140 cases reported, 90 patients had healed wounds and no sinuses at the first plaster change 8 weeks after operation. The 50 remaining had sinus formation in wounds or other locations at that time. However, there were only 15 patients who had sinuses 1 year after fusion. There were 6 wound infections in patients who had no sinuses before operation. In 7 cases sinuses persisted when patients were last seen.

Other complications. Transient tourniquet paralysis was present in several cases before the adoption of the present technique, consisting of the use of an Esmarch elastic bandage to empty the leg of blood. Temporary foot drop, due to pressure of the cast against the peroneal nerve at the fibular head, was present in several cases. Only 1 patient in the entire follow up series was incapacitated by active pulmonary tuberculosis at last examination.

Arthrodesis in very young children. There are 14 patients in the entire series who were 5 years old or less at the time of the fusion operation, the youngest being only 2. Solid bony fusion is present in every case in this group and 6 of these patients have been followed 8 to 14 years since the time of fusion. In patients with marked shortening the epiphyseal lines close to the knee have been

implicated by disease before operation. In all early cases some shortening will result due to atrophy. As I believe this to be the only series of fusions in such young patients extant, a brief resume of each case follows.

CASE J P No 49947, male. Fusion operation was performed at the age of 5 years when tuberculosis was proved. Symptoms were present since the age of 1. It is now 14 years after his operation and he is 19 years old. The knee is solidly fused but he has $4\frac{1}{2}$ inches of shortening, due to the implication of the lower femoral epiphysis by disease destruction.

CASE E S No 82121, male. Fusion operation was performed at the age of 3 years when tuberculosis was proved. Onset of symptoms occurred at the age of 2 years with an abscess of the femoral epiphysis which extended into the joint. It is now 12 years after fusion and patient is 15 years old. The knee is solidly fused in 10 degrees flexion and shortening measures 2 inches.

CASE C P No 55824, male. Fusion operation took place at the age of 3 years and case remained unproved. Symptoms were present since the age of 1 year. The last examination took place 13 years after operation. The knee was solidly fused in 5 degrees flexion. Shortening of $3\frac{3}{4}$ inches was due to the fact that upper tibial epiphysis was partially destroyed before operation.

CASE P W No 85529 female. Fusion operation at the age of 5 years proved presence of tuberculosis. Symptoms had been present for 2 years. It is now 12 years since operation and patient is 17 years old. There is shortening of 2 inches and complete fusion at 180 degrees extension.

CASE B E No 93406 female. Fusion operation at the age of 4 years proved presence of tuberculosis. Symptoms had been present for less than 1 year. The patient was followed 3 years. The knee fused in 10 degrees flexion and the shortening measured $\frac{1}{2}$ inch.

CASE W T No 99536 male. Fusion operation at the age of 5 years proved the presence of tuberculosis. Symptoms were present for 2 years. The patient was followed 4 years. At the last examination fusion was solid in 15 degrees flexion and the legs were of equal length.

CASE K L No 101147 male. Fusion operation at the age of $2\frac{1}{2}$ years proved tuberculosis. Symptoms were present over 1 year. The patient was 12 years, $3\frac{1}{4}$ years after operation when he presented solid fusion and $2\frac{1}{4}$ inches of shortening.

CASE J F No 113910 male. Fusion operation was performed at the age of $2\frac{1}{4}$ years. Onset occurred at the age of 1 year. Tuberculosis which began in abscess of upper tibial epiphysis and which involved joint secondarily was proved. The patient was last seen 8 years after fusion at which time the knee was fused in 5 degrees of flexion with 1 inch of shortening.

CASE E M No 127438, male Fusion operation was performed at the age of 4 years when tuberculosis was proved Symptoms had been present for less than 1 year The last examination took place 8 years after fusion The knee was solidly fused with 20 degrees' flexion and $1\frac{3}{4}$ inches' shortening

CASE E. D. No 131477, female Fusion operation at the age of 4 years proved tuberculosis Symptoms were present for $1\frac{1}{2}$ years The last examination took place 6 years after operation at which time shortening was $1\frac{3}{4}$ inches because the lower femoral epiphysis was implicated by disease

CASE W. J No 141612, male Fusion operation at the age of 5 years proved tuberculosis Symptoms were present for 1 year Seven years after operation the knee was fused in straight alignment with $1\frac{1}{4}$ inches of shortening

CASE B R. No 143464, female Fusion operation at the age of 2 years (the youngest case in the entire series) proved tuberculosis Symptoms were present for 6 months The patient was last seen 6 years after operation with the knee fused in 5 degrees' flexion and shortened $\frac{1}{2}$ inch

CASE H B No 152587, male Fusion operation at the age of 4 years proved tuberculosis Symptoms were present for $1\frac{1}{2}$ years The patient was last seen 2 years after operation with $\frac{3}{4}$ inch shortening Fusion took place in full extension with slight knock knee.

CASE R S No 184967, male Fusion operation at the age of 5 years proved tuberculosis Symptoms were present 7 months The knee was solidly fused in straight alignment with $\frac{3}{4}$ inch shortening $2\frac{1}{2}$ years after fusion The lower femoral epiphyseal line had been destroyed by cavitation before operation

THE PHOSPHATASE DETERMINATION IN THE DIFFERENTIAL DIAGNOSIS OF BONE LESIONS

CLIFFORD C. FRANSEEN, M.D., CHANNING C. SIMMONS, M.D. F.A.C.S. and
REGINA MCLEAN, B.S., Boston, Massachusetts

THE enzyme phosphatase has been shown to be present in several tissues of the body in varying amounts, being highest under normal conditions in the intestinal mucosa, renal tissue and in tissue forming new bone (28). Its presence in the intestine is thought to be related to absorption, and in the kidney to excretion of phosphorus. The presence of phosphatase in tissue which is producing new bone is intimately associated with the process of ossification, and it has been suggested by Robison and Soames that the enzyme is the product of young osteoblasts and hypertrophic cartilage cells. Experimental evidence has shown that its function is to hydrolyze the phosphoric esters of the body to render phosphate ions available for incorporation into the chemical structure of bone (27).

Since Robison, in 1923, first indicated the important rôle of phosphatase in the process of ossification, much experimental effort has been expended in defining the occurrence and characteristics of the enzyme. The reports by Kay in 1929 (16) and Roberts in 1930 (25) of quantitative phosphatase determinations on the blood of patients with disturbances of bone introduced this procedure into the clinical study of bone lesions and demonstrated the phosphatase activity of the blood to be especially high in osteitis deformans. The phosphatase activity of the blood was soon examined by others in many types of bone lesions, and elevated values were found in lesions of such diverse nature as rickets, secondary carcinomatous lesions of bone, hyperparathyroidism with bone involvement, and osteogenic sarcoma.

The earlier work on phosphatase was comprehensively reviewed by Kay in 1932 (19). Besides the earlier reports by Kay and Roberts referred to, additional series of phos-

phatase determinations on the blood of patients with the bone lesions under consideration here have been reported by Kay (18), Bodansky and Jaffe, Auston and Cogg, Franseen and McLean, Simmons and Franseen, Pautrat, Woodard, Twombly, and Coley, Gutman, Tyson, and Gutman, and Woodard and Higinbotham. The reader is referred to these publications and to the recent review of plasma phosphatase in disease by Morris and Peden for a more exhaustive bibliography. Bone lesions such as rickets, osteomalacia, osteomyelitis, and fractures, in all of which the phosphatase of the blood has been reported to be increased, have been omitted from individual consideration here, as well as conditions with a non osseous source of increased phosphatase activity of the blood, as for example, liver damage with or without jaundice.

Certain generalizations can be derived from the contributions to the study of blood phosphatase in relation to its production by the osteoblastic cells. It is clear that any abnormal osteoblastic activity is reflected as an elevated phosphatase activity of the circulating blood, roughly proportional to the extent and intensity of the attempt at ossification. The phosphatase activity of the blood has been found to be increased in such groups of bone lesions as (1) abnormal or neoplastic proliferation of bone (osteitis deformans, osteogenic sarcoma, myositis ossificans), (2) frustrated attempts at osteogenesis (rickets) with the production of osteoid tissue, and (3) reparative processes accompanying or following inflammatory traumatic or neoplastic destruction of the architecture or the continuity of bone (repair of fractures, repair of areas destroyed by osteomyelitis, or repair of areas being destroyed by carcinomatous metastases). This diversity of type among the bone lesions associated with an elevation of the

phosphatase activity of the circulating blood is also good evidence, first, that this increased activity is not specific for any particular disturbance of bone, and second, that it is the result of the disease rather than its cause. In more slowly reparative or proliferative processes (e.g. osteoma, osteochondroma), the osteoblastic activity is not intense enough to be reflected in the circulating blood. In these cases, the destruction or elimination of the phosphatase present in the circulating blood is perhaps as rapid as its production. Similarly, in purely destructive lesions as, for example, myeloma, the normal level of the phosphatase activity of the blood is at most only very slightly disturbed. This is probably due to the fact that the normal phosphatase content of adult bone is so slight that its liberation in the process of dissolution of the bone does not measurably alter the activity of the circulating blood, and furthermore, reactive osteoblastic activity is practically nil in these lesions. When destructive and reparative processes occur simultaneously, as in carcinomatous metastases in bone, the constructive process alone is reflected in the phosphatase activity of the blood serum or plasma. In tumors without bone or liver involvement the phosphatase activity of the blood is normal.

In an earlier paper (31) we reported a comparative study of the phosphatase activity of the blood and tumor tissues in a series of cases with bone tumors. Our study suggested that the quantitative determination of the phosphatase activity of the blood and tissue was of value in the study of these tumors. Since the publication of the above report, we have had the opportunity to bring the number of our observations to a total of 473 determinations in 202 cases to support our previous findings. The reader is referred to this report and to the paper by Franseen and McLean for detailed accounts of the values obtained in the various groups of bone tumors. We wish now to reaffirm the value of the phosphatase determination in the differential diagnosis of these conditions by reviewing the subject again to include the additional experience gained through our more recent observations together with the observations reported by others. We wish also to indicate how closely the theory of an

osteoblastic source of phosphatase is supported in cases with bone tumors, and how the range of phosphatase values may roughly be predicted from the gross and microscopic characteristics of the various types of lesions.

Most of our phosphatase determinations on blood plasma have been made according to a technique closely following that of Kay (17), and described in a previous paper (10). A few of the determinations on blood serum have been made by the Bodansky (6) method by the chemical laboratory of the Massachusetts General Hospital through the courtesy of Dr. Fuller Albright. In a number of cases, the determinations have been made by both methods. We do not favor one or the other method, since we have always found them to corroborate one another within the limits found significant for clinical use.

In normal adults, the phosphatase values for blood are most commonly found between 0.12 and 0.2 Kay units per cubic centimeter of blood plasma, with an average value of about 0.16 units, or, in Bodansky units, 2.5 to 4.0 units per 100 cubic centimeters of blood serum, with an average value of about 2.9 units. When interpreting the results, we have regarded all values in Kay units as normal up to 0.26 units per cubic centimeters of plasma, since we have obtained values up to this level in apparently healthy individuals. In Bodansky units we have regarded 5.0 units per 100 cubic centimeters of serum as the extreme upper limit of normal.

OSTEITIS DEFORMANS

Osteitis deformans was the first disease in which a high phosphatase activity of the blood was demonstrated (16), and a high value has been shown repeatedly to be the rule in well established cases. In most of the cases with this disease the only abnormality found in the blood is the increased phosphatase activity. Roberts (25) and Kay (18) suggested early that a rough proportionality existed between the level of the blood phosphatase activity and the extent of the bone involvement. This has since been confirmed by several investigators (8, 13, 22). Values varying from a normal figure in cases with quiescent monostotic lesions to the highest

values reported for any disease (30 to 40 times normal) have been found in cases of osteitis deformans with polyostotic lesions

The source of the high phosphatase activity in osteitis deformans appears to lie in the osteoblasts of the osteogenic tissues, for Franseen and McLean have demonstrated a very high phosphatase content of the actively proliferating tissue in the affected calvarium and ilium of an active case which came to autopsy, and Gutman, Tyson, and Gutman (14) have noted that extensive involvement of the skull is almost invariably associated with relatively high phosphatase values in the blood

The phosphatase level of the blood appears to depend upon the degree of activity and the extent of the disease, and the fact that it may show only minor fluctuations at a high level over a period of years as Gutman and Gutman have reported, indicates that the disease often may have long periods of sustained activity. The phosphatase level of the blood may recede at times also, and, by following the elevations and recessions of this level, the phosphatase test is found to be of clinical value in assaying the status of the disease at any time in an individual case or in indicating progress or arrest of the disease in any case followed over a period of time. It may thus serve as an index of the efficacy of any form of treatment employed and may also give an index of the prognosis in the study of an individual case. For example, we have cited (10) two cases in which fluctuations in the phosphatase values were observed at extraordinary high levels over many months. Both patients eventually died of osteogenic sarcoma.

The elevated level of the phosphatase activity of the blood in osteitis deformans is of limited value in corroborating a diagnosis made clinically or roentgenographically. In early monostotic cases, the phosphatase level of the blood may not be elevated and, unfortunately, in cases in which there may be confusion in differential diagnosis between osteitis deformans and for example osteoplastic carcinomatous metastases the phosphatase determination will probably be of no assistance since the phosphatase level is also elevated in this process with which osteitis deformans is perhaps most often confused.

HYPERPARATHYROIDISM WITH BONE INVOLVEMENT

Increased phosphatase values in hyperparathyroidism were first reported by Kay (16) and Hunter in 1929. In a review of this disease in 1934, Albright, Aub, and Bauer showed that the phosphatase level of the blood was proportional to the degree of involvement of the bones and independent of the degree of hyperparathyroidism. Gutman, Tyson, and Gutman have recently collected from the literature 28 cases of hyperparathyroidism with bone changes. The blood phosphatase was found to be increased in every instance from $1\frac{1}{4}$ to 16 times the normal maximum value.

The phosphatase level, in this disease also is probably related to osteoblastic activity in the lesions, but we have had no opportunity to examine the phosphatase content of the tissue in the lesions themselves. The fact that the level of the blood phosphatase does not fall immediately after removal of the parathyroid lesion, is to be expected if we assume that the phosphatase is not produced by the parathyroid adenoma but by the osteoblasts attempting to repair the bone lesions. Under the same tenet it is not remarkable that the level of blood phosphatase activity should even rise somewhat during the acceleration of the osteoblastic activity in the repair process subsequent to the operative removal of the offending adenoma.

As a matter of fact, in one case of their series, Gutman, Tyson, and Gutman noted a fair degree of correlation between the rate of redeposition of bone observed roentgenographically after operation and the level of the serum phosphatase. At biopsy Albright, Aub, and Bauer found the osteoclasts already to have disappeared from the bone lesions 9 days after removal of a parathyroid adenoma.

It must be clearly recognized that the blood calcium and phosphorus determinations are distinctly of greater value than is the blood phosphatase determination in the study of this disease, since the phosphatase value merely indicates the degree of osteoblastic activity, hence of bone involvement, and not necessarily the degree of parathyroid activity.

Thus, a patient with hyperparathyroidism without bone lesions may have a normal phosphatase level

MYELOMA

Microscopically, the lesions of myeloma are purely destructive. As might be anticipated from this fact, no phosphatase activity is found in the tissues of the lesions (10), and the phosphatase level of the blood is practically unaltered even in the presence of numerous lesions. It is by virtue of the normality of the blood phosphatase in this disease that the quantitative determination of this enzyme may be of assistance occasionally in differentiating between a case with multiple myelomatous lesions and a case with carcinomatosis of the bones.

All investigators have reported normal levels of blood phosphatase activity in multiple myeloma, or at most a very slight elevation, with the exception of Rowntree, who reports that he has encountered "increased values in several cases." This is contrary to the theoretical expectation from the histological facts and from the demonstrable absence of phosphatase activity in the lesions themselves. When the phosphatase activity is elevated in the presence of multiple bone defects, a suspicion of carcinomatous metastases, hyperparathyroidism, or even lymphoma of bone should be entertained rather than myeloma.

CARCINOMATOUS METASTASES TO BONE

A small but definite phosphatase activity has been demonstrated by Franseen and McLean in the tissues comprising the metastatic carcinomatous lesions in bones; and in spite of the fact that the lesions may appear to be purely destructive roentgenographically, some reactive attempt at repair by the osteoblasts is invariably seen when the lesions are examined histologically. In single lesions the phosphatase activity of the tissues may be too small to be reflected in the level of the blood phosphatase, but when this activity is increased by multiplicity of lesions, there is invariably an elevation of the blood phosphatase level even in cases with the osteolytic type of metastases.

As might be anticipated, the blood phosphatase levels found in cases with carcinomatous metastases vary over a wide range, depending on the type and extent of the metastatic lesions. Theoretically, in the case of osteoplastic metastases, the increased osteoblastic activity should become manifest in the blood phosphatase value earlier, that is, when the lesions are fewer or smaller than in the case of osteolytic lesions. Gutman, Tyson, and Gutman's comparative series demonstrates this fact clearly. A large number of osteoplastic metastases may raise the blood phosphatase level to values among the highest reported for any disease, for example, Gutman, Tyson, and Gutman have reported values as high as 120.4 Bodansky units per 100 cubic centimeter of blood serum.

It has been suggested that the elevation of the plasma phosphatase in destructive metastatic disease in bone is due to a mobilization of the enzyme normally present in the bone which is undergoing destruction. The amount of phosphatase present in normal adult bone, however, is practically nil (10), and the fact that the plasma phosphatase level is almost invariably normal in myeloma, in spite of multiple and very extensive areas of dissolution of bone, is strong evidence against this theory.

A word of caution must be given in the interpretation of phosphatase values in the presence of either incipient or established jaundice in cases with bone lesions, particularly in cases with carcinomatous metastases, because jaundice itself is frequently associated with elevated values of blood phosphatase of non-osteoblastic origin. The significance of the increased phosphatase activity of the blood in jaundice and toxic hepatitis has been thoroughly reviewed by several workers (3, 4, 7, 11, 26, 29) and is pertinent to the study at hand only insofar as the presence of latent or manifest jaundice and liver injury vitiates the value of the test in cases with concurrent bone lesions.

That concomitant affections of the liver markedly influence the phosphatase level of the blood should be taken into account in interpreting the values obtained in cases with bone lesions. This is well shown by the case

with a chondral exostosis recently reported by Lamb and Blakely in which our determination showed 0.83 Kay units of phosphatase per cubic centimeter of blood plasma. This patient also had syphilis and was receiving arsenphenamine. Two days after the blood was taken for the phosphatase determination, the patient became jaundiced and it is believed that liver damage was the cause of the high reading. Woodard, Twombly, and Coley also found the phosphatase level of the blood in variably to be elevated after administration of Coley's toxins, and it is reasonable to suppose this elevation to be due similarly to a toxic effect upon the liver.

Minor degrees of obstruction produced by metastases in the liver, even when insufficient to produce clinical jaundice, may increase the phosphatase activity of the blood. Our experience agrees with that of Gutman, Tyson, and Gutman who state that, on the other hand there may be at times a large number of metastases in the liver without any significant elevation of the blood phosphatase. The possibility of the presence of metastases causing obstruction in the biliary system should, nevertheless, be borne in mind when interpreting the phosphatase values in cases with carcinomatous metastases in the bone owing to the likelihood of concomitant metastases to the liver. Usually the latter does not need to be considered in primary bone tumors, however, since metastases from them to the liver are very rare.

OSTEOMAS, CHONDROMAS, AND OSTEOCHONDROMAS

The osteoblastic activity, and consequently the phosphatase production, in this group of benign bone tumors is usually so slight that it does not measurably elevate the blood phosphatase. As we have suggested, the rate of its excretion or destruction may possibly keep pace with its rate of production.

According to our observations, the blood phosphatase values in the benign bone tumors such as osteoma, chondroma, and osteochondroma, have been quite constantly normal. At most, in uncomplicated cases, they have just exceeded the normal values. The phos-

phatase determination has been of no value in determining the possibility of the occurrence of malignant changes in a chondroma, since in 4 cases with chondrosarcomas the highest value found was 6.7 Bodansky units or 0.29 Kay units. At times, however, the increased osteoblastic activity in the malignant degeneration of a benign tumor which is producing new bone may be suggested by the increased phosphatase activity of the blood.

GIANT CELL TUMORS

Giant cell tumors of bone of non parathyroid origin are essentially destructive in character with little tendency toward new bone formation. The paucity of osteoblastic activity is evidenced by the inconstant slight rise in the blood phosphatase values. In the 8 cases in which we have had the opportunity to examine the blood the phosphatase has been at most only slightly elevated, usually to a high normal value. One patient, a child of 6 years and another with an accompanying pathological fracture, had moderately elevated values, 0.41 Kay units and 7.4 Bodansky units, respectively. The phosphatase activity of the tissues in the giant cell lesions is only slightly greater than that of osteochondromas.

EWING'S TUMOR

Since Ewing's tumor is chiefly destructive, the phosphatase level of the blood may be expected to be only slightly disturbed. This has been true of the 8 patients we have examined, none having had more than twice the highest normal value for phosphatase activity in the blood. We have had no opportunity, however, to test the phosphatase activity in the type of Ewing's tumor seen especially in the shaft of the fibula and characterized by marked reactionary, new bone formation in which it would seem likely that the phosphatase level of the blood would be considerably elevated. Owing to the inconstancy of osteogenesis in Ewing's tumor, the level in the blood bears no constant relation to the extent of the disease, and the tissues of the lesions themselves which we have examined have shown only a trace of phosphatase activity.

OSTEOGENIC SARCOMA

The phosphatase level of the blood in cases with osteogenic sarcoma is almost invariably elevated to some degree. This level depends primarily upon the product of 2 factors; namely, the rate of growth, i.e., the osteoblastic activity of the lesions; and the size of the lesion, i.e., the number of malignant osteoblasts producing phosphatase. The level may vary from a very low one to levels among the highest reported for any disease. The highest value in our group was 4.79 Kay units per cubic centimeter of blood plasma, practically 20 times the highest normal value.

That the phosphatase elevation of the blood is the result of this lesion and not the cause of it, and that the osteogenic lesion is the source of the increased phosphatase activity of the blood, is strongly suggested by our observations showing that after removal of the lesion by amputation, the blood phosphatase returns to normal limits within a short period of time, usually in about 2 weeks. Our previous report (31) on this phenomenon was based on observations in 6 cases. We have since had the opportunity to study 5 additional cases in which a similar effect was observed.

The phosphatase level of the blood may become elevated again after the initial post-operative fall when latent metastases have become apparent. We have been unable, however, in the cases we have had an opportunity to follow, to prophesy the subsequent appearance of latent pulmonary metastases by the changes in the phosphatase values prior to the demonstration of the lesions roentgenographically. An example of this is the case of a 14 year old girl with an osteogenic sarcoma of the femur, whose serum phosphatase fell promptly to normal after amputation. However, one month after a normal phosphatase value had been obtained, she reported with clinical and roentgenographic evidence of pulmonary metastases. Thus, the phosphatase test appears not to be sufficiently sensitive to reveal small foci of osteogenesis. It has been found that pulmonary metastases must be of considerable size or number before they can be detected by the phosphatase determination, perhaps due to the fact that pulmonary metastases not infrequently show only minor de-

grees of osteogenesis. A roentgen examination of the chest is the best means for their detection.

That the osteogenic tumor is the source of the elevated blood phosphatase in this disease is further strengthened by the fact that very high degrees of phosphatase activity have been demonstrated in the tumor tissues themselves. Even metastases which are isolated from bone have been demonstrated to be high in phosphatase activity, as for example, metastases from osteoblastic tumors in the lungs or in the superficial soft parts. We have reported values as high as 95 Kay phosphatase units per gram of tissue in an osteogenic pulmonary metastasis in a young man of 23 years, and 209 units per gram in a primary osteogenic sarcoma in an adolescent boy (10).

DIFFERENTIAL DIAGNOSIS

In the differential study of cases with bone lesions, it must be conceded that the roentgenological examination of suspected cases of bone lesions makes the greatest independent contribution toward the establishment of the diagnosis; but even the X-ray picture is frequently equivocal, and confirmation or exclusion of the suggested diagnosis before operation often must rest upon the reports of the chemical laboratory. The importance of blood chemical determinations other than phosphatase, i.e., calcium, phosphorus, and serum protein, in the study of bone lesions obviously cannot be denied, and their values must also be considered together with the facts obtained from roentgenological and physical examinations, historical data, or additional laboratory data such as serological tests for syphilis, examinations of blood smears, and tests for Bence-Jones protein in the urine.

If the rôle of the phosphatase determination in the differential diagnosis of bone lesions is to be discussed with any degree of completeness, the rôle of other chemical constituents of the blood, especially calcium and phosphorus must be considered at the same time. Gutman, Tyson, and Gutman have made a comprehensive review of the chemical findings in reported cases of the bone lesions herein discussed, together with the histories of their own patients. We have also made cal-

with a chondral exostosis recently reported by Lamb and Blakely in which our determination showed 0.83 Kay units of phosphatase per cubic centimeter of blood plasma. This patient also had syphilis and was receiving arsphenamine. Two days after the blood was taken for the phosphatase determination, the patient became jaundiced and it is believed that liver damage was the cause of the high reading. Woodard, Twombly, and Coley also found the phosphatase level of the blood in variably to be elevated after administration of Coley's toxins, and it is reasonable to suppose this elevation to be due similarly to a toxic effect upon the liver.

Minor degrees of obstruction produced by metastases in the liver, even when insufficient to produce clinical jaundice, may increase the phosphatase activity of the blood. Our experience agrees with that of Gutman, Tyson, and Gutman who state that, on the other hand, there may be at times a large number of metastases in the liver without any significant elevation of the blood phosphatase. The possibility of the presence of metastases causing obstruction in the biliary system should, nevertheless, be borne in mind when interpreting the phosphatase values in cases with carcinomatous metastases in the bone owing to the likelihood of concomitant metastases to the liver. Usually the latter does not need to be considered in primary bone tumors, however, since metastases from them to the liver are very rare.

OSTEOMAS, CHONDROMAS, AND OSTEOCHONDROMAS

The osteoblastic activity, and consequently the phosphatase production, in this group of benign bone tumors is usually so slight that it does not measurably elevate the blood phosphatase. As we have suggested, the rate of its excretion or destruction may possibly keep pace with its rate of production.

According to our observations, the blood phosphatase values in the benign bone tumors such as osteoma, chondroma, and osteochondroma have been quite constantly normal. At most, in uncomplicated cases, they have just exceeded the normal values. The phos-

phatase determination has been of no value in determining the possibility of the occurrence of malignant changes in a chondroma, since in 4 cases with chondrosarcomas, the highest value found was 6.7 Bodansky units or 0.29 Kay units. At times, however, the increased osteoblastic activity in the malignant degeneration of a benign tumor which is producing new bone may be suggested by the increased phosphatase activity of the blood.

GIANT CELL TUMORS

Giant cell tumors of bone of non parathyroid origin are essentially destructive in character with little tendency toward new bone formation. The paucity of osteoblastic activity is evidenced by the inconstant slight rise in the blood phosphatase values. In the 8 cases in which we have had the opportunity to examine the blood, the phosphatase has been at most only slightly elevated, usually to a high normal value. One patient, a child of 6 years, and another with an accompanying pathological fracture, had moderately elevated values, 0.41 Kay units and 7.4 Bodansky units, respectively. The phosphatase activity of the tissues in the giant cell lesions is only slightly greater than that of osteo chondromas.

EWING'S TUMOR

Since Ewing's tumor is chiefly destructive the phosphatase level of the blood may be expected to be only slightly disturbed. This has been true of the 8 patients we have examined none having had more than twice the highest normal value for phosphatase activity in the blood. We have had no opportunity, however, to test the phosphatase activity in the type of Ewing's tumor seen especially in the shaft of the fibula and characterized by marked reactionary, new bone formation in which it would seem likely that the phosphatase level of the blood would be considerably elevated. Owing to the inconstancy of osteogenesis in Ewing's tumor, the level in the blood bears no constant relation to the extent of the disease and the tissues of the lesions themselves which we have examined have shown only a trace of phosphatase activity.

OSTEOGENIC SARCOMA

The phosphatase level of the blood in cases with osteogenic sarcoma is almost invariably elevated to some degree. This level depends primarily upon the product of 2 factors; namely, the rate of growth, i.e., the osteoblastic activity of the lesions; and the size of the lesion, i.e., the number of malignant osteoblasts producing phosphatase. The level may vary from a very low one to levels among the highest reported for any disease. The highest value in our group was 4.79 Kay units per cubic centimeter of blood plasma, practically 20 times the highest normal value.

That the phosphatase elevation of the blood is the result of this lesion and not the cause of it, and that the osteogenic lesion is the source of the increased phosphatase activity of the blood, is strongly suggested by our observations showing that after removal of the lesion by amputation, the blood phosphatase returns to normal limits within a short period of time, usually in about 2 weeks. Our previous report (31) on this phenomenon was based on observations in 6 cases. We have since had the opportunity to study 5 additional cases in which a similar effect was observed.

The phosphatase level of the blood may become elevated again after the initial post-operative fall when latent metastases have become apparent. We have been unable, however, in the cases we have had an opportunity to follow, to prophesy the subsequent appearance of latent pulmonary metastases by the changes in the phosphatase values prior to the demonstration of the lesions roentgenographically. An example of this is the case of a 14 year old girl with an osteogenic sarcoma of the femur, whose serum phosphatase fell promptly to normal after amputation. However, one month after a normal phosphatase value had been obtained, she reported with clinical and roentgenographic evidence of pulmonary metastases. Thus, the phosphatase test appears not to be sufficiently sensitive to reveal small foci of osteogenesis. It has been found that pulmonary metastases must be of considerable size or number before they can be detected by the phosphatase determination, perhaps due to the fact that pulmonary metastases not infrequently show only minor de-

grees of osteogenesis. A roentgen examination of the chest is the best means for their detection.

That the osteogenic tumor is the source of the elevated blood phosphatase in this disease is further strengthened by the fact that very high degrees of phosphatase activity have been demonstrated in the tumor tissues themselves. Even metastases which are isolated from bone have been demonstrated to be high in phosphatase activity, as for example, metastases from osteoblastic tumors in the lungs or in the superficial soft parts. We have reported values as high as 95 Kay phosphatase units per gram of tissue in an osteogenic pulmonary metastasis in a young man of 23 years, and 209 units per gram in a primary osteogenic sarcoma in an adolescent boy (10).

DIFFERENTIAL DIAGNOSIS

In the differential study of cases with bone lesions, it must be conceded that the roentgenological examination of suspected cases of bone lesions makes the greatest independent contribution toward the establishment of the diagnosis; but even the X-ray picture is frequently equivocal, and confirmation or exclusion of the suggested diagnosis before operation often must rest upon the reports of the chemical laboratory. The importance of blood chemical determinations other than phosphatase, i.e., calcium, phosphorus, and serum protein, in the study of bone lesions obviously cannot be denied, and their values must also be considered together with the facts obtained from roentgenological and physical examinations, historical data, or additional laboratory data such as serological tests for syphilis, examinations of blood smears, and tests for Bence-Jones protein in the urine.

If the rôle of the phosphatase determination in the differential diagnosis of bone lesions is to be discussed with any degree of completeness, the rôle of other chemical constituents of the blood, especially calcium and phosphorus must be considered at the same time. Gutman, Tyson, and Gutman have made a comprehensive review of the chemical findings in reported cases of the bone lesions herein discussed, together with the histories of their own patients. We have also made cal-

cium and phosphorus studies in many of our own cases. From this combined experience we have constructed the accompanying table in summary of the results of calcium, phosphorus, and phosphatase determinations among the bone lesions herein considered. Hyperproteinemia and Bence Jones proteinuria have also been included because of their importance in the differential diagnosis when present.

The difficulty in making a differential diagnosis by blood chemical means among hyperparathyroidism, multiple myeloma, and multiple carcinomatous skeletal metastases in which no primary source has been found (all of which may at times be confused roentgenographically) lies in the fact that hypercalcemia has at times been reported in all 3 conditions. Thus, hypercalcemia occurs almost as a rule in hyperparathyroidism, especially in cases with bone involvement, it occurs frequently in multiple myeloma and occasionally in cases with widespread skeletal metastases. In the latter 2 conditions it has been suggested that the hypercalcemia is related to the mobilization of the calcium in the dissolution of the bone or to co incident renal insufficiency. The almost invariable association of hypophosphatemia with the hypercalcemia in hyperparathyroidism is of occasional assistance, but hypophosphatemia has also been found in cases of carcinoma with advanced skeletal metastases associated with cachexia, and also in multiple myeloma, but in the latter 2 conditions, a normal or elevated serum phosphorus is found more commonly even when hypercalcemia is present (2, 14). The blood phosphatase determination is occasionally of assistance among these patients, owing to the fact that even in the presence of extensive lesions of multiple myeloma, the blood phosphatase is almost invariably normal, whereas with multiple lesions from either metastatic carcinoma or hyperparathyroidism the phosphatase level would be elevated at least somewhat, and occasionally elevated to quite a high level. In the differential diagnosis between metastatic carcinoma and hyperparathyroidism, the blood phosphatase perhaps would not be of much assistance, though it is probably higher in the latter condition when the lesions are of comparable extent.

The blood chemical findings may at times only add to the confusion. For example, Gutman, Tyson, and Gutman report that they have encountered findings similar to those which are usually thought characteristic of hyperparathyroidism in occasional cases of carcinoma with advanced skeletal metastases. They suggest that the hypercalcemia in these cases is related to the destruction of the bone by the neoplastic process, the hypophosphatemia probably to cachexia, and the increased blood phosphatase to involvement of the bone or liver. In such cases, the phosphatase determination would not be of much assistance in differential diagnosis, but fortunately at the stage of the disease when this confusion over the clinical findings would arise, the primary carcinomatous lesion is often evident.

The determination of the presence or absence of Bence Jones proteinuria may be of value, since Bence Jones proteinuria has been observed in cases of hyperparathyroidism only in rare instances, and then only in very small amounts (1), and its occurrence in cases with skeletal metastases from carcinoma is probably also quite rare. The finding of Bence Jones proteinuria is of assistance in diagnosis only in 50 to 70 per cent of the cases with multiple myeloma in which it may intermittently appear. The occurrence of hyperproteinemia, also, may be of some assistance in suggesting the diagnosis of myeloma. It is only of irregular occurrence, however, and often does not appear until late in the disease. The serum protein level is probably always normal in carcinoma with metastases and in hyperparathyroidism.

Osteitis deformans may occasionally enter into differential diagnosis especially with osteoplastic skeletal metastases from carcinoma or possibly, in an early exceptional case of Ewing's tumor in an older individual in whom the only changes present in the bone may be an increase in density. In early cases the blood phosphatase level may be slightly elevated in all 3 conditions. In more advanced cases with osteoplastic metastases from carcinoma and in osteitis deformans also the blood phosphatase is always elevated, perhaps relatively more in the latter. In

TABLE I—ANALYTICAL FINDINGS IN VARIOUS BONE LESIONS

Bone lesion	Blood phosphatase	Hypercalcemia	Hypophosphatemia	Hyperproteinemia	Bence-Jones proteinuria	Tissue phosphatase
Hyperparathyroidism (with bone lesions)	Moderately elevated	Almost always	Usually	Absent	Rarely	?
Osteitis deformans	Usually very high	Practically never	Practically never	Absent	Absent	Slight to high
Metastatic carcinoma	Normal to high	Rarely	Very rarely	Absent	Very rarely	None to slight
Osteogenic sarcoma	Moderately elevated to high	Absent	Absent	Absent	Absent	Slight to very high
Multiple myeloma	Almost invariably normal	Often	Very rarely	Often	Often	None
Ewing's tumor	Normal to slight	Absent	Absent	Absent	Absent	None to slight

Ewing's tumor, however, the elevation has never been found to be great even in late stages of the disease. In all 3 conditions the serum calcium and phosphorus values of the blood are normal, except in rare cases with associated renal insufficiency in which both the calcium and phosphorus may be somewhat elevated (14, 23).

It must be remembered, also, that osteitis deformans may exist concurrently with other tumors. In our own series a case occurred with a sarcoma in the head of the tibia of a woman 50 years of age, and the question of the simultaneous occurrence of Paget's disease of the bones of the pelvic girdle arose. In this instance the blood phosphatase value was high, and contrary to the usual experience after removal of a tumor of osteogenic character, it did not return to normal after amputation. Subsequently, the diagnosis of Paget's disease became unequivocal and the blood phosphatase activity continued at an elevated level. The tumor in this case was fibrous in character with only a small amount of reactionary, new bone formation in the periosteum. There was no phosphatase activity of the homogeneous tumor tissue taken at a distance from the periosteum.

In all cases with multiple bone lesions the possibility of malignant lymphoma should also be borne in mind. In the differential diagnosis of the latter the characteristics of the blood smear, the presence of hepatomegaly, splenomegaly, or enlargement of the lymph nodes are helpful in suggesting the diagnosis. Since the lesions of lymphoma are often osteoplastic as well as osteolytic, as Dresser and Spencer

have shown, the phosphatase values may be expected to be quite variable in this disease, especially when hepatic changes may be concomitant and may themselves produce an elevated phosphatase activity of the blood. Four of five cases with lymphoma and bone involvement showed phosphatase activity above normal, but varying from a slight elevation (0.27 Kay units per cubic centimeter) to a rather high value (0.95 Kay units per cubic centimeter) in a case with extensive osteoplastic lesions.

Criticism has been directed against the diagnostic value of the phosphatase determination in bone lesions because of its lack of specificity, but chemical determinations absolutely specific for definite diseases are exceedingly rare, all must be interpreted in relation to other findings. Neither the occurrence of hypercalcemia nor even of Bence-Jones proteinuria is specific, yet none would deny their diagnostic value. The phosphatase activity of the blood is an important member of the group of chemical determinations on the blood, namely, calcium, phosphorus, serum protein, and phosphatase, all of which are of value in the differential diagnosis of bone lesions.

SUMMARY

Evidence is adduced to support the theory that the increased phosphatase activity of the blood in patients with bone lesions is the product of the intracellular activity of the osteoblasts. The level of the phosphatase activity found in the blood in the presence of a bone lesion corresponds closely to the theoretical expected level determined by a study of

the gross and microscopic evidence of the osteoblastic activity in the lesion

Owing to the fact that the phosphatase activity of the blood varies in proportion to the osteoblastic propensities of the individual type of bone tumor, the phosphatase determination is often useful in the differential diagnosis of bone lesions

The relationship of the phosphatase activity of the blood to calcium, phosphorus, and serum protein values found in various bone lesions is discussed

EXPERIMENTS CONCERNING LIGATION AND REFRIGERATION IN RELATION TO LOCAL INTOXICATION AND INFECTION

FREDERICK M. ALLEN, M.D., New York, New York

SEVERAL previous papers (1) have described a plan of animal experiments in which limbs or viscera are deprived of circulation by means of a tourniquet and then kept at a temperature near 0 degrees C for various periods, up to 16 hours for intestine and more than 2 days for limbs, with the result that they can afterward be restored intact without local necrosis or systemic shock. Suggestions were also made for possible clinical applications of this method. This paper describes experimental observations pertaining to intoxication and infection and discusses points which may merit clinical investigation.

EXPERIMENTS WITH STRYCHNINE

Strychnine sulphate was chosen as an example of a poison which is quickly absorbed and quickly oxidized. If a fatal dose of 1 milligram or slightly more be injected into the leg of a 2 kilogram rabbit, it may be possible to wait more than 1 minute until the first beginning of muscle spasms, and then check the symptoms by applying a tourniquet. For the sake of brevity, it may suffice to state only the course of events when a huge excess is injected, for example, 10 or 12 milligrams, or about 10 times the fatal dose. It is not possible then to wait 1 minute, for by the time of the first muscle spasm the absorption is so great that a tourniquet can no longer save life. In this case the tourniquet should be applied arbitrarily in 30 seconds or at least at the first detectable increase of reflexes. If the necessary course of tourniquet applications were to be performed at ordinary temperatures, considerable local inflammation and perhaps systemic shock would result. These consequences are avoided by immediately immersing the leg in ice water. In this condition the animal is safe for an indefinite number of

hours, but the strychnine remains. Therefore, the ordinary procedure is the following: After an arbitrarily chosen period of 15 to 30 minutes the leg is removed from the ice water and the tourniquet is released. After 30 seconds the tourniquet is re-applied and the leg is again immersed. This process is repeated until cautious tests show that the diminished store of the poison permits the lengthening of the time of release to 1 minute and then several minutes. Watchfulness is necessary right to the end, for fatal strychnine convulsions have sometimes developed more than 15 minutes after the last tourniquet release. Depending upon the length of the periods of ligation and release, the rabbit may be finally freed in perhaps 16 to 24 hours without any important damage to the leg and without having shown any symptom of poisoning from 10 times the fatal dose.

Some rabbits which received enormous doses have died from simple weakness within a few days. It is undecided whether this result represents a delayed action of the strychnine, perhaps upon some organ other than the nervous system, or whether it is due to carrying through the experiment too rapidly or to any indefinite injury or strain of the procedure. It does not occur with smaller doses and is not significant for the present subject.

The only clinical example of poison entering through the limbs with any frequency seems to be snake bite. This differs from strychnine in that the poison is slowly absorbed, slowly destroyed, and is capable of serious local damage. The refrigeration method may with some modifications prove useful occasionally according to experiments with snake venom published elsewhere (2).

Another practical use of the refrigeration method is its use in infections in limbs. The cases must be divided into those in which

there is to be an attempt to save the limb and those in which the limb is to be amputated

REFRIGERATION WITHOUT AMPUTATION

Since blood and various tissues can be kept in a state of suspended animation in the ice box for several weeks or months without evident impairment of vitality, and since the normal legs of animals can likewise be kept ligated and refrigerated in ice water for at least a day or two and then restored to function, there is some temptation to learn what will happen if this procedure is applied to infected limbs. The speculation centers about the fact that the tourniquet instantly cuts off the flow of toxins from the limb, while the temperature presumably inhibits growth and other activity of the bacteria in the limb. In addition to the possible chance of devising any treatment for the limb at this temperature, there is the principal consideration of giving the patient at least a brief vacation from the intoxication, during which he may gain in strength and nutrition, receive any general or specific treatment, or develop antibodies which he may not have had time or ability to produce in the presence of an advancing infection. On the other hand the danger lies in the chance that removal of the tourniquet may not merely restore the status quo ante, but that the refrigeration period may entail damage to the limb or perhaps an overwhelming accumulation of bacterial or tissue toxins.

One series of experiments consisted in injections of a heavy suspension of rat feces into the legs of cats and dogs. Local abscesses and necrosis and systemic malaise and intoxication ranging from slight to fatal in degree, could thus be produced in a fairly controllable manner according to the dose. The refrigeration treatments may be divided roughly into short and long. In the former the stoppage of circulation and immersion in ice water lasted from 2 to 5 hours. The effects were only slight and as far as the course of the infection was changed at all it was slightly for the worse. In the long treatments the use of the tourniquet and refrigeration was continued for periods of 24 to 48 hours. Spectacular improvement was obtainable during such periods in dangerously intoxicated animals. The imme-

diately benefit was greater than with amputation because of the absence of the shock of amputation. At the time of release of the tourniquet the limb appeared unchanged and the circulation returned promptly. Extensive masses of tissue, however, quickly turned dark and gangrenous, vessels became thrombosed, and the absorption of poison was so rapid that often the animals died in spite of early and high amputation. The rapidity of these changes created the impression that the chilling abolished certain vital barriers to the diffusion of bacterial products, that while the growth of bacteria might be inhibited, their existing toxins were able to spread with increased freedom and to form chemical combination with the protoplasm. The practical lesson at least was plain, namely that prolonged ligation and refrigeration are positively contra indicated in the presence of any necrotizing infection if it is planned to restore the circulation afterward.

In another series of experiments with the aid of Dr C A Vicens and Mr J G Rice, the attempt was made to imitate another type of infection. This was done by injecting pure cultures of various streptococci into the legs of rabbits. The results were either a trivial local process or an overwhelming systemic invasion according to the dose. Also the addition of vegetable mucin to the injections failed to reproduce the desired clinical condition, namely, a local cellulitis and lymphangitis spreading up the leg and finally inducing septicemia. Treatments with the tourniquet and refrigeration were of no value whether long or short. Necessarily the infection was held in check during the period of treatment but the ultimate outcome was always more or less in favor of the untreated animals and with certain doses of culture it was possible for the untreated animals to live while the treated ones died. This result might readily be accounted for by the general strain and chilling in such a feeble animal as the rabbit. There was no opportunity to make the real test which would consist in holding an invasive infection in check for a day or two to give the animal time to develop antibodies under favorable conditions. The most definite fact elicited seemed to be that the streptococcus and its toxins did

not cause any gross tissue necrosis during the refrigeration or any gangrene after release of the tourniquet. In general, therefore, further trials of refrigeration in coccal infections did not seem to be entirely precluded.

Granting, as assumed above, that chemical combinations of bacterial products can occur during refrigeration, it was a natural suggestion to make use of the principle with antisera. In the refrigerated limb without circulation, not only may the increased permeability favor the penetration of the serum throughout the tissues, but it is also feasible to keep a high concentration of serum in direct contact with the tissues for long periods in a manner which is impossible with the blood flowing. Furthermore, it seems conceivable that the low temperature may alter the permeability of the membranes or protective envelopes of the bacteria themselves.

Accordingly, a few experiments were tried in which rabbits' legs were injected with streptococcus cultures, and subsequently with a polyvalent antistreptococcus serum.¹ The tourniquet and refrigeration were then applied as usual for several hours. These experiments had to be broken off in a preliminary stage before either positive or negative results could be definite. Such a research demands bacteriological facilities, also a true local infection and the appropriate antiserum. As some of these requirements could not be fulfilled, no conclusion could be reached.

A single clinical observation was made:

An obese woman, aged 56 years, evidently diabetic long before the diagnosis 11 years previously, had gangrene of the right foot 9 years before, and as the arterial changes were chiefly below the knee, amputation through the upper tibia was successful. In the subsequent years she violated diet repeatedly, several small gangrenous infections caused losses of portions of toes of the right foot but healed each time on control of the sugar. One week before admission an infection of a different type began with painful swelling in the ball of the foot, which extended rather rapidly in spite of treatment by her local doctor together with adequate insulin and diet control. She was admitted to the hospital in a supposedly critical condition, with extremely painful swelling up to mid-calf, pink and white mottling was present but no dark color anywhere, and temperature ranged between 102 and 104 degrees. With local measures and strict diabetic treatment for 4 days the process ex-

tended almost to the knee. It was regarded as probably a streptococcal cellulitis. Roentgenograms showed no bone involvement, blood cultures were negative, but septicemia was feared and a surgeon was called to consider possible amputation. A short incision at the original point of swelling in the sole yielded only a thin serous discharge from which a culture was taken. It was decided to take the chance with refrigeration treatment as follows.

A tourniquet of rubber tubing was applied below the knee tightly enough to stop all circulation. The leg was immersed in ice water up to this tourniquet. The pain, which had been excruciating, began to subside within a few minutes and within half an hour was absent. Then 150 cubic centimeters of Lederle's polyvalent streptococcus-staphylococcus serum (purchased at a local drug-store) was diluted with an equal volume of Ringer solution, and the mixture was injected by multiple punctures so as to infiltrate the foot and leg as thoroughly as possible. After 3 hours the leg was removed from the ice water and the tourniquet released. Severe pain soon returned but no bad effects were evident. The rectal temperature steadily fell within 3 days to 100 degrees, and general and local recovery quickly followed. The culture from the foot yielded *Staphylococcus aureus* and a non-hemolytic streptococcus.

The patient left the hospital after 2 weeks, apparently in good condition except for considerable persisting pain. After another week, although the small exploratory incision was nearly healed and all obvious infection was absent, another small painful area developed more posteriorly and began to turn dark. Amputation was therefore performed below the knee, with a tourniquet and refrigeration for 4 hours as the only anesthetic. The subsequent course was uneventful except for the extrusion of 2 small sequestra.

There is no proof that the treatment with refrigeration and serum was of any value, for recovery might have occurred similarly without it. Evidently infiltration of the chilled tissues was a mistake, for such tissues become so firm and resistant that the infiltration probably causes breaks and tears, which may be suspected as the cause of the prolonged pain and perhaps also of injuries to small blood vessels. It therefore appears preferable to infiltrate with added novocain or other anesthetic after the placing of the tourniquet but before refrigeration. On the other hand, in view of the history and the state of the leg, there is no proof that the treatment was responsible for the failure to save the limb. At least the amputation was delayed and the field restricted so that healing was obtained below the knee instead of the thigh amputation which would have been necessary at the beginning. With 2

¹Supplied for the purpose through the courtesy of Lederle & Co.

good knees the patient is looking forward to a rather active life. The single experience shows that no acute catastrophe need occur from brief refrigeration even of a badly nourished and infected limb. A second refrigeration for amputation was followed by healing which seemed very satisfactory under the conditions. Owing to the uncertainties, there is no present intention of using the refrigeration method again for limbs not to be amputated unless more definite experimental support is obtained.

It should be emphasized that the above reservations apply only to infected parts. For non infected parts the existing experimental evidence is believed to establish positively the benefits of refrigeration, in creating tolerance for longer deprivation of circulation with less injury than at higher temperatures. Examples of probable clinical application are as follows: (1) for embolectomy and all other emergency operations after stoppage of the main artery of a limb, (2) for plastic or other operations which involve the use of a tourniquet for 1 to several hours, so that at least ice bags and iced sponges should be used during all such operations, (3) as a simple and harmless local anesthetic under various conditions. In general, the hopes are for an extension of the limits and improvement of the results of reparative and emergency surgery of limbs, inasmuch as immediate refrigeration can certainly keep a bloodless limb in much better condition during a more or less extended period before operation can abolish pain and shock, and can perhaps mitigate the effects of trauma so as to favor subsequent healing.

REFRIGERATION PREPARATORY TO AMPUTATION

The technique consists in applying a rubber tube (not a broad tourniquet) well above the proposed level of amputation tightly enough to stop circulation after elevating the limb to drain out blood. The limb may then be immersed in ice water to slightly above the tourniquet or for a weak patient it may be surrounded with ice inside a rubber sheet, for example by channeling a block of ice for the thigh to rest on and piling cracked ice above it. Though sedatives may be desirable for discomfort or nervousness at the outset, within

about half an hour there is relief from even the most severe pain of gangrene. If the procedure is properly carried out, within 4 or 5 hours, depending on the thickness of the limb, there is such anesthesia present that the sciatic nerve can be cut without reaction. After ordinary preparation of the field, the operation can be done bloodlessly and apparently without the bad consequences which formerly contra indicated the use of a tourniquet in diabetic and arteriosclerotic limbs. Sponging is done with iced saline, etc. Shortly before skin closure the tourniquet is released so any bleeding points may be ligated. The anesthesia persists about long enough for the skin suture.

Surgeons are often prejudiced against the novel idea of chilling the tissues and also the mess created by the use of ice. If usage warrants, it doubtless will be feasible to devise an apparatus for dry refrigeration which will fulfill the requirements of accurate chilling without freezing. Aside from incidental advantages, the proposed plan has a rationale similar to Crile's anoci association. It is based upon the belief that in spite of anesthesia of the central or peripheral nervous system, tissues react to severe trauma in a manner which is detrimental to local healing and which also involves production of the toxic substances causing shock. Refrigeration certainly inhibits its shock and perhaps favors healing. The method has been used for only 3 human amputations and it can be said with due reservation that in this small experience no harm has been perceptible either to the tissues from the chilling or to the arteriosclerotic vessels from the tourniquet. The main basis of the suggestion is a large series of animal experiments. The results seem to warrant the hope that an amputation method which obviates pain, shock, and anesthesia may have some clinical usefulness. The incidental advantages of the method may be discussed with respect to (A) shorter and (B) longer refrigeration periods.

A. A patient with gangrene or infection is often received in a state of severe pain, intoxication, and weakness, and nevertheless must wait often 6 to 12 hours before operation during which time he is quieted with somewhat detrimental doses of morphine. If a member of the house staff should merely apply a tour

niquet and chill the limb, the patient would shortly be comfortable without drugs; there would be a better response to routine treatment and an appreciable subsidence of intoxication and fever, and everything could be in readiness upon the surgeon's arrival for operation without the usual anesthesia and other preliminaries. Such an amputation would be done a little below level of tourniquet as described.

B An occasional patient is in such desperate condition that he will probably die from the operation and will certainly die without it. In such a case there is need for a method which will even temporarily offer the benefits of amputation without its dangers. Several surgeons have stated in personal communications that under these conditions they have sometimes applied a tourniquet at ordinary temperature in order to gain a respite of only a few hours. The advantage of refrigeration is that it extends these time limits, so that without any of the shock of amputation a patient can be kept comfortable for 2 days or if necessary longer, with the source of pain, toxemia, or bacteremia cut off as effectively as if there had been an amputation, thus furnishing opportunity for transfusion or other restorative treatments. Amputation should then be performed not below but at the level of the tourniquet, since the viability of tissues in a diseased or infected limb could not be trusted after such prolonged absence of circulation. If necessary, a higher tourniquet could be applied and the refrigeration carried correspondingly higher for a few hours to provide anesthesia for the operation.

SUMMARY AND CONCLUSIONS

1 When a poison such as strychnine is injected into a limb, a suitable series of treatments with tourniquet and refrigeration makes it possible to tolerate many times the fatal dose without harm.

2 A temperature slightly above 0 degrees C in a limb reduces the metabolism of the tissues so as to enable them to withstand absence of circulation safely for hours or even days, a fact based on the same principle by which blood corpuscles and tissue fragments are preserved for weeks or months in the ice box without loss of vitality. It is believed

that this principle has definite applications in practical limb surgery, as discussed, especially for emergency and reparative operations.

3 As the low temperature must also arrest bacterial activity almost completely, the speculative question arose whether the tourniquet and refrigeration could be used to stop the flow of toxins or bacteria from an infected limb, so as to allow an interval for rest and development of strength and antibodies. The question included also the possibility of special treatments during this interval, especially the effects of infiltrating the isolated limb with a specific antiserum which could thus be held for a long time in high concentration in the infected area. It was learned positively that long treatments cannot be used for any necrotizing infections, because of the gangrene which results from the prolonged contact of such toxins with the tissues even at low temperature. Also refrigeration for more than a few hours is believed to be contra-indicated in any limb which is to be saved. Short treatments of this kind do not cause gangrene in infections with organisms such as the ordinary cocci, and the method was actually tried in one human case. The investigation had to be abandoned for lack of facilities, and there is at present no proof that the plan is beneficial or that it may not be slightly harmful.

4 The refrigeration method can obviate pain, shock, toxic absorption, and the need for anesthetics. It can probably, therefore, have at least occasional usefulness in preparation for amputations. Owing to the very small clinical experience in comparison with the numerous animal experiments, the statements are largely theoretical and the exact clinical benefits or limitations still await decision.

ANALYSIS OF IMMEDIATE POSTOPERATIVE COMPLICATIONS IN 2,000 CASES OF INGUINAL HERNIA

FENWICK BEEKMAN, M D, F A C S, and JOHN E. SULLIVAN, M D
New York, New York

THIS study was undertaken to obtain facts concerning postoperative complications in a group of apparently healthy individuals who underwent similar types of operations. All of these persons were operated upon for simple inguinal hernia, either oblique or direct in type. Consecutive cases have been chosen, except that any case in which an abnormality was noted at the time of the pre-operative physical examination or a complication of the hernia was recorded at the time of operation was disqualified from inclusion in this series. All of these individuals had, to the best of our knowledge, normal cardiovascular renal and respiratory systems and none of the hernias were incarcerated or strangulated. The majority of these individuals had some type of test for syphilis and, if positive, this case was eliminated. The operations were performed by some fifteen different surgeons of the surgical staff of the Hospital for the Ruptured and Crippled, between the dates of January 1, 1933, and July 1, 1936. Approximately the same technique was used by all.

In the 2,000 cases there were 1,508 operations for single and 492 for bilateral hernias (2,402 actual operations). Of the single hernias 858 were on the right side (56 per cent) and 650 on the left. Only sixty-two (3.1 per cent) were in females. Fifty-seven per cent of the single hernias in the males and 60 per cent in the females were on the right side. Twenty-five per cent of the males were operated upon for bilateral hernia and only 12.3 per cent of the females. Only 88 (4.5 per cent) of the individuals were over 60 years of age; the ages of the remainder were distributed fairly evenly through the first 6 decades of life. The smallest number in this last group (8.3 per cent) were in the second decade. Seventy-five per

cent of the individuals were between the ages of 20 and 59 years, inclusive.

There were 321 cases (16 per cent) in which postoperative complications were noted (Table I) with 5 deaths (0.25 per cent). All of the deaths were in cases of single hernia in men. Two were due to pneumonia and 3 to pulmonary emboli.

Almost twice as many complications occurred in patients operated upon for bilateral hernia (23.1 per cent) as for single (13.7 per cent). The rate of complications was slightly higher in those operated upon for right inguinal hernia (14.5 per cent) than for left (12.6 per cent). Complications followed operation more often in the case of the male than in that of the female patient; in 1938 cases of the former there were 313 (16.3 per cent) who developed complications and, in the 62 of the latter, 8 (12.9 per cent).

Considered according to age there was a well marked increase in complications occurring from the third decade of life onward (Chart 1). During the first two decades of

TABLE I — COMPLICATIONS

	Cases	Per cent

Unexplained diarrhea	1	0.5
Toxic erythema	1	0.5

From the General Surgical Service of the Hospital for the Ruptured and Crippled

life the rate was low in cases of both single (11 per cent) and bilateral (9 per cent) hernias. During the third decade the rate remained approximately the same as in the previous decades in the cases of single hernia (9 per cent), but there was a sharp rise (17 per cent) in the rate for those of bilateral hernia. After the thirtieth year there was a fairly uniform rise in the rate of complications for each succeeding decade in the cases of single hernia, to a maximum of 24 per cent in persons over 60 years of age. A similar rise was noted in the cases of bilateral hernia; the steepness of the curve, however, was more marked and finally reached 35 per cent for individuals over 60 years of age.

There were 2,492 operative wounds in the 2,000 cases. In 17 instances postoperative hematoma was noted. This rate of 0.8 per cent for this complication per number of cases and 0.7 per cent per number of wounds appears to be unduly low. For an explanation, it is fair to assume that in many other instances hematomas occurred, became contaminated, and were subsequently recorded as infections. The frequency of hematomas in cases of single hernia was 1.1 per cent, in bilateral hernia 1 per cent by cases and 0.5 per cent by wounds. There was no instance of hematoma in both wounds in any case of bilateral hernia. The rate of hematomas by decades of life was first, 0; second, 0.6 per cent, third, 0.5 per cent; fourth, 1.3 per cent, fifth, 1.3 per cent, sixth, 0.8 per cent, and over 60, 1.1 per cent. With the use of catgut or silk as suture material, the frequency of this complication was 0.8 per cent and 0.9 per cent, respectively, kangaroo tendon or ox fascia, 1.3 per cent, and autogenous fascia, 0. Only 0.7 per cent of the cases in which general or spinal anesthetics were used were complicated by hematoma, while 1.2 per cent of those in which a local anesthesia was used were so complicated.

There was a total of 99 cases of wound infection, 4.9 per cent per number of cases and 4 per cent per number of operative wounds. We have divided the wound infections into three groups, according to their severity. (A) Superficial infections, stitch abscesses or infections occurring on a raw surface, the result

Chart 1 Age group—all types of complications

of improper coaptation of the wound edges, (B) moderate infections, in which the subcutaneous tissue was involved but the hospital stay of the patient was not prolonged, (C) deep infections, in which the deeper tissues were involved, causing slough and prolonged hospitalization of the patient.

There were 53 cases of superficial infection (2.6 per cent). Thirty of these were in patients operated upon for single hernia, 2 per cent of the 1,508 cases, and 23 were in the group of 492 individuals with bilateral hernia, a rate of 4.7 per cent of infection. The moderate infections, 11 in number, for single hernia showed a rate of 0.7 per cent and for bilateral hernia, 4 in number, a rate of 0.8 per cent. The number of deep infections for the single hernia was 18, a rate of 1.2 per cent, and for the bilateral, 13, 2.6 per cent.

The rate by cases for moderate and deep infections was 2.3 per cent, in the group of cases of bilateral hernia it was 3.4 per cent. This was nearly double the rate for the cases of single hernia, which was 1.9 per cent. However, if figured by wounds, the rate for all wounds was 1.8 per cent. It was slightly less in cases of bilateral hernia than in those of single (29 infections in 1,508 wounds of single hernias, 1.9 per cent, and 17 infections in 984 wounds of bilateral hernias, 1.7 per cent).

Chart 2 Age group—types of infections

Chart 3 Infections in relation to time length of operation

The superficial infections in cases of single and bilateral hernia showed much the same relationship, 2 per cent for the single and 2.3 per cent for the bilateral.

An analysis of cases by age groups (Chart 2) showed a rate of less than 0.2 per cent for the moderate and deep infections during the first three decades of life, the rate then increased. The deep infections continued to increase each succeeding decade, reaching a maximum of 3.4 per cent in persons over 60 years of age. The rate of moderate infections, after the thirtieth year rose to around 1 per cent, where it remained during the later years. The rate of superficial infections appeared to be higher in younger persons, a little above 2 per cent, during the first three decades, it then rose to 4 per cent during the fourth decade and, finally, declined, being lower each succeeding decade, finally reaching 1 per cent in persons over 60. Studied by the number of wounds, the rates by age were slightly lower, the curve of the graph though similar in form to Chart 2, shows, however, lower percentage values.

Wound infection was studied in reference to the elapsed time of operation. It was found that in the cases of both single and bilateral hernia there was an increase in the rate of infection in all types, superficial, moderate and

deep, in direct relationship to the length of time of operation (Chart 3). This, as can be seen, is most marked in the case of deep infection, in which the rate rises to a maximum of 18.7 per cent after 1½ hours of elapsed operation time. By combining the moderate and deep infection rates and analyzing them in relation to elapsed time of operation, it is found that the rise of the infection rate in the case of single hernia occurred after a shorter period of elapsed operation time and rose more abruptly as this time lengthened, than in the case of the curve of the bilateral hernia (Chart 4).

Table II gives the data of wound infections in relation to the type of anesthesia that was used. The highest rate of wound infection per cases (3.6 per cent), as well as per wounds (2.7 per cent), occurred among the individuals on whom a spinal anesthesia was used. The rates of wound infection in the persons on whom general or local anesthetics were used were about equal, the latter being slightly lower (general anesthesia by cases 2.4 per cent and by wounds 1.7 per cent, local, by cases 1.8 per cent and by wounds 2.5 per cent).

Catgut was used in 1,529 cases or in 1,903 wounds, silk in 326 cases or 395 wounds, kangaroo tendon or fascia in 73 cases, or 90 wounds, and autogenous fascia in 72 cases, or

102 wounds Chart 5 shows the percentage rate of all types of infections by cases, when these different kinds of material were used.

The lowest rate of infection occurred among individuals operated upon with the use of silk (2.7 per cent by cases, 2.3 per cent by wounds) Those with catgut were next in frequency (4.9 per cent by cases, 3.9 per cent by wounds) This was followed by those in which kangaroo tendon or ox fascia was used (6.8 per cent by cases, 5.6 per cent by wounds) By far the highest rate of infection was in those cases in which autogenous fascia was used as the suture material (13.8 per cent by cases, 9.8 per cent by wounds).

Not only were there marked differences in the rates of moderate and deep infections, in relation to the different kinds of suture material that were used, but also in the case of the superficial ones. This last type occurred in the following order of frequency according to the type of suture material that was used kangaroo tendon or ox fascia, 1.3 per cent; silk, 1.5 per cent; catgut, 2.8 per cent, and autogenous fascia, 5.5 per cent

Grouping the moderate and deep infections together, the order of frequency of infection in relation to suture material was silk (by cases 1.2 per cent, by wounds 1 per cent), catgut (by cases 2.1 per cent, by wounds 1.7 per cent, kangaroo tendon or ox fascia (by cases 5.5 per cent, by wounds 4.4 per cent) and autogenous fascia (by cases 8.3 per cent, by wounds 6 per cent) With the use of each type of material the rate of infection in the cases of bilateral hernia was twice that of single, except in the cases in which silk was used as suture material.

Chart 4 Moderate and deep infections in single and double hernias in relation to time length of operation

There were 171 (8.6 per cent) cases of respiratory complications following operation; only 71 (3.5 per cent) were of a serious nature, 46 cases of atelectasis (2.3 per cent); 13 cases of pneumonia (0.7 per cent); and 12 cases of pulmonary embolus (0.6 per cent). There were 21 cases of upper respiratory infections (1.1 per cent), 77 (3.8 per cent) of severe cough without any demonstrable lesion, and 2 (0.1 per cent) of bronchitis. Those operated upon for bilateral hernia showed a much higher frequency of respiratory complications

TABLE II—WOUND INFECTIONS IN RELATION TO ANESTHESIA

Types of anesthesia	Single hernias			Bilateral hernias			Total hernias			Wounds of bilateral hernias			Total wounds

Number of moderate and deep infections in relation to different types of anesthesia

Chart 2 Age group—types of infections

Chart 3 Infections in relation to time length of operation

The superficial infections in cases of single and bilateral hernia showed much the same relationship, 2 per cent for the single and 2.3 per cent for the bilateral.

An analysis of cases by age groups (Chart 2) showed a rate of less than 0.2 per cent for the moderate and deep infections during the first three decades of life; the rate then increased. The deep infections continued to increase each succeeding decade, reaching a maximum of 3.4 per cent in persons over 60 years of age. The rate of moderate infections, after the thirtieth year, rose to around 1 per cent, where it remained during the later years. The rate of superficial infections appeared to be higher in younger persons, a little above 2 per cent, during the first three decades; it then rose to 4 per cent during the fourth decade and finally declined, being lower each succeeding decade, finally reaching 1 per cent in persons over 60. Studied by the number of wounds, the rates by age were slightly lower; the curve of the graph though similar in form to Chart 2, shows however, lower percentage values.

Wound infection was studied in reference to the elapsed time of operation. It was found that in the cases of both single and bilateral hernia there was an increase in the rate of infection in all types, superficial, moderate and

deep in direct relationship to the length of time of operation (Chart 3). This, as can be seen, is most marked in the case of deep infection, in which the rate rises to a maximum of 18.7 per cent after 1½ hours of elapsed operation time. By combining the moderate and deep infection rates and analyzing them in relation to elapsed time of operation, it is found that the rise of the infection rate in the case of single hernia occurred after a shorter period of elapsed operation time and rose more abruptly as this time lengthened than in the case of the curve of the bilateral hernia (Chart 4).

Table II gives the data of wound infections in relation to the type of anesthesia that was used. The highest rate of wound infection per cases (3.6 per cent), as well as per wounds (2.7 per cent), occurred among the individuals on whom a spinal anesthesia was used. The rates of wound infection in the persons on whom general or local anesthetics were used were about equal; the latter being slightly lower (general anesthesia by cases 2.4 per cent and by wounds 1.7 per cent, local by cases 1.8 per cent and by wounds 1.5 per cent).

Catgut was used in 1,529 cases, or in 1,905 wounds, silk in 326 cases or 395 wounds, kangaroo tendon or of fascia in 73 cases or 90 wounds, and autogenous fascia in 72 cases or

Chart 6 Respiratory complications in relation to age

there were 23 complicated cases, 15.9 per cent. Seventy-five operations took over 75 minutes, complications followed in 5 cases, 6.7 per cent. The frequency of the mild types of respiratory infection conformed to this rule, as well as the more severe. Only in the case of pulmonary embolus was there any variation.

The frequency of atelectasis as a postoperative complication in 1,780 cases in which operations were performed in less than 60 minutes was 2 per cent, in 220 cases in which the operation took over 60 minutes, the frequency was 5 per cent (Chart 7). The rate of frequency of pneumonia in the first group was 0.6 per cent and in the second 1.4 per cent.

The incidence of pulmonary embolus, when analyzed in its relationship to the elapsed time of operation, did not conform to those of the other types of respiratory complication. The rate of frequency rose from 0.4 per cent for individuals whose operations took less than 30 minutes, to a maximum of 0.9 per cent when the operations were performed in from 45 to 60 minutes, and then fell to zero when the time was longer than 75 minutes (Chart 7).

General anesthesia (ether, nitrous oxide, ethylene or a combination of one of the gases with ether) was used in 1,013 cases; spinal anesthesia (novocain) was used in 417; and

Chart 7 Respiratory complications in relation to time length of operation

local (novocain) in 570 cases. There were 74 (7.3 per cent) cases of respiratory complication following general anesthesia; 38 (9.1 per cent) following spinal anesthesia; and 59 (10.3 per cent) following local.

Cases of upper respiratory infection and of unexplained cough occurred with almost equal frequency regardless of what type of anesthesia was used.

Atelectasis followed in 3.4 per cent of the cases in which spinal anesthesia was used, 3.3 per cent in which local was used, and only 1.3 per cent in which general anesthesia was used. Pneumonia, on the other hand, appeared most frequently after general anesthesia, 1 per cent; and 0.2 per cent and 0.4 per cent, respectively, for spinal and local anesthetics.

The frequency of pulmonary embolus as a postoperative complication appeared more frequently when a local anesthesia was used (0.9 per cent); the frequency for spinal (0.2 per cent) and general (0.5 per cent) anesthesia was less in both cases when an analysis is made of the entire series. However, if the 394 cases of individuals under the age of 20 years are eliminated, as no case of pulmonary

Chart 5 Wound infections in relation to suture material

than those for single hernia, 12.6 per cent and 6.7 per cent, respectively. This difference, however, is not apparent in persons under 20 years of age, in whom the more common complication were more often the mild types of infections which were equally distributed in the younger and older groups. The frequency of atelectasis following operation in the cases of single hernia was 2 per cent and for bilateral hernia 3.2 per cent. pneumonia followed operation for single hernia at a frequency of 0.5 per cent and in that of bilateral at 1.2 per cent. Pulmonary embolus however, followed operation for single hernia more often than for bilateral hernia (0.7 per cent for former, 0.2 per cent for latter).

Taking the number of respiratory complications as a whole, their frequency did not appear to be affected by the age of the patient. Individually, however, the age of the patient apparently played some part in the rate of occurrence. Upper respiratory infections occurred in 7 (3.1 per cent) of the 228 children, but in only 14 (0.8 per cent) of the 1,772 older individuals. The frequency of postoperative cough increased in proportion to the age of the individuals by decades.

Cases of atelectasis appeared during all the decades of life (Chart 6), the rate was lowest during the first 2 (0.4 per cent and 1.2 per cent, respectively) and remained the same (2.7 per cent) in the succeeding ones.

Pneumonia was more common in the aged (Chart 6), occurring in 6 instances (1.9 per

cent) in 325 cases of individuals older than 49 years and in but 7 instances (0.4 per cent) in 1,675 cases of persons who were younger than 50 years. Two individuals died from postoperative pneumonia (15.4 per cent), each was over 50 years of age.

There was not a single case of pulmonary embolus in the 394 patients under 20 years of age (Chart 6), an incidence of 0.3 per cent occurred during the third and fourth decades which increased to 1.3 per cent during the fifth then fell to 0.8 per cent in the sixth and finally reached a high of 3.4 per cent in persons over 59 years of age. There were 3 deaths in this group (25 per cent), 1 of these individuals was in his fifth decade of life and the other 2 were over 60 years of age.

The study of respiratory complications, in relation to elapsed time of operation (Chart 7), showed a definite increase in the morbidity for each succeeding period of time up to 75 minutes and from there onward a decrease in the frequency. However in the latter group there were only 75 cases—perhaps too few to obtain a true value. There were 1,440 operations which were performed on an average of under 45 minutes in these there were 110 cases with complications 7.6 per cent. Three hundred and forty operations were done in an average time of between 45 and 60 minutes, 33 of these individuals had complications, a rate of 9.7 per cent. One hundred and five operations were finished in an average period of time of 60 to 75 minutes, in this group

less uniformly through all the decades of life. Mild types of upper respiratory infection were frequently encountered in the children and young adults. The more serious complications, however, were found more often in the older individuals, their frequency increasing as age advanced (Chart 6). Atelectasis was relatively uncommon in those under 20 years of age, after this it was equally frequent in each succeeding decade. Pneumonia appeared equally as often in each of the first five decades of life and then its frequency increased rapidly during the succeeding years. No cases of pulmonary embolus occurred during first twenty years of life, but from then on there was a decided increase by decades.

Elapsed time of operation The period of time used in performing the operation played an important part in the rate of frequency of both wound infection and severe respiratory complications. The frequency of all types of wound infection increased as the elapsed time of operation was lengthened. This was, however, most evident in the cases of moderate and deep infection (Chart 3). The curve for these types of infection rose rapidly from less than 0.5 per cent, for a 30 minute period, to 25 per cent, when the operation took longer than 1½ hours to perform. The curve is much the same for cases of both single and bilateral hernia, though, as would be expected, the rise of the curve for the latter type of case lags slightly behind the former (Chart 4).

Respiratory complications occurred more frequently as the period of time for operation was lengthened. This was evident in the mild types of upper respiratory infection, as well as the more serious pulmonary complications. Under a period of one hour, the frequency of atelectasis remained about 2 per cent and then rapidly rose. The frequency of pneumonia increased in proportion to the length of elapsed time of operation (Chart 7). (Both of these curves fell to zero when the time was longer than 90 minutes. However, this may have been due to the small number of cases in this group, only 16.) The curve for the frequency of cases of pulmonary embolus rose from a low in the shortest period of time,

reached its high when the elapsed time of operation was between 45 minutes and 1 hour, and returned to zero when the time was under an hour and a quarter.

Anesthesia The morbidity from wound infection was slightly lower in those cases in which a local anesthesia was used (Table II), that for general anesthesia was a quarter again as high, and that for spinal twice that for local anesthesia. Considering the rate of frequency in relation to the wounds, that of general and local anesthesia was about equal and a third less than that of spinal.

The type of anesthesia which was used did not affect morbidity from mild upper respiratory infections. However, it did appear to affect that from the more serious pulmonary complications. Atelectasis appeared almost twice as frequently when local or spinal anesthesia was used, as it did when a general anesthesia was used.

Pneumonia, on the other hand, occurred more than twice as often following the use of general anesthesia. Pulmonary embolus appeared as a complication one-third as often following spinal anesthesia, as it did following either general or local anesthetics.

Suture material The frequency of wound infection following the use of silk was nearly one-half that of catgut, one-third that of kangaroo tendon or ox fascia, and one-fifth that of autogenous fascia (Chart 5).

The more serious pulmonary complications occurred about twice as often among those cases in which kangaroo tendon or ox fascia or autogenous fascia were used, as among those in which silk or catgut were used.

SUMMARY

The immediate postoperative complications in a series of 2,000 cases of simple oblique and direct inguinal hernias have been analyzed. This analysis has been made in relation to whether the individual had a single or bilateral hernia and as to sex, age of the patient, and elapsed time of operation, the type of anesthesia used, and the kind of suture material that was employed at operation. Seven graphs illustrate these complications.

embolus appeared among them and as the majority (91 per cent) received general anesthesia, the frequency of this complication, in relation to the type of anesthesia that was used, becomes changed. Under this change it is found that in the cases in which local or general anesthesia were used, in each instance pulmonary embolus appeared at a frequency of 0.9 per cent, while with spinal anesthesia it was only 0.2 per cent.

Comparing the frequency of atelectasis, pneumonia, and pulmonary embolus as postoperative complications, to the type of suture material employed, the 1,606 cases of persons over 19 years of age have been used for this analysis as it is believed a fairer conclusion can be reached, as in the younger group of individuals kangaroo tendon, or fascia, and autogenous fascia were seldom used and because these complications were infrequent under the age of 20 years. These pulmonary complications were found to be higher in frequency when kangaroo tendon or or fascia (7.6 per cent) and autogenous fascia (7.1 per cent) were employed, than when catgut (3.7 per cent) or silk (4.4 per cent) were used as suture material. The frequency of atelectasis was 2.4, 3, 3, and 5.9 per cent in the use of catgut, silk, kangaroo tendon or or fascia and autogenous fascia, in the order given. The frequency of pneumonia was 0.4, 1, 3, and 1.4 per cent, in the above order, and pulmonary embolus was 0.9, 0.3, 1.5 and 0 per cent.

Thrombophlebitis was a complication in 6 cases, 3 of single hernia (0.2 per cent) and 3 of bilateral (0.6 per cent). The frequency did not appear to be affected by the type of anesthesia or the kind of suture material.

CONCLUSIONS

Any conclusion that may be drawn from a statistical report is open to correction and should not be considered as final. The opportunities for the occurrence of erroneous conclusions are many. The greatest of these is the inability to study a large enough series of cases, so that the smaller groups may contain a sufficient number to obtain true values. Further, erroneous conclusions are bound to occur when there are multiple factors to be considered in obtaining results, as it is often

impossible to separate the true elements that contribute to a given conclusion from the others that may be present. This study of a series of 2,000 cases of simple inguinal hernia, in which the immediate postoperative results are analyzed, is open to both of these objections. However, it is believed that the conclusions that are drawn are of sufficient value to publish, in the hope that later others may add their experiences to ours.

Bilateral hernia. The risk of complications in operations for bilateral inguinal hernia was nearly twice that of single hernia. During the first two decades of life this danger was not evident, but in each subsequent one the postoperative morbidity in the case of bilateral hernia was far greater than in the case of single (Chart 1).

Wound infection occurred more than twice as often in cases of bilateral hernia. This ratio was manifested in the group of mild or superficial infections as well as in those of the moderate and deep types. However, if studied by wounds, infection was as frequent in those of single hernia as of bilateral.

The risk of respiratory complications in the cases of bilateral was much greater than in the cases of single hernia. Both atelectasis and pneumonia followed operation twice as often in the former group as they did in the latter. Pulmonary embolus, however, followed operation twice as often in cases of single hernia. Thrombophlebitis was more commonly observed among the cases in the bilateral group.

Age. The age of the patient was an important factor in relation to the rate of morbidity (Chart 1). Up to 30 years of age, complications were relatively infrequent, from then on there was a steady rise in their frequency in each succeeding decade.

The frequency of cases of mild or superficial wound infection apparently was not affected by age, but the frequency of cases of moderate and deep infection, which remained uniformly low during the first three decades of life, rose rapidly in proportion to the age of the patient during the later decades (Chart 2).

The frequency of respiratory complications taken as a whole, were distributed more or

Fig 1 Drawing to show the vas deferens exposed and divided in the upper part of the scrotum. A hypodermic needle has been inserted into the proximal end for irrigation of the seminal vesicle with 1:80 carbolic acid.

Fig 2 Roentgenogram of the left vas deferens, the left seminal vesicle and the prostatic urethra outlined by sodium iodide which has been injected into the lumen of the vas just below the external abdominal ring. The shadow above the seminal vesicle represents an excess of sodium iodide which has flowed back from the prostatic urethra into the bladder.

is rapidly sealed by scar tissue. The patient is now placed in the Trendelenburg position and the surgeon proceeds to expose the bladder by a sub-umbilical incision. The fluid contents are evacuated by a special trocar and cannula which acts by suction. The appearance of the internal meatus, in cases of adenomatous disease of the prostate is always instructive, therefore visualization of the internal meatus, though not an essential part of the technique, is an aid to understanding of the causes at work which produce retention. It is also helpful in determining why the patient develops residual urine in these cases. With patients in whom a large amount of residual urine is present the internal meatus may have been pushed forward so far by the developing adenomatous mass that it lies within an inch of the anterior wall of the bladder.

The pathological mass of adenomatous tissue is then enucleated from within the prostatic bed by the intra-urethral method. The finger is inserted into the internal meatus and the mucous membrane is ruptured. The finger is swept round the tumor which is easily separated from the surrounding glandular tissue. The urethra is then fractured as near to the verumontanum as is possible. The amount of urethra left behind proximal to the triangular ligament is dependent upon the extent of the growth. If the whole of the prostatic portion is surrounded by adenomas, the fracture occurs at the point where the urethra passes through the triangular ligament. On the other hand, if the main mass is intravesical, a considerable length of prostatic urethra can be left behind.

The surgeon, after the pathological mass has been removed, then inserts into the bladder the special illuminated retractors (Fig 3), to each

fenestrated blade of which is attached a small electric lamp. The blade which retracts the posterosuperior wall of the bladder is so shaped that it not only retracts this part of the bladder but also the base. With the aid of these three lamps the interior of the bladder is so well flood lighted that a perfect view is obtained of every detail, excluding, of course, the prostatic cavity.

After removal of any clots which have collected in the operation area, the illuminated anterior retractor (Figs 4 and 5) together with the prostatic speculum is inserted into the prostatic cavity (Figs 6 and 7). The blades of the speculum not only act as retractors by opening up the entrance to the prostatic cavity, but also by their pressure upon the lateral walls function as temporary hemostats. The prostatic cavity is flood lighted by two tiny lamps attached to the anterior retractor, within the handle of this instrument is a three voltage dry cell battery. The prostatic cavity is so well visualized by this instrument that it is possible not only to see the floor of the cavity but also the prostatic surface of the triangular ligament with the protruding torn portion of the prostatic urethra (Fig 9). The trigonal flap of the mucous membrane is now stitched if possible to the mucous membrane of the urethra. If this is not possible because of the extent of prostatic urethra removed by enucleation, the flap is stitched as near the triangular ligament as is possible. The stitching is done with the aid of the boomerang

CLINICAL SURGERY

FROM ST PETER'S HOSPITAL FOR URINARY DISEASES

THE RECONSTRUCTION OPERATION FOR ADENOMATOUS DISEASE OF THE PROSTATE

CLIFFORD MORSON O.B.E. F.R.C.S. (Eng.), London, England

THE surgeon who designs an operation intended to restore an organ to its normal anatomical and physiological states following the removal of diseased tissues which have caused dysfunction must be guided by the following principles (1) hemorrhage must be under complete control, (2) sepsis must be avoided and (3) tissues which have been divided must be brought together again in correct alignment. These are well known principles which the medical profession has put into practice since the introduction of antiseptic and aseptic surgery but until recent date they have been considered impossible of achievement in operations on the prostate gland. The anatomical position of the organ and the frequent presence of chronic sepsis have led surgeons to believe that they cannot carry out in this region of the body the technique which embodies the principles taught them from their student days.

Today the introduction of flood lighting in a body cavity and the invention of instruments designed to overcome successfully an operator's difficulties with manipulation of deep seated tissues have placed the technique of prostatectomy on an equality with that of the surgery of any other organ. The pioneer surgeons of successful prostatectomy showed fine courage and tenacity of purpose against severe criticism, but it was a crude operation. The procedure was a blind one. The open operation which replaced it in 1916 was an attempt under direct vision to control hemorrhage and sepsis. Reconstruction was looked upon as an idle dream.

The purpose of this article is to describe a technique which under certain conditions makes reconstruction following total removal of adenomas of the prostate a successful operation.

For this technique the pre-operative preparation is similar to that for any other operation upon the prostate gland. The tests for determining renal function to all intents and purposes are now

standardized and exact but we have yet to find some method which will measure with accuracy the resistance to infection of the kidneys following upon these operations. At one time it was hoped that the estimation of the blood cholesterol would help to solve this problem but experience has shown that no reliance can be placed on it.

Anesthesia. Either anesthesia is employed in all cases with induction by gas and oxygen. In very nervous patients a small dose of sodium evipan, sufficient to produce unconsciousness for 10 minutes, is given intravenously before the patient is transferred from his bed to the anesthetic room. Spinal anesthesia is not recommended. Relaxation by inhalation ether is just as satisfactory as by a drug injected into the spinal theca, for the lowering of blood pressure associated with spinal anesthesia is a distinct disadvantage. Lung complications also are not ruled out by this method of anesthesia administration.

As soon as the patient has been placed upon the operating table, a catheter is passed and the bladder is washed out with 1,000 c.c. of a 1% solution of mercuric iodine. The organ is then distended with about 10 ounces of this solution. The surgeon now proceeds to dissect out the vas deferens immediately below the external abdominal ring and divide it (Fig. 1). Through the proximal end of the cut vas a blunt hypodermic needle is passed into its lumen and with a syringe 10 cubic centimeters of a solution of 1:80 carbolic acid are injected into the seminal vesicle (Fig. 2). The object of division of the vas is to prevent epididymo-orchitis and by irrigating the seminal vesicles before the bladder is opened we ensure sterilization of these organs. In patients who have submitted to pre-operative bladder drainage by a tied-in catheter, vesiculitis is extremely common. Irrigation, therefore, of these organs removes bacteria which have gained access through the irritation caused by the indwelling catheter. There is no need to ligature the divided ends of the vas deferens for the lumen

Fig 6, left The anterior illuminated retractor with the prostatic speculum is seen in position. The prostatic bed and the torn end of the prostatic urethra are visualized. The boomerang needle has been passed through the mucous membrane of the trigonal flap and the catgut suture has been attached to it.

Fig 7 A drawing to show the first maneuver of the trigonal flap suture.

cases a small angular White's tube suffices to assist in bladder drainage. It is essential, when primary closure is practiced, to drain the prevesical space by means of a corrugated rubber wick. Slight leakage of urine always occurs into this space, but will cause no trouble if there is a vent for its escape. Lastly, the ends of the silkworm gut suture which maintains the catheter in its correct position are immobilized by metal buttons of the Emesay pattern (Fig 14).

Before the patient's return to bed the bladder should be irrigated through the catheter. If hemorrhage has been efficiently controlled, the return of fluid will be scarcely blood stained.

Immediately the patient is returned to the ward, the head of his bed is raised about two feet from the ground. Not only does this position assist drainage from the bladder, but it adds enormously to the comfort of the patient. The catheter (Fig 15) is attached to a special glass urinal which lies between the patient's thighs. It is instructive to note how little discomfort is caused by the presence of a soft rubber catheter in the urethra, maintained in position by the technique which has just been described. The catheter in the urethra strapped to the penis is a form of torture which is entirely dispensed with by this method of fixation. It is an important step forward in adding to the patient's comfort during postoperative convalescence. The degree of urethritis is negligible and the catheter, so long as the silkworm gut suture is intact, never alters its position, however much it may be dragged on.

A convalescence free from complications is largely dependent upon efficient after-treatment. By elevating the head of the bed better bladder drainage, via the catheter, is assured. For the

first 24 hours, the bladder must be irrigated through the catheter, at intervals of 2 hours, with not more than 2 ounces of a solution of 1:8000 oxycyanide of mercury at a temperature of 90 degrees F. For the first few days after operation, the bladder is intolerant of distention by more than 2 or 3 ounces. It is for this reason that care must be taken not to inject more than this amount each time. If primary closure has been practiced, it is advisable to irrigate every hour for the first day. Sometimes a small clot will block the catheter, this can be easily removed by using the syringe as a suction apparatus.

The day following operation the irrigation should be reduced to four hourly. The necessity for using a solution at a temperature of not more than 90 degrees F. is apparent, if one realizes how sensitive the bladder mucous membrane is to heat, also fluid of a temperature above body heat is likely to increase the oozing of blood. The urine remains

Fig 8 The boomerang needle. Special instrument used for threading boomerang needle.

Fig. 3 The special illuminated bladder retractor

needle. Because of the tendency of the trigonal flap to retract when a Lambert suture is used, a special stitch, as shown in the illustration, is adopted. Care must be taken that the boomerang needle (Fig. 8) is inserted only through the trigonal flap and the superficial tissues forming the prostatic bed (Fig. 10). There is no need to insert the needle deeply into these tissues for all that is required is to bind down the mucous membrane of the trigone to the floor of the prostatic cavity. The criticism which has been made that the point of the needle may be inserted too deeply can be justified only if the operator is ignorant of the principles involved in this operation. As soon as this stitch has been tied (Fig. 11), a soft rubber catheter of the Malascol type, No. 22 French in size and with two eyes, is inserted by means of an introducer through the urethra and prostatic cavity

into the bladder. This catheter should be about 15 inches in length. The catheter is now drawn out through the bladder wound, the mushy end is cut off and a silkworm gut suture is passed through it immediately distal to the second eye. This is the suture which will retain the catheter in its correct position.

The operator now proceeds to reconstruct the internal meatus by means of a figure of eight stitch (Fig. 11). This is inserted into the mucous membrane and submucous tissues which form the lateral walls of the prostatic cavity, on no account should this suture be inserted into the tissues external to the flaps. Figure 11 shows clearly how this suture is inserted. It has a twofold purpose: (1) reconstruction as already stated, and (2) to act as a hemostat. The reconstruction part of the operation is now complete. The catheter is placed in position so that both eyes are within the bladder. Before the retractors are removed all clots must be swabbed out from the bladder and the new internal meatus visualized. The latter has two striking features: first it is on a level with the base of the bladder thus entirely obliterating the post prostatic pouch and second, it closely resembles the appearance of the internal meatus in a normal bladder. The surgeon now proceeds to pass the silkworm gut suture (Fig. 13) holding the catheter in position through the bladder and abdominal walls and out through the skin. Care must be taken not to puncture the deep epigastric vessels with the needle by keeping close to the cut edges of the skin.

The next step is to close the anterior wall of the bladder, but primary closure must be practiced only if the urine before the operation is sterile and the surgeon is sure that he has controlled the bleeding of the lateral walls of the prostatic cavity (Fig. 13). Therefore the contra-indications for primary closure are infective pyelonephritis, severe cystitis and inadequate hemostasis. In these

until the sixth week. It was found that the healing process in this region was extremely slow. Even at the end of the sixth week there was still non-union between the mucous membrane of the trigone and that of the urethra. So long as a raw surface persists there must be pyuria. From 2 to 3 months, therefore, elapse before the tissues at the neck of the bladder, following prostatectomy, become normal, if there has been no attempt to cover up the raw surface of the prostatic bed by mucous membrane, as in the blind, or Freyer, operation, this healing process cannot be complete for at least 4 to 6 months. This accounts for the fact that if postprostatectomy obstruction is going to occur, it does not manifest itself for about 6 months following removal of the diseased prostate. We are satisfied that the large majority of patients are discharged from hospital long before healing is complete at the internal meatus. Posterior urethoscopic examination demonstrates quite clearly the importance of bringing the mucous membrane of the base of the bladder as near to the torn end of the prostatic urethra as is possible. The more extensive the area of raw surface uncovered at the time of operation, the greater will be the formation of scar tissue and, therefore, contraction at the bladder neck.

It must be understood that a reconstruction operation such as the writer has outlined in the previous pages can be performed only if it is possible to obtain adequate exposure of the bladder and, also, adequate visualization of the prostatic cavity. For both special retractors and powerful illumination are needed. In a few cases of a second stage prostatectomy, the bladder is so contracted that it is impossible to insert any form of retractor which will give sufficient exposure of the internal meatus without tearing the posterosuperior wall of the bladder and making an opening into the peritoneal cavity. It is obvious that, in this class of case, a reconstruction operation is out of the question.

What are the immediate results from this technique compared with those of the Freyer or blind operation, and the Judd-Thompson Walker open operation? It is found that a reconstruction operation shortens convalescence by about a fortnight

Fig 15 Catheter Glass urinal

This is particularly so when primary closure is practiced. Convalescence in those cases in which a small suprapubic tube is inserted is a little longer. Most noticeable of all the changes is the control of postoperative hemorrhage. The comfort of the patient in not having a large suprapubic tube discharging urine and blood and the absence of an Irving apparatus is too obvious to need emphasis.

The control of sepsis, however, is still an unsolved problem. Surgical interference with a diseased prostate, whether it be by an open operation or by transurethral resection, admits organisms to the bladder which flourish in the wound at the vesicle neck. The larger the raw surface, the greater the infection. It is claimed for the reconstruction operation that sepsis is less pronounced than in the older technique, because the major part of the prostatic bed is covered by mucous membrane. Post-prostatectomy obstruction, a remote complication of the blind operation — the Judd-Thompson Walker open method, and transurethral resection — never occurs in the reconstruction technique. In fact, one of the most striking results is the ease with which urethral instruments such as the cystourethroscope can be passed.

Finally, it is stressed that in all those cases in which a complete cure for adenomatous disease of the prostate is indicated, the operation technique should be that described in this paper.

blood stained for about 3 days. If an angular White's tube has been inserted at the time of operation, it can be removed on the fourth or fifth day. The catheter remains *in situ* for 10 days. It is easily withdrawn by dividing the silkworm gut suture beneath one of the buttons. This suture is then pulled out with the aid of the other button.

If the prevesical space has been drained by means of a corrugated rubber wick, its retention is not needed for longer than 3 or 4 days.

Directly the catheter is removed, the patient passes urine by the urethra. For some days micturition is about two hourly, but by the time the patient leaves the hospital on an average about the twenty fourth day micturition has become four hourly.

The abdominal wound should be securely healed within 3 weeks of the operation in many cases the healing is complete by the fourteenth day. The extent of urine leakage when a White's angular tube has been inserted is so slight during the first few days after its removal that the dressing need be changed only once a day. In cases of primary closure of the bladder wall the abdominal wound heals by first intention. In every case of prostatectomy no matter what may be the technique, the urine on the patient's discharge from hospital contains pus and bacteria. The reason for this infection so long after the operation is easily explained.

An investigation was made by J. E. Semple and the writer with the aid of the posterior urethroscope of the changes which take place in the prostatic bed from the fifteenth day after operation.

BURN CONTRACTURES OF THE HAND

H M BLACKFIELD M D San Francisco California

SEVERE burns of the hand and their sequelae—loss of tissue, infection, scar tissue, and contractures—may so damage a hand that reconstructive surgery is of little or no avail. Early skin grafting will prevent these complications in many instances thereby eliminating the necessity for difficult and time consuming secondary reconstructive procedures.

During recent years after a group of early burns of the hand and late healed contractures

early unhealed cases the extent of the loss of tissue is usually recognized easily, but in old healed cases this is not always true. One is frequently amazed at the degree of anatomical distortion which occurs simply as a result of the loss of skin. In the late cases the function of each anatomical structure must be carefully evaluated before the plan of repair is decided upon.

It has been found that the contracted joints of children and young adults if not directly involved

Fig 1 Method of suturing of split graft to hand defect

Fig 2 Method of applying pressure dressing to split graft

have been treated some definite conclusions have been reached. Based upon these experiences rules have been adopted to guide our management of burns of the hand and contractures following such burns.

The importance of a detailed examination of the injured member and a diagnosis of its altered anatomy cannot be stressed too strongly. In

From the Department of Surgery University of California Medical School

by burns will usually return to normal function following the release of the contracture. For this reason contracted fingers in children should rarely be amputated. Elastic traction may be necessary for some weeks or months following grafting before the final result is achieved. This is particularly so if the contracture is of some years standing. A return to normal is not the rule in the later decades of life where changes in the joints and permanent loss of function are

Fig 3 A, B, C, Application of tied in local pressure for Wolfe grafts

thickness of the skin and may be obtained easily in large sheets by means of his suction boxes and knife. This graft is thicker than its predecessor, the Thiersch graft, contracts less and with stands trauma to a greater degree. In most instances it takes even though the field is not perfectly clean. Its greatest use is in the covering of granulating areas when deeper structures are not involved, particularly on the dorsum of the hand. In children suffering from the loss of large

areas of skin from the hand, Blair's graft is of considerable value. In marked contractures of the dorsal surface of the hand, for which gradual traction may be necessary, this graft is useful as a preliminary step and may even obviate the use of pedicle flaps. This graft should be used only temporarily on the volar aspect of the hand or fingers, as it does not stand trauma well in this region.

The free full thickness skin graft is functionally and cosmetically better than the split graft. It

should be used, however, only on freshly excised or avulsed surfaces, as it will not take in the

presence of infection. It is highly recommended for all small losses of skin, particularly on the fingers. Inexperienced surgeons should use this graft cautiously, as their success will be limited.

For the covering of most large areas, particularly if deeper structures such as muscles, tendons, nerves or joints are involved, dermosubcutaneous pedicle flaps should be used. This type of graft properly fashioned, produces the best functional and cosmetic result. Inasmuch as two or more operative steps are always required for its construction and application, the additional surgery must be justified.

OPERATIVE TECHNIQUE

Split grafts (Blair Brown technique) The surface of the donor skin is coated with a thin layer of white vaseline. By means of the Blair suction boxes and knife, a graft of the desired size and

thickness is cut, immediately placed on the denuded area, and sewed into place by a continuous horsehair suture. The suture approximates the overlapping edge of the graft to the cut edge of the defect and the central portion of the graft to the underlying granulating area (Fig. 1). V shaped incisions are made in the graft for drainage. A pressure dressing is applied consisting of layers of scarlet red oxyquinoline gauze, moist gauze and moist sea sponges held in place by adhesive tape. If this type of graft is used on a granulating area of questionable cleanliness, Dakin tubes are included in the dressing thus permitting the intermittent injection of warm saline solution to keep the dressings warm and moist (Fig. 2). The dressing is changed in from 3 to 7 days, depending on the patient's course and the amount of secretion

which occurs. The pressure dressing is changed as necessary and maintained from 7 to 10 days, varying with the completeness of the take.

Wolfe grafts One must remember that these grafts are hair-bearing and the donor site must be carefully chosen. A pattern of the defect is made of thin lead plate. The pattern is placed against the donor skin, and its outline is traced. By means of small skin hooks and a small knife, the full thickness of the skin is dissected from the underlying subcutaneous tissue. No subcutaneous tissue should be left on the graft. The graft is fitted accurately to the defect and is sutured into place by interrupted fine silk sutures which are left long. A continuous suture of horse-hair is also used to approximate the edges of the graft to the skin. "V" shaped incisions are made in the graft for drainage (Fig. 3, A). A pressure dressing of scarlet red gauze and moist gauze is tied in place by the long silk sutures (Fig. 3, B and C). Further pressure is added by means of additional gauze and moist sea sponges (Fig. 4, A, B, C and Fig. 5, A and B). This dressing is not changed for 10 days. At that time the sutures are removed and pressure dressings, compresses, or grease gauze are applied as indicated.

Pedicle flaps The abdomen, if unscarred, is usually chosen as the donor area. Two parallel incisions are made with the desired width of skin between them, conforming with Sanger's lines if possible. This flap of skin and subcutaneous tissue between the two parallel lines is raised from its bed, replaced, and resutured. The base beneath the flap may be grafted at the time, if later closure is impossible. After 2 weeks, the distal extremity of the flap is resected, replaced, and sutured. A few days later after its viability has been demonstrated, the flap is raised again and approximated to the defect by interrupted catgut sutures subcutaneously and silk sutures in the skin. The skin sutures are left long, and are tied over a pressure dressing to eliminate dead space and prevent venous stasis and edema (Fig. 6, A and B). This pressure is not disturbed for from 10 to 14 days, when the sutures are removed, the pedicle is resected, and the proximal portion of the pedicle replaced.

For the replacement of large areas on the dorsum of the hand, the gauntlet or glove flap is used. The abdomen is always used as the donor site unless this is contra-indicated. If only the dorsum of the hand is involved, a bi-pedicle

flap may be used. If the fingers are also involved, they may be syndactylized under the skin flap and later separated, or smaller pedicles may be fashioned initially as a part of the main flap. If multiple small narrow pedicles are used, only one side should be cut at a time or the circulation may not be sufficient to keep the small flap alive. An interval of from 5 to 7 days is usually sufficient. Tubed pedicles may be used for reconstruction of the hand, but this graft is usually too bulky after its application, requiring additional steps for thinning.

The rules governing our use of these grafts in burns and contractures of the hand may be tabulated as follows:

EARLY CASES

(unepithelialized)

Split graft

for cases in which deep structures are not involved (Fig. 7, A and B)

Dermosubcutaneous flap

for cases in which deep structures are involved (Fig. 8, A to E)

LATE CASES

Volar Surface Contractures

Wolfe graft

for fingers, webs, and distal portion of palm (Fig. 9, A to D and Fig. 10, A, B, C, D)

Split graft

for webs

Dermosubcutaneous graft

pedicle flap for palm (Fig. 11, A to D)

Dorsal Surface Contractures

Wolfe graft

for small areas and fingers

Split graft

for hyperextension (Fig. 12, A to D)

Glove pedicle graft

(Fig. 13, A to E and Figs. 14, 15, 16, and 17)

CONCLUSIONS

1 Burn contractures of the hand may frequently be prevented by early and proper skin grafting.

2 A detailed examination of the altered anatomy and a careful evaluation of its function must be carried out before a plan of reconstruction is decided upon.

3 The standard types of skin grafts used for hand surface reconstruction are enumerated.

4 The technique essential for the successful use of these grafts is briefly described.

5 Principles governing our use of these grafts in burns of the hand and contractures due to burns are presented.

Fig 17. A Hand under glove pedicle. Ulnar pedicle has been cut. B After cutting and suturing ulnar pedicle. C After cutting and suturing portions of thumb and index finger pedicles. D F and G After completion of case. H Appearance of abdomen.

presence of infection. It is highly recommended for all small losses of skin, particularly on the fingers. Inexperienced surgeons should use this graft cautiously as their success will be limited.

For the covering of most large areas, particularly if deeper structures such as muscles, tendons, nerves, or joints are involved, dermosubcutaneous pedicle flaps should be used. This type of graft properly fashioned, produces the best functional and cosmetic result. Inasmuch as two or more operative steps are always required for its construction and application, the additional surgery must be justified.

OPERATIVE TECHNIQUE

Split grafts (Blair Brown technique) The surface of the donor skin is coated with a thin layer of white vaseline. By means of the Blair suction boxes and knife, a graft of the desired size and

thickness is cut immediately placed on the denuded area and sewed into place by a continuous horsehair suture. The suture approximates the overlapping edge of the graft to the cut edge of the defect and the central portion of the graft to the underlying granulating area (Fig 1). 'V' shaped incisions are made in the graft for drainage. A pressure dressing is applied consisting of layers of scarlet red oxyquinoline gauze, moist gauze and moist sea sponges held in place by adhesive tape. If this type of graft is used on a granulating area of questionable cleanliness, Dakin tubes are included in the dressing, thus permitting the intermittent injection of warm saline solution to keep the dressings warm and moist (Fig 2). The dressing is changed in from 3 to 7 days, depending on the patient's course and the amount of secretion.

important diagnostic point, and in all cases demonstration of the presence of a tumor is a source of satisfaction

Prior to operation the stomach should be emptied by means of a soft rubber catheter. If gastric lavage is done before operation, it is well to allow the catheter to remain in the stomach until the operation is completed. The tendency of these patients to suffer disruption of the wound has been commented on by several writers, but the importance of this tendency cannot be over-emphasized. The operative procedure entailed in the Ramstedt type of operation does not necessitate a large incision. An incision 3 centimeters in length is sufficient. This should be located in the

TECHNICAL NOTES ON HYPERTROPHIC PYLORIC STENOSIS

STANLEY J. SIEGGER, M.D., F.A.C.S. Milwaukee, Wisconsin

THE Ramstedt operation has been generally accepted as the operative procedure of choice in hypertrophic pyloric stenosis. The apparent simplicity of this procedure is one of its principal dangers. An exact knowledge of the anatomical arrangement of the pyloric ring and the duodenal mucosa is necessary to avoid the accident of opening the duodenum. A small wound through the duodenal mucosa is easily overlooked unless one is aware of the danger of this accident and makes examination for its presence a routine step in the operative management. In dividing the tumor and separating it from the mucous layer great care must be exercised not to overlook obstructing fibers.

The symptoms and sign of hypertrophic pyloric stenosis need not be recounted here. Palpation of the tumor is a diagnostic sign of importance concerning which a difference of practice exists in various clinics. Some clinicians are reluctant to refer patients for operation unless the tumor can be palpated. Others search for the tumor rather casually and failure to palpate it is not considered of great importance. Unless palpation for the tumor is done in a methodical manner it will be felt in only a small percentage of cases but when one is willing to exercise patience it can

From the Milwaukee Children's Hospital

Fig. 1. Palpation of the tumor. The tumor can be felt in most instances when the technical details of palpation are carefully observed.

usually be felt. When palpation for the tumor is practised the infant should be placed on a table and the operator seated to the patient's right with the left hand on the right lumbar area and with the right hand on the anterior wall of the abdomen. The table and chair should be of such a height as to allow the operator's arms to rest in a comfortable position. The hands of the operator should be warm. Under these circumstances, bimanual palpation over the pyloric area will usually enable one to feel the tumor. Should the child be tense and the abdomen be held rigid because of crying a bottle of warm water should be offered. After this has been taken palpation should be resumed. The child usually vomits quite promptly and during the temporary relaxation following the throwing up of the fluid frequently one is able to feel the tumor. If vomiting does not occur the stomach should be emptied by a soft rubber catheter. Relaxation may also be obtained by immersion of the infant in a warm bath.

While palpation of the tumor is not essential to the diagnosis it is in some cases a very

EXTRAPERITONEAL IMPLANTATION OF THE COLON

One-Stage Resection for Carcinoma

WILLIAM T HARSHA, M D, F A C S, and WILLIAM T HARSHA, Jr., M D,
Chicago, Illinois

IN cancer of the colon a method of extraperitoneal resection is employed in a one-stage operation, which permits adequate excision and avoids both peritonitis and fistula. Because of the production of fecal fistulas two or more stage operations are repugnant both to the patient and the physician (1, 2). This technique is applicable only to certain selected cases of carcinoma of the cecum, ascending and descending colon, and sigmoid. Individual variations in the technique, necessitated by the position of the tumor, may suggest themselves to the surgically qualified reader, and possibly he may desire to extend its limitations.

The advent of modern roentgenological technique and the wider dissemination of popular knowledge concerning cancer have aided in earlier diagnosis, and it is only through early diagnosis that such an approach as is herein described can be used.

An accurate localizing diagnosis must be made before the onset of total obstruction, otherwise preliminary colostomy or enterostomy is necessary. The patient is put upon a liquid diet for 5 or 6 days. The intestinal tract is thoroughly cleaned out and decompressed by mild catharsis prior to operation.

The steps in the operation are shown in the illustrations.

An incision is made from the costal margin on the left side, following the lateral margin of the left rectus muscle, downward to about 2 inches above Poupart's ligament (Fig. 1, A). The external oblique aponeurosis is incised and the aponeurosis is split longitudinally just lateral to the

lateral border of the rectus. This incision of the external oblique aponeurosis is carried downward to a point just above the external inguinal ring. This division of the external oblique aponeurosis is done with scissors and follows the lateral margin of the rectus in the whole length of the skin incision (Fig. 1, B).

The internal oblique and transversalis muscles are split transversely in the direction of their fibers, as in the McBurney incision, at a point opposite to the anterior superior spine of the ilium. This is to afford access to the retroperitoneal line of cleavage between peritoneum and musculature of the abdominal wall. Then the abdominal wall is carefully separated from the peritoneum with the hand, working upward and

Fig 1 A, Line of incision, B, division of external oblique aponeurosis

Fig 7 Photograph of mucous surface of stomach pyloric area and duodenum in a case of hypertrophic pyloric stenosis illustrating the reduplication of the duodenal mucosa and its proximity to the peritoneal surface at the caudal end of the tumor

pylorus is easily effected by the gentle elevation of the lower margin of the right lobe of the liver by means of a small straight blade retractor

When the stomach is identified, a small portion on the anterior wall should first be brought into the wound and then drawn to the patient's right. When the stomach is then brought over to the left, the pylorus comes easily into view. The tumor as well as the adjacent duodenum is held in the left hand between the thumb and the index finger

In patients who have a marked degree of obstruction, the tumor is frequently somewhat edematous. Such tumors are easier to separate from the mucosa and bleed less than do those in which there is no edema. Acting on this observation we have injected from one to $1\frac{1}{2}$ cubic centimeters of water or normal saline solution into the tumor in most cases, and have found that this facilitates the ease with which separation of the muscularis from the mucosa can be accomplished. Bleeding from the cut edge should always be observed, and if it is found that any points bleed actively they should be controlled by means of ligation.

A thorough knowledge of the anatomical arrangement of the duodenal mucosa at its junction with the pylorus is of great importance when one is performing the Ramstedt operation. The arrangement has been commented on by several writers and is illustrated in standard anatomical textbooks but has not been sufficiently emphasized (1). The pyloric ring produces a sharp constriction of the mucosa of the stomach and duo-

denum. There is practically no danger of puncturing the gastric mucosa as one separates the mucosa from the mucous membrane upward on the gastric side. The duodenal mucosa which has been constricted by the pyloric ring, approaches the wall of the duodenum at a right angle or at an acute angle which points toward the stomach. For this reason, in approaching the duodenum in the separation of the tumor from the mucosa, one must exert extreme care not to puncture the membrane, the angle of which is quite superficial at this point. The pyloric tumor not infrequently has pushed into the duodenum so that its anatomical relation to the bowel is quite similar to that of the cervix to the wall of the vagina.

On completing dissection of the tumor and separation from the mucous membrane by spreading with a forceps one should carefully examine the area for possible puncture of the duodenum. This is best done by holding the duodenum and the tumor between the thumb and index finger of the left hand and by holding the stomach just above the tumor between the thumb and index finger of the right hand. By gently approximating the two hands one can exert sufficient pressure to demonstrate any damage to the mucosa.

Puncture of the duodenum however is not a serious complication if one notes that it has occurred and repairs the damage properly. The accident is easily overlooked and we have seen instances in which this has occurred. The puncture wound may be small but it can be identified by the everted mucous membrane and usually a small bubble of bile stained fluid can be expressed. Montgomery has suggested that the area suspected of puncture be moistened with normal saline solution. Pressure upon the duodenum if it is punctured will produce small bubbles which enable one to identify a very small opening. When the duodenum is perforated the defect should be closed by one or at the most two simple mattress sutures of No. 6 chromic catgut. By using a Connell type of suture the margin can be inverted. The area should then be covered with the omentum which is fixed in place with several stitches.

We prefer ether anesthesia by the open drop method in these cases. The operation does not consume much time and a small amount of ether affords complete relaxation. We have never regretted its use. The operation can be performed by local infiltration anesthesia and this method is preferred by some surgeons. The relaxation afforded by this method is not as satisfactory as

that which is secured under ether anesthesia and in several instances, during the process of operation we have noted untoward symptoms such as mild convulsive seizures, which we have attributed to the novocain solution. In no instances have these symptoms been followed by serious complications.

EXTRAPERITONEAL IMPLANTATION OF THE COLON

One-Stage Resection for Carcinoma

WILLIAM T. HARSHA, M D, F A C S, and WILLIAM T. HARSHA, Jr, M D,
Chicago, Illinois

IN cancer of the colon a method of extraperitoneal resection is employed in a one-stage operation, which permits adequate excision and avoids both peritonitis and fistula. Because of the production of fecal fistulas two or more stage operations are repugnant both to the patient and the physician (1, 2). This technique is applicable only to certain selected cases of carcinoma of the cecum, ascending and descending colon, and sigmoid. Individual variations in the technique, necessitated by the position of the tumor, may suggest themselves to the surgically qualified reader, and possibly he may desire to extend its limitations.

The advent of modern roentgenological technique and the wider dissemination of popular knowledge concerning cancer have aided in earlier diagnosis, and it is only through early diagnosis that such an approach as is herein described can be used.

An accurate localizing diagnosis must be made before the onset of total obstruction, otherwise preliminary colostomy or enterostomy is necessary. The patient is put upon a liquid diet for 5 or 6 days. The intestinal tract is thoroughly cleaned out and decompressed by mild catharsis prior to operation.

The steps in the operation are shown in the illustrations.

An incision is made from the costal margin on the left side, following the lateral margin of the left rectus muscle, downward to about 2 inches above Poupart's ligament (Fig 1, A). The external oblique aponeurosis is incised and the aponeurosis is split longitudinally just lateral to the

lateral border of the rectus. This incision of the external oblique aponeurosis is carried downward to a point just above the external inguinal ring. This division of the external oblique aponeurosis is done with scissors and follows the lateral margin of the rectus in the whole length of the skin incision (Fig 1, B).

The internal oblique and transversalis muscles are split transversely in the direction of their fibers, as in the McBurney incision, at a point opposite to the anterior superior spine of the ilium. This is to afford access to the retroperitoneal line of cleavage between peritoneum and musculature of the abdominal wall. Then the abdominal wall is carefully separated from the peritoneum with the hand, working upward and

Fig 1 A, Line of incision, B, division of external oblique aponeurosis

Fig 2 A Separation of abdominal wall from peritoneum B peritoneum exposed

Fig 3 A Colon withdrawn through peritoneal incision and tumor located Prentiss clamp applied B C and D further steps in removal of tumor and closure of stumps

Fig 4 A and B, Steps in lateral anastomosis, C, complete isolation of the extruded anastomosis from peritoneal cavity

downward from this split in the internal oblique and transversalis muscles. Then with scissors the transversalis and internal oblique are cut again, paralleling the rectus margin. This longitudinal division of the internal oblique and transversalis is also carried parallel to the skin incision, equaling the skin incision in length, and parallel to the division of the external oblique aponeurosis. This exposes unopened peritoneum. The peritoneum must be carefully protected against injury, particularly in the upper part of the incision. It is more firmly attached above the level of the umbilicus than it is below it (Fig 2, A and B).

With this large incision and complete separation of the fascia and muscles of the abdominal wall access is obtained to the retroperitoneal space behind the colon, and in relation above to the kidney and below to the retroperitoneal tissue, fat, areolar tissue, and muscles of the true and false pelvis. Extraperitoneal separation of the colon from the posterior parietal wall is done by blunt dissection with the fingers and with gauze. This exposure of the peritoneum laterally permits palpation of the bowel and determination of the tumor mass, its site and extent, prior to incision of the peritoneum.

When carefully done, the separation of the colon posteriorly is easy and bloodless. When extended toward the midline the ureter should be identified.

The tumor mass to be resected is identified through the peritoneum by palpation and the site of its extrusion is chosen. An incision into the peritoneum, about 2 inches in length, is made lateral and anterior to the position of the tumor, and the portion of the colon to be resected is

Fig 5 A, The abdomen is firmly closed in layers and stab wound in side for drain, B, sectional view. Care is taken to prevent leakage

withdrawn through the peritoneal incision and isolated. With proper mobilization the descending colon is accessible in most of its length. The field is properly protected with gauze. Examination is made for local lymph glands and the extent of the tumor mass is further ascertained. The site of resection is then chosen (Fig 3, A).

The tumor mass as drawn through the peritoneal incision is excised between Prentiss clamps with the electro cautery. A needle threaded with

Fig 6 Photograph of specimen removed

Fig 7 Roentgenogram before operation

double linen is passed through the Prentiss clamp and tied. A purse string invaginates the tied ends and this pursestring is buried by additional sutures further invaginating and protecting the stump from opening. Both ends are carefully sealed and then approximated to each other (Fig 3, B, C and D).

At a distance of about 1.5 inches from the blind and sealed stumps a lateral anastomosis of colon to colon is done with two layers of linen (Fig 4, B).

The peritoneum is now sutured to the bowel proximal to the area with interrupted linen sutures closely approximating peritoneum to bowel serosa and completely isolating the extruded anastomosis from the peritoneal cavity about 1 inch proximal from the side-to-side anastomosis (Fig 4, C).

A large free stab wound is made in the flank just above the iliac crest, and a fenestrated rubber tube drain placed below the blind stumps. The abdomen is firmly closed in layers (Fig 5 A).

The blind ends are sutured together (8) in the hope of better maintaining the physiological integrity of the bowel, with consideration to the peripheral nervous mechanisms within it, as well as its support from the abdominal wall and to further prevent leakage (Fig 5 B).

The extrusion of a blind stump was first suggested and called the thumb method by Blood

Fig 8 Roentgenogram after operation

good (9) and used successfully by him. His approach was an intraperitoneal one and the anastomosis was left intraperitoneally.

The side-to-side anastomosis was used because of previous failures in attempts at end-to-end anastomosis. While fistulas have developed in end-to-end anastomoses by this extraperitoneal method they have remained extraperitoneal and without systemic repercussion.

Considering the mobility of the colon from an embryological and anatomical point of view (1) and the distribution of its blood supply from central sources in a manner permitting considerable elasticity, it would seem that an operation requiring considerable mobilization is morphologically sound.

The extraperitoneal approach is an old one antedating the days of antiseptic surgery by its use in the older cesarean sections and in the pre-antiseptic methods of approach to carcinoma of the large bowel. The later uses of the extraperitoneal approach have been mostly in modern cesarean section and in work on the kidney and ureter such as done by Hugh Cabot.

The approach seems a logical one in properly located and selected tumors of the bowel. Properly speaking it is not entirely extraperitoneal as the peritoneum is opened for the delivery of the tumor. Practically by exclusion of the operative field from the peritoneal cavity the operation can in this sense only be called extraperitoneal. It is

seen that none of the features of this technique are new, yet the combination of them has resulted in a satisfactory approach. This extraperitoneal position of the anastomosis is of great advantage in avoiding peritoneal infection.

The two-stage operation suggested by Heinecke and published by Oscar Bloch in 1892 was popularized by Mikulicz and has superseded the one-stage operation as a measure of safety in certain cases of carcinoma of the colon. Adopted by Bruns and Mayo (9) it is now called the Mikulicz-Bruns-Mayo operation. The production of slow closing fistula adds to the difficulty of the operation. One-stage intra-abdominal operations by lateral anastomosis are often chosen in preference to the Mikulicz procedure. In no other circumstance is surgical judgment as to the type of operation more difficult (3). It is to be hoped that the

method may be an addition to those at our disposal.

A WAI KING IRON FOR IMMEDIATE USE ON WET PLASTER CASTS

BERNARD B. LARSEN, M.D., F.A.C.S., Cleveland, Ohio

THE use of walking irons on fractures of the lower extremities is advocated because of increased comfort and decrease in economic loss to the patient and because of the prevention to a great extent of muscle atrophy which in turn means a decrease in the time necessary for the return of maximum function. This therapy is best suited to fractures of the ankle in which the weight bearing is not greatly interfered with, such as fractures of one or both malleoli or fracture dislocations with the posterior portion of the tibia broken off. This method may also be applied in some fractures of the foot, and in fractures of the long bones or of the os calcis if Steinmann pins or Kirschner wires are properly incorporated in the plaster so as to bear the weight. Many men who are convinced of the benefits of walking on a fractured extremity when the nature of the fracture permits do not generally use walking irons because of the technical difficulties involved. In the hope that this type of therapy will be better applied and further popularized, this article introduces a modification of the old type walking iron which overcomes some of the technical difficulties of application as well as provides greater safety to the patient.

To my knowledge all walking irons, whether the loop, crutch tip, or skate type are now made of the same weight material throughout. Any such walking iron of sufficiently heavy material to carry the patient's weight is of necessity difficult to bend and therefore the accurate fitting of such an iron to a cast requires patience, skill and labor, especially if proper bending irons are not available. The iron must not be applied until after the cast is well hardened so that pressure caused on the cast by the necessarily imperfect fit of the iron will not be transmitted through onto the extremity. The failure to observe this rule and the failure to use unpadded plaster are the principal causes for a great deal of pain and not a few of the pressure sores produced by the use of walking irons.

To minimize these difficulties, we have devised a walking iron with flexible upright portions

which we have used with universal success the past 18 months (Fig. 1). The flexible uprights fit themselves to the curves of the plaster when applied and though they are thin and very flexible being made of spring brass they are able to bear weight because they are held tightly between the layers of the plaster cast and perforations made with a nail from the inside out through these uprights keep them from slipping. The stirrup portion is of rigid duraluminum and wide enough so that it does not impinge on the plaster over the malleoli. On the stirrup is a metal peg covered with a crutch tip which rotates in a simple swivel joint facilitating rotation without much friction. This makes walking easier and the rubber crutch tip wears much longer than if the peg is used. We believe patients are less apt to slip or trip on a swivel type crutch tip than on a loop or skate type of iron. The construction of this walking iron is simple and inexpensive. It does not rust and may be used time and time again.

This iron is applied according to the method of Boehler² after local anesthesia is applied at the site of fracture. If the edema is not marked it is massaged away so as to allow accurate molding of the plaster. If edema is marked some other form of immobilization is used until the edema subsides. It must be borne in mind that the quickest and easiest way to get rid of swelling is to reduce the fracture. This is usually done with the patient sitting on a table with the injured extremity being supported by the operator's knee (Fig. 2) and the foot held in the optimum position. The patient's other foot is placed on a stool for balance. A piece of stockinette about 6 inches wide is slipped on and placed just below the knee and over the lower portion of this fastened with adhesive is placed a 2 inch strip of thin felt (Fig. 2). A very wet plaster strip 4 to 6 inches wide about six layers thick and of a previously measured length is then placed stirrup fashion around the foot and leg directly on the unshaven skin (Figs. 3 and 4) and held in place by a single layer of gauze bandage so that the operator may mold the plaster about the foot.

¹The walking iron may be purchased from the Rees Ship Co. A. Co., Ltd., 700 Third Avenue, Cleveland, Ohio, and the D.F.Y.C. Co., 110 North La Salle Street, Chicago, Illinois. ²Boehler, L. O. The Treatment of Fractures. 4th ed. pp. 410-422. Translated by Ernest W. H. G. 1935. Baltimore: W. B. Saunders Co. 1935.

prominences with the flat of the hands without creases or wrinkles (Fig 5) After this stirrup splint has set well enough to hold its shape, the supporting gauze bandage may or may not be cut and removed and a posterior splint of wet plaster 4 to 6 inches wide and about six layers thick is applied, the strip being notched at the bend in the heel so as to lie smoothly (Fig 6) It is absolutely essential that these strips be applied while wet and soft If they are not absolutely soft, uneven pressure with its sometimes disastrous results will follow The circular plaster bandage is now applied, care being taken that it is absolutely smooth over the anterior portion, making any reverses or turns over the previously applied splints (Fig 7) This plaster is quite tightly applied, especially over the upper portion of the cast

Without delay the walking iron is put into position exactly in the weight bearing line (Fig 8)

It will be noted in the anterior view (Fig 9) that the heavy duraluminum portion of the splint is wide enough to avoid pressure on the malleoli If the extremity is supported as shown in Figures 8 and 9, care must be taken that the patient does not put much weight on the stirrup, it is usually best to continue supporting the foot as was done when the splints were applied The stockinette at the upper edge of the cast is now turned down so as to make this edge smooth With the walking iron held in position, one or two plaster bandages are now applied over it, thus molding the flexible uprights to fit the contours of the cast without uneven distribution of pressure (Figs 10 and 11) Care must be taken to cover also the rigid portion of the uprights The cast is trimmed exactly at the base of the toes so that the toes may be moved freely, care must be taken not to trim the cast proximal to the base of the toes or

A WALKING IRON FOR IMMEDIATE USE ON WET PLASTER CASTS

BERNARD B. LARSEN, M.D. F.A.C.S. Cleveland Ohio

THE use of walking irons on fractures of the lower extremities is advocated because of increased comfort and decrease in economic loss to the patient and because of the prevention to a great extent of muscle atrophy which in turn means a decrease in the time necessary for the return of maximum function. This therapy is best suited to fractures of the ankle in which the weight bearing is not greatly interfered with such as fractures of one or both malleoli or fracture dislocations with the posterior portion of the tibia broken off. This method may also be applied in some fractures of the foot and in fractures of the long bones or of the os calcis if Steinmann pins or Kirschner wires are properly incorporated in the plaster so as to bear the weight. Many men who are convinced of the benefits of walking on a fractured extremity when the nature of the fracture permits do not generally use walking irons because of the technical difficulties involved. In the hope that this type of therapy will be better applied and further popularized this article introduces a modification of the old type walking iron which overcomes some of the technical difficulties of application as well as provides greater safety to the patient.

To my knowledge all walking irons whether the loop crutch tip or skate type are now made of the same weight material throughout. Any such walking iron of sufficiently heavy material to carry the patient's weight is of necessity difficult to bend and therefore, the accurate fitting of such an iron to a cast requires patience, skill and labor especially if proper bending irons are not available. The iron must not be applied until after the cast is well hardened so that pressure caused on the cast by the necessary imperfect fit of the iron will not be transmitted through onto the extremity. The failure to observe this rule and the failure to use unpadded plaster are the principal causes for a great deal of pain and not a few of the pressure sores produced by the use of walking irons.

To minimize these difficulties, we have devised a walking iron with flexible upright portions,

which we have used with universal success the past 18 months (Fig. 1). The flexible uprights fit themselves to the curves of the plaster when applied and though they are thin and very flexible being made of spring brass they are able to bear weight because they are held tightly between the layers of the plaster cast and perforations made with a nail from the inside out through these uprights, keep them from slipping. The stirrup portion is of rigid duraluminum and wide enough so that it does not impinge on the plaster over the malleoli. On the stirrup is a metal peg covered with a crutch tip which rotates in a simple swivel joint facilitating rotation without much friction. This makes walking easier and the rubber crutch tip wears much longer than if the peg is fixed. We believe patients are less apt to slip or trip on a swivel type crutch tip than on a loop or skate type of iron. The construction of this walking iron is simple and inexpensive. It does not rust and may be used time and time again.

This iron is applied according to the method of Boehler² after local anesthesia is applied at the site of fracture. If the edema is not marked it is massaged away so as to allow accurate molding of the plaster. If edema is marked some other form of immobilization is used until the edema subsides. It must be borne in mind that the quickest and easiest way to get rid of swelling is to reduce the fracture. This is usually done with the patient sitting on a table with the injured extremity being supported by the operator's knee (Fig. 2) and the foot held in the optimum position. The patient's other foot is placed on a stool for balance. A piece of stockine te about 6 inches wide is slipped on and placed just below the knee and over the lower portion of this fastened with adhesive is placed a 2 inch strip of thin felt (Fig. 2). A very wet plaster strip 4 to 6 inches wide about six layers thick and of a previously measured length is then placed stirrup fashion around the foot and leg directly on the unshaven skin (Figs. 3 and 4) and held in place by a single layer of gauze bandage so that the operator may mold the plaster about the bony

¹The walking iron is to be purchased from the Bryant Iron Co. 614 Wood St. Cleveland, Ohio. It is also sold by the D.P. Co. Warren, Indiana.

SURGICAL ASPECTS OF NEUROGENIC TUMORS OF THE ABDOMEN

V L SCHRAGER, M D , F A C S , Chicago, Illinois

NEUROGENIC tumors of the abdomen encountered in general surgery have seldom been diagnosed accurately before exploration. These neoplasms have no pathognomonic characteristics by which they may be readily recognized. The conjectural diagnostic aspects are not settled even by exploration, as the surgeon usually bases his opinion upon his impression of the gross appearance of the tumor and upon resemblance with other neoplasms with which he is familiar. Competent histopathological reports disclose the identity and nature of the tumor, which usually intrigue the surgeon heretofore unfamiliar with these rare neoplasms.

The present study is based upon clinical and surgical experiences with two types of neurogenic tumors (a) schwannoblastoma (neurinoma) and (b) retroperitoneal sympatheticoblastoma (neurocytoma).

SCHWANNBLASTOMA (NEURINOMA)

José Verocay was the first to describe these tumors and differentiate them from neuromas on histological grounds. He coined the term "neurinoma" in 1910. Verocay and Antoni were of the opinion that these tumors originated from the sheath of Schwann, or from the cellular ancestors of the sheath, designated by them as lemmoblasts.

The terminology of this type of tumor is varied and may be explained as follows: (a) gross diagnosis without histological verification, or inaccurate histological interpretation, (b) divergence of opinion among histopathologists and personal preference of terminology.

This accounts for such terms as schwannoblastoma, neurinoma, solitary neurofibroma, perineural fibroblastoma, peripheral glioma, sarcoma, fibrosarcoma, fibromyxosarcoma, malignant leiomyoma. A more definite study of these neoplasms will tend to reduce the terminology to that most frequently used in medical literature, i.e., neurinoma and schwannoma, or schwannoblastoma.

Arthur Purdy Stout objects to the term neurinoma because it suggests nerve fiber tumor, when in reality the tumor originates from the sheath of Schwann. F. H. Vizetelly, editor of the *New Standard Dictionary*, prefers neurilenoma instead of neurinoma.

The scarcity of these neoplasms may be inferred by the absence of mention in collective reviews of benign neoplasms of the stomach. Balfour and Henderson, who reported 58 cases of benign tumors of the stomach from the Mayo Clinic, do not speak of schwannoma. Likewise, Eliason and Wright in a discussion of benign tumors of the stomach failed to mention this type of tumor.

Schwannoblastoma usually develops from the stomach wall, although it has been encountered in other tissues, such as appendix, extremities, upper respiratory organs, tongue, eye, and orbit. Schwannoma in the first portion of the duodenum was described by Lemonnier and Peycelon. Peretz reported a case of neurinoma of the appendix. Dyggve Petersen reported 20 cases of intrathoracic neurinomas, all occurring in women and shown by x-rays to be in the paravertebral area.

Etiologically, there is no definite accounting for the origin of these tumors. The factors which initiate these tumors and spur them on to growth are shared by the growth of tumors in general. However, some pertinent and highly suggestive observations have been made to the effect that nerve proliferation is frequently observed in inflamed gastric mucosa on the edge of an active or cicatrizing ulcer (Masson). Jentzer found small neurinomas in the callous portion surrounding small gastric ulcers. Okkels observed marked proliferation in the nerves of the gastric walls surrounding the ulcer margin, which he defines as neurinoma scar. Similar observations have been made by Askenazy in gastric ulcers, the wall of a previously inflamed appendix, or in chronic obliterative appendicitis. These proliferative processes may attain neoplastic proportions and, thus, may explain in some measure the neoplastic origin from a simple proliferative process.

Since most of these tumors originate in the myenteric plexus of Auerbach, it may not be amiss to review briefly the arrangement of the nerve plexuses of the stomach wall. There are in

painful swelling of the dorsum of the foot may occur. The plantar portion of the cast is left long to protect the toes.

This completes the cast but the patient should remain in bed with the leg elevated for 24 hours. After this period if no abnormality is noticed, it is safe to begin weight bearing if there are signs of poor circulation to the toes the patient should remain in bed with the leg elevated until circulation is adequate, or if severe the cast should be removed and reapplied when edema has subsided. If the cast and iron are properly applied on properly chosen cases in which the fracture can be accurately reduced there should never occur painful and dangerous pressure areas. If pressure pain does occur, however the cast must be removed. Walking is sometimes not comfortable for the first 2 days until the patient has become accustomed to the apparatus. This accommodation occurs rapidly, especially in children and young adults and all are grateful to have a walking cast instead of having to hobble about on crutches since most of them go about their business with surprisingly little limitation of activity.

The cast if applied as here described is comparatively light. This walking iron weighs 14 ounces and the average total weight of cast and iron is 3½ pounds when dry. Likewise with this type of apparatus the circumference of the leg is not greatly increased and therefore it is not cumbersome.

After having used various types of light padding we are completely satisfied that unpadded plaster properly applied is more comfortable and less dangerous to the patient when walking irons are to be used. Padding tends to wad up and wrinkle with consequent pressure areas and discomfort and the fragments are more apt to slip out of position. In unpadded plaster there is practically no friction within the cast.

The removal of this skin tight plaster is not difficult. The hair on the leg changes about every 3 weeks so after this interval there is no pain on removal of the cast. Usually, if convenient, we have the patient soak the cast in water for an hour or two after which it is easily cut off. The cast is usually not removed until the fracture is quite well healed because the walking on the fractured extremity is physiotherapy in itself. Muscle atrophy is minimal. In many cases the patient puts on a shoe and walks immediately after the plaster is removed with surprisingly little discomfort or swelling.

SKILLARS

A new type of walking iron with flexible upright portions, a rigid stirrup, and a swivel type crutch tip is described.

This walking iron is immediately incorporated in a wet plaster cast without the danger of causing pressure areas.

The technique of applying an unpadded plaster boot with this walking iron is described.

SURGICAL ASPECTS OF NEUROGENIC TUMORS OF THE ABDOMEN

V L SCHRAGER, M D , F A C S , Chicago, Illinois

NEUROGENIC tumors of the abdomen encountered in general surgery have seldom been diagnosed accurately before exploration. These neoplasms have no pathognomonic characteristics by which they may be readily recognized. The conjectural diagnostic aspects are not settled even by exploration, as the surgeon usually bases his opinion upon his impression of the gross appearance of the tumor and upon resemblance with other neoplasms with which he is familiar. Competent histopathological reports disclose the identity and nature of the tumor, which usually intrigue the surgeon heretofore unfamiliar with these rare neoplasms.

The present study is based upon clinical and surgical experiences with two types of neurogenic tumors (a) schwannoblastoma (neurinoma) and (b) retroperitoneal sympathicoblastoma (neurocytoma).

SCHWANNOLASTOMA (NEURINOMA)

José Verocay was the first to describe these tumors and differentiate them from neuromas on histological grounds. He coined the term "neurinoma" in 1910. Verocay and Antoni were of the opinion that these tumors originated from the sheath of Schwann, or from the cellular ancestors of the sheath, designated by them as lemmoblasts.

The terminology of this type of tumor is varied and may be explained as follows: (a) gross diagnosis without histological verification, or inaccurate histological interpretation, (b) divergence of opinion among histopathologists and personal preference of terminology.

This accounts for such terms as schwannoblastoma, neurinoma, solitary neurofibroma, peripheral fibroblastoma, peripheral glioma, sarcoma, fibrosarcoma, fibromyxosarcoma, malignant leiomyoma. A more definite study of these neoplasms will tend to reduce the terminology to that most frequently used in medical literature, i.e., neurinoma and schwannoma, or schwannoblastoma.

From the Department of Surgery of Northwestern University Medical School and Cook County and Mt Sinai Hospitals, Chicago

Arthur Purdy Stout objects to the term neurinoma because it suggests nerve fiber tumor, when in reality the tumor originates from the sheath of Schwann. F H Vizetelly, editor of the *New Standard Dictionary*, prefers neurilenoma instead of neurinoma.

The scarcity of these neoplasms may be inferred by the absence of mention in collective reviews of benign neoplasms of the stomach. Balfour and Henderson, who reported 58 cases of benign tumors of the stomach from the Mayo Clinic, do not speak of schwannoma. Likewise, Eliason and Wright in a discussion of benign tumors of the stomach failed to mention this type of tumor.

Schwannoblastoma usually develops from the stomach wall, although it has been encountered in other tissues, such as appendix, extremities, upper respiratory organs, tongue, eye, and orbit. Schwannoma in the first portion of the duodenum was described by Lemonnier and Peycelon. Peretz reported a case of neurinoma of the appendix. Dyggve Petersen reported 20 cases of intrathoracic neurinomas, all occurring in women and shown by x-rays to be in the paravertebral area.

Etiologically, there is no definite accounting for the origin of these tumors. The factors which initiate these tumors and spur them on to growth are shared by the growth of tumors in general. However, some pertinent and highly suggestive observations have been made to the effect that nerve proliferation is frequently observed in inflamed gastric mucosa on the edge of an active or cicatrizing ulcer (Masson). Jentzer found small neurinomas in the callous portion surrounding small gastric ulcers. Okkels observed marked proliferation in the nerves of the gastric walls surrounding the ulcer margin, which he defines as neurinoma scar. Similar observations have been made by Askenazy in gastric ulcers, the wall of a previously inflamed appendix, or in chronic obliterative appendicitis. These proliferative processes may attain neoplastic proportions and, thus, may explain in some measure the neoplastic origin from a simple proliferative process.

Since most of these tumors originate in the myenteric plexus of Auerbach, it may not be amiss to review briefly the arrangement of the nerve plexuses of the stomach wall. There are in

painful swelling of the dorsum of the foot may occur. The plantar portion of the cast is left long to protect the toes.

This completes the cast, but the patient should remain in bed with the leg elevated for 24 hours. After this period if no abnormality is noticed it is safe to begin weight bearing, if there are signs of poor circulation to the toes the patient should remain in bed with the leg elevated until circulation is adequate, or if severe, the cast should be removed and reapplied when edema has subsided. If the cast and iron are properly applied on properly chosen cases in which the fracture can be accurately reduced there should never occur painful and dangerous pressure areas. If pressure pain does occur, however, the cast must be removed. Walking is sometimes not comfortable for the first 2 days until the patient has become accustomed to the apparatus. This accommodation occurs rapidly, especially in children and young adults and all are grateful to have a walking cast instead of having to hobble about on crutches since most of them go about their business with surprisingly little limitation of activity.

The cast if applied as here described is comparatively light. This walking iron weighs 14 ounces and the average total weight of cast and iron is $3\frac{1}{2}$ pounds when dry. Likewise with this type of apparatus the circumference of the leg is not greatly increased and therefore it is not cumbersome.

After having used various types of light padding we are completely satisfied that unpadded plaster properly applied is more comfortable and less dangerous to the patient when walking irons are to be used. Padding tends to wad up and wrinkle with consequent pressure areas and discomfort, and the fragments are more apt to slip out of position. In unpadded plaster there is practically no friction within the cast.

The removal of this skin tight plaster is not difficult. The hair on the leg changes about every 3 weeks so after this interval there is no pain on removal of the cast. Usually, if convenient we have the patient soak the cast in water for an hour or two after which it is easily cut off. The cast is usually not removed until the fracture is quite well healed because the walking on the fractured extremity is physiotherapy in itself. Muscle atrophy is minimal. In many cases the patient puts on a shoe and walks immediately after the plaster is removed with surprisingly little discomfort or swelling.

STIMMARY

A new type of walking iron, with flexible upright portions, a rigid stirrup and a swivel type crutch tip is described.

This walking iron is immediately incorporated in a wet plaster cast without the danger of causing pressure areas.

The technique of applying an unpadded plaster boot with this walking iron is described.

Fig 2 Sagittal section through stomach, tumor, and colon

all of the median epigastric masses or tumors, such as indurated pancreatitis, pancreatic cysts, also some of the more lateral masses, such as movable kidney, enlarged spleen, hydrops of the gall bladder, hydatid cysts of the liver, and retroperitoneal tumors

The indications for operation are the presence of a tumor mass, vague symptoms which do not come within the range of well defined gastro-intestinal clinical entities, with evidence of mechanical interference of function or the presence of hemorrhages

The removal of these tumors offers no difficulties. The tumor shells out well and the pedicle, often present, may be either ligated or sutured. If there is encroachment upon the lumen, a segment of the stomach may have to be removed and subsequently repaired

SUMMARY HISTORY OF CASE OF SCHWANNBLASTOMA

Mrs I G, age 46 years, was admitted to Cook County Hospital, Chicago, May 17, 1937, and discharged July 17, 1937.

For about one year patient complained of loss of appetite. She experienced a sense of fullness in the pelvis. She noticed an abdominal mass and an enlargement of the abdomen for about 1 year. She was free of gastro-intestinal symptoms except for occasional fullness after meals, no nausea or vomiting. She had a daily bowel movement. She had frequent urination but no pain. There was no loss of weight.

Examination revealed a slender woman in a state of fair general nutrition. Examination of the heart and lungs revealed nothing abnormal clinically. The abdomen was large and slightly tender to pressure, especially on the right side. There was an old operative scar in the middle line between the umbilicus and the symphysis pubis. A large

Fig 3 Relation of tumor to neighboring organs, before and after removal

mass, hard and fixed and filling the entire right half of the abdomen, could be readily palpated. There was a fluid wave present. Vaginal examination revealed a freely movable cervix, painless to movements. The fornices were free of masses or infiltration. Patient's menses ceased in 1933.

Patient had a gynecological laparotomy performed in 1934 at which time a 6 pound tumor had been removed. She states that at the time there was a great deal of fluid in the abdomen. She was never told what the nature of the tumor was.

X-ray investigation read as follows: moderate amount of opacity in the lower two-thirds of the abdomen. There is a scoliosis of the lower dorsal and upper lumbar spine. From the x-ray standpoint there was an extrinsic pelvic mass producing pressure defect on the pars pylorica of the stomach. There is also a rather constant irregularity of the lesser curvature of the stomach suggesting an intrinsic gastric lesion.

The clinical impression of the interne who wrote the history was ovarian tumor—probably Krukenberg tumor, ovarian cyst, gastro-intestinal malignancy.

Surgical exploration A large mass was found, the size of a large pumpkin, over which was plastered on the lower

Fig 1 Tumor mass as seen by artist at operation

the stomach and intestines two sets of nervous plexuses one is located in the submucous plexus (Meissner), the other between the annular and longitudinal muscular planes of the stomach with clusters of ganglion cells at nodal points (Auerbach) Schwannoblastoma originates in the myenteric plexus of Auerbach from the sheath of Schwann Since the nerve sheath has a dual origin ectodermal and mesodermal, the histological picture of schwannoma may be classified either as ectodermal (v. Recklinghausen) or mesodermal (Verocay) Penfield, in American literature, rejects the ectodermal origin

Schwannoma is usually a small tumor but may attain a large size if there is anatomical chance for expansion As a rule, it is single exceptionally multiple Occasionally, it is associated with multiple cutaneous fibromatosis (v. Recklinghausen's disease) Schwannoma has a preference for centrally located tissues whereas neurofibroma prefers the periphery Schwannoma often invades the spinal cord roots, especially the posterior It is often found in the root of the acoustic nerve, especially its peripheral branch (Henschen, Cushing) The tumor is well encapsulated and while it may displace other tissues it does not infiltrate It is soft on cut surface its color varying from brown to gray Here and there areas of cystic degeneration with colored fluid and cystic spaces brownish spots evidence of old hemorrhage Gastric schwannoma grows peripherally and if it encroaches upon the lumen of the stomach it does not as a rule ulcerate the gastric mucosa In Gosset's collection of 4 cases of gastric schwannoma, there was no involvement of the mucosa in

21 cases Some cases however ulcerate the mucosa and cause hemorrhages as it occurred in the case of Lemonnier and Peycelon In the case of Dupuy the neurinoma caused both ulceration of the mucosa and perforation of the gastric wall The tumor may be situated on the anterior wall either intramurally or subserous

Schwannoma is essentially a benign tumor It is well encapsulated and while it may recur *in situ* it does not as a rule become malignant or metastasize The tumor is often pedunculated grows slowly and does not impair the patient's health which explains its long latency

In the case of Paul Carnot there were metastases in the heart Kurt Denecke reported 2 cases of schwannoma from the Pathological Institute of the University of Freiburg one in the duodenum the other in the stomach both of which were malignant and metastasized in the liver

Clinically schwannoblastoma of the abdomen is characterized by a long period of latency and the presence of a mass in the upper abdomen located medially There is no pain or discomfort except if there is interference with neighboring organs by sheer pressure In Gosset's collection there were no gastro-intestinal symptoms in 27 cases However, in a number of cases the patients had gastro-intestinal symptoms which simulated gastric ulcer and in a few a penetrating ulcer In the intestines schwannoma is more apt to ulcerate and cause intestinal hemorrhages

The presence of a mass in mid epigastrium expressed in terms of gastric ulcer in association with v. Recklinghausen's disease is highly suggestive of schwannoblastoma

Antoni taking into account the histological pattern describes two types of schwannoblastoma

Type A (Antoni) *Fibrillary type* made up of long slender fibers either straight or undular regularly grouped cells with elongated nuclei arranged in palisades whorls, similar to those seen in meningiomas Type A is a neurofibrinous structure at the height of its development

Type B (Antoni) *Reticular type* made up of fibers and cells without orderly arrangement cysts and spaces filled with fluid Type B indicates retrogressive changes and degenerative phenomena and is a sort of jellyfication of Type A

Both types show unequal distribution of capillaries with evidence of dilatation thrombosis or hemorrhage

In addition to the diagnostic earmarks given x ray pictures may show a round shadow with a depressed area, suggesting a penetrating ulcer In the differential diagnosis one has to consider

Fig 5 Histological appearance of tumor, low power

Fig 6 Histological appearance of tumor, high power

from the ganglionic crest, which have not differentiated."

Symptomatology Sympathetic tumors may be silent for a long time and are often discovered quite accidentally in the course of a systematic physical examination. They give rise to clinical symptoms by interference with the function of neighboring organs with which they are in intimate contact. They may compress or infiltrate

neighboring veins, as it happened in our case, and may be the first clinical evidence of pelvic or abdominal compression by a tumor mass. Edema of one or both legs of unknown origin, and in the absence of thrombophlebitis, calls for a careful examination of the pelvis.

Diagnosis and differential diagnosis One has to differentiate these tumors from other intraperitoneal or retroperitoneal tumors. The simple

Fig 7 Lymph node with neoplastic infiltration

Fig 8 Histology of tumor embolus in right auricle

Fig 4 Schwannoblastoma. Histological appearance of segment of tumor

border and on the outer surface a segment of transverse colon in hot shoe fashion. The mass was lobulated and had very large tortuous veins on its surface. On further investigation it was disclosed that the mass was located in the gastrocolic omentum being attached rather firmly to the stomach wall at one point. In the attempt to free the mass from the surrounding structure there was a good deal of hemorrhage from the greatly distended veins. The gall bladder came close to the outer margin of the tumor but was not attached to it. The wall of the gall bladder was very thick. As a matter of fact the gall bladder was a solid mass (Fig 1).

Although the situation looked somewhat spectacular at first there was no difficulty in freeing the tumor except for the attachment to the stomach and the intimate connection of the colon which as described covered the lower and outer surface of the mass. It was necessary to remove a segment of the stomach to separate the tumor from it the gastric defect being closed in the usual manner. The colon could not be freed without obvious injury to its walls and blood supply. It was therefore divided a short distance beyond the tumor circumference after which an end-to-end anastomosis was made. A drain was placed in the upper abdomen which was closed in the usual manner (Figs 2 and 3).

The patient had a very stormy convalescence and at times seemed to be in a hopeless state. Yet with the assistance of numerous cardiac stimulants several blood transfusions and meticulous postoperative care on the

part of the internes the patient eventually made a fairly good recovery. During convalescence there was some drainage from the upper part of the wound which was due to colon bacillus infection. Wet dressings frequently applied cleared up the infection within a short time.

Pathological report. The specimen consists of a huge tumor mass previously located in the gastrocolic omentum to which was attached a portion of the transverse colon. The latter was markedly adherent to the mass which did not communicate with the lumen. However the muscularis was firmly adherent in places. The colon measured 18 centimeters in length. The tumor mass measured 12 by 10 by 17 centimeters in the greatest dimensions. On section it was found to be composed of light yellowish gray tissue mixed with purple red. The portion of the tumor mass which was attached to the large bowel was grayish white with a central liquefaction which was also filled with blood stained material.

Microscopical report. Section of the tumor with attached transverse colon revealed an intact mucosa, submucosa and muscularis. Attached to the serosa and intimately adherent to it was a large tumor mass composed of islands of elongated cells resembling epithelium with slightly irregular nuclei containing a granular chromatin. The cytoplasm was eosinophilic and granular. The cell borders were indistinct. These islands and cords of cells were separated from each other by a pinkish to bluish staining fibrillated and vacuolated substance. In the more dependent portion of the tumor away from the colon these cells were transformed into spindle and stellate forms with much intercellular fibrillary stroma. In this portion of the tumor mass only occasional islands of the previously described cells were seen. The capillaries were few, thin walled congested and in places surrounded by small focal hemorrhages (Fig 4).

Diagnosis. Schwannoblastoma, a tumor derived from the sheath of Schwann from its cells or nerve fibers. Histologically there is but slight evidence of malignancy chiefly in the form of mitotic figures.

SYMPATHICOBLASTOMA (NEUROCYTOMA)

Reid and Andrus define this type of tumor as a highly malignant tumor arising from undifferentiated cells of the primordium of the autonomic and chromaffin system.

It is stated that Kuester in 1905 was the first to recognize these neoplasms as being glial tissue and he, therefore, classified them as nervous structures. Kuester's histological studies revealed that the fine fibers did not stain red with van Gieson's stain but yellow and that the pattern of rosettes resembled those of glioma.

According to Herzheimer, who collected all cases up to 1914 the first case was described by G. Parker.

The nomenclature of these tumors varies according to the histological pattern and to the examiner's interpretation and preference. We therefore, encounter the following terminology: neurocytoma, sympathicoblastoma (Pick, Bielschowsky, Wright), ganglioma embryonale, sympathicum (Pick), sympathicogonioma (Herzheimer), Bailey and Cushing prefer the term sympathicoblastoma a tumor made up of wandering cells

Pick, on the basis of histological pattern, distinguishes two types (a) cellular (b) fibrocellular. In the first instance, the cells arrangement may be either diffuse or alveolar, in the second instance, one finds palisades.

Treatment I am as unfamiliar with the sensitivity of these tumors to x-rays or radium, as are radiologists and radium therapists. Surgeons will usually decide upon removal when the tumor is discovered. In my only experience with such neoplasms, I was stunned by the great tendency of the tumor to extensive hemorrhages at the slightest touch and the utter helplessness of controlling a massive hemorrhage, even though the tumor is well encapsulated and free from neighborhood attachments.

ABSTRACT OF CLINICAL HISTORY

M G, age 51 years, female, white, was admitted to hospital January 10, 1938, and died January 13, 1938.

The history revealed sudden onset of unilateral edema of the right leg of 6 weeks' duration. She had not noticed any change in temperature, color, pain, or local symptoms other than pitting edema. She was treated locally with slight improvement. One week prior to entrance a mass was found in the abdomen. The patient had not noticed this previously and had had no symptoms referable to the mass. The patient did not suffer from loss of weight, anorexia, or change in bowel habit. There were no gastrointestinal symptoms. She had a gradual decrease in frequency of menses for the past 2 years and at the present time they occurred every 4 to 6 months, with moderate flow. There was no intermenstrual bleeding. The remainder of the history was essentially negative.

Physical examination The head, neck, heart, and lungs, were negative. There were no adenopathies. The blood pressure was 150/84. The abdomen showed marked distention recti through which it was easy to palpate a large, firm, round mass, about the size of a large orange, in the right lower quadrant about the level of the ovary. It was somewhat fixed to deeper structures and not tender to touch. Vaginal and rectal examinations were not done. There was present pitting edema of the right leg to the thigh. There was no tenderness or temperature change. The blood count showed, hemoglobin, 90 per cent, red blood cells, 4,500,000, white blood cells, 7,600, polymorphonuclears, 63—band forms, 1, small lymphocytes, 38, monocytes, 2. The urine was negative.

On January 11, she was sent to x-ray department for a flat plate and barium enema.

On January 13, under general anesthesia a midline incision was made. A large retroperitoneal mass was found in the right lower quadrant. In attempting to remove it, massive hemorrhage was incurred. The patient's blood pressure dropped to systolic of 50 and the pulse was imperceptible. She was given stimulants, saline, gum acacia, and 500 cubic centimeters of whole blood. Three packs were inserted and the patient taken to room and put in oxygen tent. The pulse and blood pressure never picked up. Despite further shock therapy, the patient expired at 10 55 a m.

Summary of postmortem examination The clinical diagnosis was retroperitoneal neurocytoma, surgical shock.

Gross anatomical diagnosis—	Histological diagnosis
Right leg Edema	
Eyes, Conjunctival petechiae	
Peritoneal cavity Hemoperitoneum, status after laparotomy—old scar of abdomen	
Heart Eccentric hypertrophy	
Anemia	
Tumor embolus in right auricle	Sympathicoblastoma
Thrombus in vena cava inferior—	Sympathicoblastoma
Lungs Partial atelectasis of both lobes (left)	
Acute emphysema (right)	Atelectasis
Anemia	
Spleen Acute anemia	Acute passive congestion
Liver Acute anemia	
Kidneys Hydronephrosis (right)	Acute passive congestion
Ureters Compression of right ureter by tumor resulting in right hydronephrosis and hydronephrosis	Sympathicoblastoma
Uterus Multiple fibroids (intra-uterine and subserous) (one calcified)	
Cervical polyp	
Rectal polyp	Rectal polyp (benign)
Psoas muscle	Sympathicoblastoma
Lymph nodes	Sympathicoblastoma
Cause of death	
Acute anemia due to hemorrhage	
Tumor embolus in right auricle	
Retroperitoneal sympathicoblastoma originating at bifurcation of right common iliac artery, compressing the arteries, invading the veins	

Autopsy Microscopic examination of the sections of the lung tissue showed extensive atelectasis. In the liver sections were small accumulations of lymphocytes in the interacinar connective tissue. The yellow nodule in kidney was due to the presence of adrenal cortical tissue. No evidence of malignancy was found in the rectal polyp. A diffuse infiltration with tumor tissue of the same structure as seen in the primary tumor was noted in some of the lymph nodes. The other lymph nodes showed marked hyperplasia of the reticulo-endothelium and foci of calcification.

Sections of the tumor mass specimen show a very cellular growth with extensive hemorrhages. The cells show very scanty cytoplasm and medium size oval shaped nuclei with an abundant amount of chromatin that is finely distributed. Between the cells there are present fine, very indistinctly staining fibrils. The connective tissue stroma between the cell accumulations is not very abundant. The vascularization is very rich. The cells are arranged in very dense layers around the blood vessels. The structure is in every way identical with the structure reported in the retroperitoneal tumor removed at operation on January 13, 1938. The picture is that of a neurocytoma or sympathicoblastoma.

A thrombus was present in vena cava inferior. Sections of the psoas muscle show infiltration of muscle tissue with tumor tissue. An embolus in the heart was of identical structure with the structure of the tumor. Figure 8 illustrates the histology of a tumor embolus.

Pick, on the basis of histological pattern, distinguishes two types. (a) cellular (b) fibrocellular In the first instance, the cells arrangement may be either diffuse or alveolar, in the second instance, one finds palisades

Treatment I am as unfamiliar with the sensitivity of these tumors to x-rays or radium, as are radiologists and radium therapists. Surgeons will usually decide upon removal when the tumor is discovered. In my only experience with such neoplasms, I was stunned by the great tendency of the tumor to extensive hemorrhages at the slightest touch and the utter helplessness of controlling a massive hemorrhage, even though the tumor is well encapsulated and free from neighborhood attachments

ABSTRACT OF CLINICAL HISTORY

M G., age 51 years, female, white, was admitted to hospital January 10, 1938, and died January 13, 1938

The history revealed sudden onset of unilateral edema of the right leg of 6 weeks' duration. She had not noticed any change in temperature, color, pain, or local symptoms other than pitting edema. She was treated locally with slight improvement. One week prior to entrance a mass was found in the abdomen. The patient had not noticed this previously and had had no symptoms referable to the mass. The patient did not suffer from loss of weight, anorexia, or change in bowel habit. There were no gastrointestinal symptoms. She had a gradual decrease in frequency of menses for the past 2 years and at the present time they occurred every 4 to 6 months, with moderate flow. There was no intermenstrual bleeding. The remainder of the history was essentially negative.

Physical examination The head, neck, heart, and lungs, were negative. There were no adenopathies. The blood pressure was 150/84. The abdomen showed marked distention recti through which it was easy to palpate a large, firm, round mass, about the size of a large orange, in the right lower quadrant about the level of the ovary. It was somewhat fixed to deeper structures and not tender to touch. Vaginal and rectal examinations were not done. There was present pitting edema of the right leg to the thigh. There was no tenderness or temperature change. THE INJECTION TREATMENT OF HERNIA

H O. WERNICKE, M D , Chicago, Illinois

IN the last few years much has been written about the injection treatment of hernia. The glowing reports of complete cures of all types of hernia, even up to 100 per cent, have been very enthusiastic. This enthusiasm, unfortunately, has resulted in a wholesale onslaught on all kinds of hernias with various types of injection solutions. The indiscriminate use of these irritating solutions by those unskilled in the technique is apt to produce serious consequences. Hernias are being injected by hundreds of physicians who would not attempt surgical repair because of their lack of knowledge of the anatomy of the inguinal region and the surgical technique. Yet these same physicians will take chances on introducing a strong irritant into a human body with the hope that it will get into the proper place, and will not cause gangrene and perforation of a loop of bowel, followed by peritonitis and death. These accidents probably have occurred many times, with fatal results, but the literature records very few accidents of this type.

Berne has recently reported 2 deaths following the injection of the solution into the bowel wall with resulting gangrene, perforation, and peritonitis. Neither of these patients was injected by him. He mentions 2 others reported by Fowler. Berne also quotes Harris and White as having averaged 1 intraperitoneal injection in every 20 patients treated. But the literature, in most instances, minimizes the dangers of the injection treatment and leaves the impression that even the intraperitoneal injection of a proliferating solution is not of serious consequence. Berne's article is a timely and valuable contribution. Personal experience with complications in over two thousand injections has been quite meager. However, it might not have been if the very important precaution of always aspirating before injecting had been neglected. One patient had severe pain in the right pelvis a few minutes after an injection on the left side at the internal ring. The pain lasted about 15 minutes and was so severe that she could not lie still, rolling about on the table. Fortunately, she had no further trouble after leaving the clinic. Blood has been aspirated on 3 occasions when the needle was inserted at

the neck of the sac. The needle was withdrawn without injecting any solution, and there was no reaction. Edema of the cord is not infrequently seen, but it is not serious. Delayed pain has been complained of by a few who reported inability to work for 2 or 3 days after an injection. One abscess was encountered several days after an injection. It was incised and drained outside the hernia clinic. No culture was taken, and it is therefore unknown whether the content was sterile or infectious.

Berne rightly speaks of the greater danger of entering the peritoneal cavity when the needle is deeply introduced, and yet it appears necessary to make deep injections at the neck of the sac if the hernia is to be permanently obliterated. If the needle, while being introduced deep at the internal ring, suddenly meets with absolutely no resistance at all, and if aspiration reveals nothing, it must be suspected of having entered the peritoneal cavity and should be withdrawn to the point where resistance is encountered. This procedure will prevent injecting the irritant into the peritoneal cavity, and thereby remove the greatest danger connected with the treatment.

Bratrud mentions 2 cases seen in consultation in which the deep epigastric artery had been injected, with slough near the umbilicus. He also reports the case of a patient, treated elsewhere, who died as a result of intraperitoneal injection with perforation of the ileum and peritonitis. One of his own patients who was immediately operated upon because of severe abdominal pain following an injection showed no signs of peritonitis. All patients who experience severe abdominal pain after an injection, however, should be treated as potential peritonitis cases, and kept under observation until their symptoms have disappeared.

McKinney reported 2 strangulations due to the truss, one in a woman after fifteen injections, the other without injection. In consultation he also saw a patient who developed thrombosis or embolism of the anterior tibial artery with loss of a toe on the same side following an injection, and another who developed an abscess as a result of injection of the solution into a blood vessel of the spermatic cord. One of his patients had an abscess following injection for a recurrent hernia after appendectomy. These less serious accidents

From the Department of Surgery, University of Illinois College of Medicine, and the Hernia Clinic of Illinois Research and Educational Hospital.

Fig 1 A Transparent ruler with slide ring B The pad of the injection truss attached to the perineal band which in turn slides on the abdominal band for adjustment to right or left This pad covers internal ring and inguinal canal and does not press on symphysis C Test truss with moderately thin pad used in most cases It is 15 inches in diameter It is shown on the abdominal band of short stretch webbing D Test truss with thicker pad on perineal band for use in heavier subjects More pressure can be obtained with this pad when tightening the hernia

caused confinement of the patients in the hospital from a few days to a few weeks Another patient with symptoms of local peritonitis following injection for recurrent hernia was operated upon, and a small area of local peritonitis was found

Rice reported 12 instances in a series of 445 cured cases, of peritoneal irritation and 66 minor complications including local abscesses It is therefore obvious that the injection treatment of hernia is not devoid of serious and even dangerous complications and sequelae in the hands of skilled operators As Bratrud says There is a definite technique and unless this is learned great harm may result This cannot be too strongly emphasized

Although the literature has apparently been quite extensive and comprehensive it still appears advisable further to emphasize the fact that the injection treatment of hernia is not as simple as giving an ordinary hypodermic injection It would appear that the rules for the proper selection of cases have not been stated definitely enough for the guidance of those only occasionally using the method The indications for the injection treatment of hernia should be more specific and, as explained below, should be fewer Hernias which do not fulfill certain requirements should not be injected McKimney advises that 'the

small hernia in the young individual offers the ideal case for treatment by this method" Bratrud appears to be too inclusive when he makes the statement that "umbilical, indirect inguinal direct inguinal, and recurrent herniae give the best results," and in stating further that "laying aside the contra indications, it may be said that any inguinal hernia can be treated provided that it is reducible and can be held reduced by a properly fitting truss, and provided that there are no surgical contra indications" Wangenstein remarks that 'the selection of appropriate cases is extremely important The small reducible, indirect hernia in the young person with strong tissues seems most suitable for this method of treatment An anxiety to extend the method to cases that present large defects and poor tissues results in a large incidence of failures" However it still seems advisable to limit the indications for the selection of cases even more definitely When a hernia is a 'selected' one it should be one which is shown by experience to respond consistently to treatment In the author's opinion the injection treatment of hernia should be limited to the small indirect inguinal hernia which fulfills the indications to be described later Other types of hernia may, and occasionally do yield to treatment The indirect inguinal hernia should have a greater prospect of cure because of the length and anatomical characteristics of the canal If the canal can be obliterated the hernia can be cured In most other hernias the success of treatment depends on filling in or covering over the weak place in the abdominal wall with a layer of scar tissue Scar tissue is weak tissue and will become weaker as time progresses particularly as atrophy takes place A defect cannot be filled or covered with scar tissue strong enough to prevent herniation This is also the opinion of Crohn, and of Burdick and Coley

THE 'SELECTED CASE'

The selection of a hernia for injection treatment at the hernia clinic at the University of Illinois depends very definitely on the fulfillment of the following positive indications

- 1 Must be indirect inguinal
- 2 Must be completely reducible
- 3 Must be held reduced by test truss (see C and D Fig 1)
- 4 The external ring must be no larger than a nickel (2 centimeters in diameter)
- 5 The external oblique aponeurosis at the external ring must not be thinned out or shredded
- 6 The inguinal canal must be at least 1 inch in length

Fig 2 The anterior superior spine of the ileum and the spine of the pubis are marked with tincture of iodine. The slide ring is set on the transparent ruler half way between the two marks and iodine is applied within the circle. This locates the internal ring. This young man has no hernia on the side being marked, but was picked at random to demonstrate the method of locating the internal ring.

Fig 3 The skin over the internal ring is marked with tincture of iodine and ready for injection.

7 The patient must be in otherwise good health and of at least average co-operative mentality.

If these indications are observed there is no need of listing contra-indications, which have been voluminous. An epileptic might escape indication 7 unless a careful history is taken, obviously if the patient should have a convulsion during the injection a serious accident might be sustained. It is our opinion that only those hernias which fulfill the indications mentioned should be given the injection treatment. All others should be treated surgically or with a truss alone.

EQUIPMENT NEEDED

The syringe may be either the tuberculin or ordinary Luer type. The needle should be 22 gauge, an inch and a half in length, and with a bevel decidedly shorter than the standard short bevel. This allows more delicate feel in going through the various layers of fascia and muscle. The solution used in our clinic is the phenol-alcohol-thuya mixture. A transparent ruler with a sliding ring (A, Fig 1) has been of great convenience in determining the location of the internal ring. A "test truss" (C and D, Fig 1) is used in selecting each new case which has already fulfilled the other positive indications and thought to be suitable for the treatment. It consists of a firm pad an inch and a half in diameter, built on short stretch webbing, and can be adjusted to either right or left side. It is made with either of two pads (C and D as shown in the illustration), the thicker one being used in the heavier subjects. After the internal ring is marked with the aid of the slide ring and ruler the "test truss" pad is ad-

justed over it, the belt is tightened, and the perineal band is fastened. Then the patient tries to make the hernia descend by bearing down, coughing, and stooping. This test determines whether or not the case fulfills indication 3. The "injection truss," which is worn day and night by a patient receiving injections, is composed of two parts—an abdominal band of "short stretch" webbing and a perineal band of softer webbing which embraces the pad. The pad is attached in the front of a loop at one end of the perineal band. This loop slides on the abdominal band to allow adjustment of the pad to right or left, and is anchored to the abdominal band with needle and thread when the pad is properly placed over the internal ring. The type of pad on the "injection truss" is shown (B, Fig 1) in the illustration, attached to the perineal band. The abdominal band is an inch and a half wide. It is made of "short stretch" webbing which is so constructed that it will stretch only one inch to each foot of webbing. This is just enough to allow body freedom without allowing the pad to shift in position or relax in pressure. This truss has been found to be most satisfactory for those receiving the injection treatment because it stays in place at all times and in all positions, even when the patient lies on his back. No patient has yet complained that this truss, when properly fitted, has been uncomfortable. The "injection truss" is worn continuously for a week before injections are started, and must have held the hernia completely during all that time.

TECHNIQUE

The patient, lying flat on his back, removes his truss without straining. He is taught how to do this so that he may remove the truss for sponge baths to keep the skin and pad clean. The inguinal region is examined to make sure that the

Fig 1 A Transparent ruler with slide ring B The pad of the injection truss attached to the perineal band which in turn slides on the abdominal band for adjustment to right or left This pad covers internal ring, and inguinal canal and does not press on symphysis C Test truss with moderately thin pad used in most cases It is 1 5 inches in diameter It is shown on the abdominal band of short stretch webbing D Test truss with thicker pad on perineal band, for use in heavier subjects More pressure can be obtained with this pad when testing the hernia

caused confinement of the patients in the hospital from a few days to a few weeks Another patient with symptoms of local peritonitis following injection for recurrent hernia was operated upon and a small area of local peritonitis was found

Rice reported 12 instances in a series of 445 cured cases, of peritoneal irritation and 66 minor complications including 2 local abscesses It is therefore obvious that the injection treatment of hernia is not devoid of serious and even dangerous complications and sequelæ in the hands of skilled operators As Bratrud says, 'There is a definite technique and unless this is learned great harm may result This cannot be too strongly emphasized'

Although the literature has apparently been quite extensive and comprehensive it still appears advisable further to emphasize the fact that the injection treatment of hernia is not as simple as giving an ordinary hypodermic injection It would appear that the rules for the proper selection of cases have not been stated definitely enough for the guidance of those only occasionally using the method The indications for the injection treatment of hernia should be more specific and as explained below should be fewer Hernias which do not fulfill certain requirements should not be injected McKinney advises that 'the

small hernia in the young individual offers the ideal case for treatment by this method' Bratrud appears to be too inclusive when he makes the statement that "umbilical, indirect inguinal direct inguinal, and recurrent hernia give the best results," and in stating further that "laying aside the contra indications, it may be said that any inguinal hernia can be treated provided that it is reducible and can be held reduced by a properly fitting truss, and provided that there are no surgical contra indications' Wangenstein remarks that 'the selection of appropriate cases is extremely important The small reducible, indirect hernia in the young person with strong tissues seems most suitable for this method of treatment An anxiety to extend the method to cases that present large defects and poor tissues results in a large incidence of failures However it still seems advisable to limit the indications for the selection of cases even more definitely When a hernia is a "selected" one it should be one which is shown by experience to respond consistently to treatment In the author's opinion the injection treatment of hernia should be limited to the small indirect inguinal hernia which fulfills the indications to be described later Other types of hernia may, and occasionally do, yield to treatment The indirect inguinal hernia should have a greater prospect of cure because of the length and anatomical characteristics of the canal If the canal can be obliterated the hernia can be cured In most other hernias the success of treatment depends on filling in or covering over the weak place in the abdominal wall with a layer of scar tissue Scar tissue is weak tissue and will become weaker as time progresses particularly as atrophy takes place A defect cannot be filled or covered with scar tissue strong enough to prevent herniation This is also the opinion of Crohn and of Burdick and Coley

THE SELECTED CASE

The selection of a hernia for injection treatment at the hernia clinic at the University of Illinois depends very definitely on the fulfillment of the following positive indications

- 1 Must be indirect inguinal
- 2 Must be completely reducible
- 3 Must be held reduced by test truss (see C and D Fig 1)

4 The external ring must be no larger than a nickel (2 centimeters in diameter)

5 The external oblique aponeurosis at the external ring must not be thinned out or shredded

6 The inguinal canal must be at least 1 inch in length

Fig 5 At left, 2 weeks following injection of Solution II This solution has produced a dense scar of fibrous connective tissue, *c* Reactive vascular centers *v, v*, are seen throughout the scar already formed, with others in the surrounding subcutaneous fat, *f* At right, 4 months after injection of Solution II (thuja mixture) This scar tissue has persisted 4 months and is therefore twice as old as that described in Figure 4, right The fibrous connective tissue, *c*, shows beginning resorption with fat infiltration, *f* How-

ever, the connective tissue strands show considerably more viability and cellularity than those seen in Figure 4, right There is also evidence of continued reaction about the vascular centers, *v*, indicating that perhaps more scar will be formed Histologically one may conclude Solution II produces more lasting scar than Solution V Since duration of scar is of prime importance, Solution II should be considered the best of those solutions which were tested in this experiment

ward, and ending with the tenth dose one-half inch above the external ring The external ring is usually obliterated by this time and is rarely treated Ten injections are sufficient for most cases Some require 2 or 3 more But when 20 to 40 are necessary it would seem that the case had not been well selected and that operation should have been done

POST-INJECTION MANAGEMENT

One month after his last injection the patient returns for examination If all is well he removes his truss at night for the next month, wearing it only during the day If it is still holding satisfactorily at the end of this second month he is allowed to remove the truss entirely He is advised against only one thing—heavy lifting Otherwise he may pursue his regular and customary habits At the end of the next month, if there is no sign of hernia, he is allowed to go 2 months before being examined He is examined at intervals of 2 months until he has remained free from recurrence for one year after the truss has been discarded Then he is considered cured

RECURRENCE AND SCAR ABSORPTION

Every hernia carefully selected for the injection treatment is apparently cured at the time of the second month checkup following the last injection At this time the truss is discarded both day and night Four to 6 months later, a small percentage of these cases show a weakening at the site of the hernia, or even an actual recurrence It has been

noted that those cases which survived this period of potential recurrence remained cured This suggests that absorption of the scar tissue is the probable cause of recurrence Animal experiments confirm this suspicion Recurrent cases were given a complete new course of 10 treatments, usually with satisfactory results Those with merely a weakness in the inguinal region were given 2 to 4 additional injections

ANIMAL EXPERIMENTS

Six different solutions were used in the experiment The dogs were injected at 6 different places on the back and at one point in the rectus muscle with each solution No attempt was made to determine the immediate effects of the various solutions because this has been done by other investigators with conclusive evidence of their scar-producing effects Proof is not lacking that mature scar tissue is formed within 4 to 6 weeks after the solution has been injected But most workers have seemed to be satisfied with the knowledge that good scar tissue was formed within a given time without continuing the experiment far enough to determine how long the scar would last

Biopsies were made at periods of 2, 4, 6, and 8 weeks, and then at 3 and 4 months The results are shown in the summary of experimental work (Table I), and in the photomicrographs (Figs 4 and 5) In the first biopsies (2 weeks after injection treatment), Solution V had produced the best early scar tissue, but absorption began as

Fig. 4. Left 2 weeks following injection of Solution V as noted there is a deposition of dense scar tissue. The fatty subcutaneous tissue *f* is shown being replaced by fibrous connective tissue *c* which is being formed from the proliferation of round cells, histiocytes and fibroblasts arising

about the numerous vascular centers *v*. Right 8 weeks following injection of Solution V. The scar tissue is now hyaline in character, relatively acellular and broken up into thin strands. Fatty infiltration *f* is producing resorption of the scar.

hernia is being held by the truss. This is done before every injection as a precaution against injecting into a loop of bowel or other possible content of a hernial sac, and cannot be too strongly emphasized. The first injection is given deep at the internal ring. To make as accurate as possible the location of the internal ring is the function of the transparent ruler with slide ring, said ring being 1 centimeter above the edge of the ruler. The anterior iliac spine and the spine of the pubis are spotted with tincture of iodine. The distance between them is measured with the ruler, the slide ring adjusted half way between, and iodine is applied within the ring. This definitely marks the location of the internal ring (Figs. 2 and 3 illustrate the technique). The site of injection is prepared further with tincture of iodine, the syringe is loaded with the proper amount (8 minims) of solution plus a small amount of air for cleaning the needle at the end of the injection.

With the syringe held vertically the needle is inserted perpendicularly through the skin. The point then rests on the aponeurosis of the external oblique which offers firm resistance. The introduction of the needle through the aponeurosis requires enough pressure so that a distinct lack of resistance is felt as soon as the tip of the needle has penetrated it. The internal oblique and transversalis muscles must now be penetrated before the internal ring is reached. Here the sensation is less pronounced than when the needle passed through the aponeurosis and concentration is required to determine exactly the point at which these muscles have been penetrated and the transversalis fascia reached. It is at this location that the solution is to be deposited. But first—as a

precaution there should be at least slight resistance to the needle tip if the deep epigastric artery or peritoneal cavity have not been entered. The depth of the needle point at the neck of the sac is usually between an inch and an inch and a quarter. In very heavy subjects it is more. A minute amount of solution is injected slowly. If some of it enters the sac it may seep into the peritoneal cavity. This would cause severe pain in which case the needle should be withdrawn without injection of more solution. If there is no severe reaction after a few seconds the remainder of the solution is injected and the air in the syringe is forced through to clean the needle. This reduces the likelihood of dragging the irritant through the tissues when the needle is withdrawn and eliminates the formation of subcutaneous nodules. Theoretically a minute amount of the solution injected into the empty sac near its neck would produce sclerosis at the most desirable site but injecting the entire contents of the syringe at this point might cause intraperitoneal complications. If the patient should complain of abdominal pain during the first part of the injection no more of the solution should be injected at that time. Firm pressure with an alcohol sponge is maintained over the site of injection for about 30 seconds after removal of the needle. The patient replaces his truss without straining.

FREQUENCY AND NUMBER OF INJECTIONS

An injection is given once a week for 10 weeks. The first 6 are given deep at the internal ring. The last 4 are given along the inguinal canal just beneath the aponeurosis of the external oblique beginning over the internal ring proceeding down

OPERATIVE TREATMENT OF PES PLANUS

CHARLES S. YOUNG, M D , F A C S , Los Angeles, California

IN this paper the view will be held with others that the foot has but one arch which is a segment of a dome. Pes planus will be considered a severe pathological depression of this arch with eversion of the foot, abduction of the forefoot, and contracture of the muscles of the tendocalcaneus. Well known flatfoot operations, which have previously been described, are of three general types. They are first, arthrodesis of one or more of the intertarsal joints, second, tendon operations to modify the muscular forces which act on the foot, and third, wedge osteotomies of the tarsal bones. There may be a combination of these operations in one operative procedure.

Among the first type of operations, arthrodesis of the talonavicular joint by excision of the articular cartilage is the simplest. This procedure has a low degree of efficiency so that Soule modified it by inserting a bone peg through the navicular bone into the head of the talus. Hoke mortises a section of the cortex of the tibia between the adjoining surfaces of the navicular and first cuneiform bones after lengthening the tendocalcaneus. The arthrodesis includes the joint between the navicular and the second cuneiform bones. Miller performs an arthrodesis of the navicular-cuneiform and the first tarsometatarsal joints. In this operation he also transplants and shortens the tendon of the tibialis posterior muscle.

As an example of the tendon operations, plastic lengthening of the tendocalcaneus to relieve the contracture of its muscles as a deforming factor, is performed as part of nearly all flatfoot operations. However, lengthening of the tendocalcaneus and follow up exercises are not sufficient to expect improvement of the arch to any great extent.

Lowman combined arthrodesis of the talonavicular joint with redirection of the tibialis anterior tendon posterior to the navicular bone in the space between the latter and the talus. In this operation the insertion of the tibialis anterior was not detached. Later he modified the procedure by re-enforcing the ligaments on the medial side of the tarsus with a transplant from the tendocalcaneus or the plantaris tendon. Lord modified the Gleich (2) osteotomy of the calcaneus to overcome eversion and added various supplementary procedures as indicated. Clark per-

forms wedge osteotomies of the talus in two planes with base medial; a vertical one through the neck of the bone and the other to include the inferior surface.

The writer has endeavored to work out a simple technique which would raise the arch of the foot and balance the superimposed weight on its bones by postural tonus rather than by an arthrodesing operation or by wedge osteotomies.

TECHNIQUE OF OPERATION

A plastic lengthening of the tendocalcaneus is performed as a preliminary procedure so that the anterior end of the calcaneus can be elevated when the arch is raised. In the operation on the foot itself a slightly curved incision with convexity upward is made on its medial aspect from the shaft of the first metatarsal bone to the inferior extremity of the medial malleolus. The incision should pass superior to the medial aspect of the navicular bone. After the skin and superficial fascia are reflected, the larger branches of the medial tarsal artery in the region of the superior aspect of the navicular bone should be exposed under the deep fascia and ligated. The tendon of the tibialis posterior muscle is temporarily separated with a periosteal elevator from its attachment to the inferior surface of the navicular tuberosity. The medial one-half of the inferior surfaces of the navicular and first cuneiform bones are exposed in this dissection. A drill hole 6 or 7 millimeters in diameter is made vertically through the navicular bone lateral to the tuberosity from the superior to the inferior surface. The superior opening of the drill hole is made oval in shape with a gouge. A slot 2 millimeters wide is made with a high saw and very thin chisel from the drill hole to the posterior part of the medial surface of the navicular tuberosity. A small gouge is used to make a groove on the inferior surfaces of the first cuneiform and the navicular bones from the insertion of the tibialis anterior muscle to the drill hole at its inferior end. The sheath of the tibialis anterior tendon is exposed and incised in its distal 6 or 8 centimeters. After the tendon is freed down to its insertion, it is pulled posterior with a button hook and thrust through the slot in the navicular bone to a position in the drill hole and in the groove on the inferior surfaces of the navicular and first

early as the third biopsy at 6 weeks. It will be seen that the scar tissue produced by Solution II—the phenol alcohol thuya solution—was the most enduring, but that even that scar tissue was beginning to disappear after 3 and 4 months in spite of the fact that the material was still seen in the tissues in microscopical sections.

This absorption of scar tissue after 4 months seems to offer sufficient evidence to explain clinical failures which show up between 4 and 6 months.

SUMMARY AND CONCLUSIONS

The injection method of treating hernia is with us probably to stay. If it has merit in certain cases cannot be denied. Hundreds, if not thousands of physicians have adopted it. Many cures have been effected. It cannot supplant surgery as a better method in the majority of instances, but it has its place, which is in the treatment of small indirect inguinal hernias. Other hernias should be repaired surgically. In a series of cases carefully selected as previously described surgical repair would undoubtedly have a much lower incidence of recurrence than the injection method. This experiment would furnish a basis for comparison if in such a study one would pick out comparable cases from the series of patients treated by operation and by injection.

This method of treatment is not as simple and foolproof as the medical and pharmaceutical literature would lead one to believe. It is not without danger of serious complications even in experienced hands.

The ideal injection solution has not yet been developed. If the same dense progressive scar

tissue could be produced in the inguinal region that is produced in the lungs of silicosis cases the success of the injection treatment of selected hernias could probably be assured. An attempt to produce such a solution is now being made with various silica preparations.

The primary purpose of this report is to emphasize the necessity of following a strict technique and carefully selecting the hernias for treatment, injecting only those hernias which have a reasonable expectancy for cure lest the bad results following poor selection and ill advised injection treatment lead the method into disrepute.

The author is indebted to Mr L. J. Rossiter for his assistance in the preparation and interpretation of the microscopical slides.

OPERATIVE TREATMENT OF PES PLANUS

CHARLES S. YOUNG, M D , F A C S , Los Angeles, California

IN this paper the view will be held with others that the foot has but one arch which is a segment of a dome. Pes planus will be considered a severe pathological depression of this arch with eversion of the foot, abduction of the forefoot, and contracture of the muscles of the tendocalcaneus. Well known flatfoot operations, which have previously been described, are of three general types. They are first, arthrodesis of one or more of the intertarsal joints, second, tendon operations to modify the muscular forces which act on the foot; and third, wedge osteotomies of the tarsal bones. There may be a combination of these operations in one operative procedure.

Among the first type of operations, arthrodesis of the talonavicular joint by excision of the articular cartilage is the simplest. This procedure has a low degree of efficiency so that Soule modified it by inserting a bone peg through the navicular bone into the head of the talus. Hoke mortises a section of the cortex of the tibia between the adjoining surfaces of the navicular and first cuneiform bones after lengthening the tendocalcaneus. The arthrodesis includes the joint between the navicular and the second cuneiform bones. Miller performs an arthrodesis of the navicular-cuneiform and the first tarsometatarsal joints. In this operation he also transplants and shortens the tendon of the tibialis posterior muscle.

As an example of the tendon operations, plastic lengthening of the tendocalcaneus to relieve the contracture of its muscles as a deforming factor, is performed as part of nearly all flatfoot operations. However, lengthening of the tendocalcaneus and follow up exercises are not sufficient to expect improvement of the arch to any great extent.

Lowman combined arthrodesis of the talonavicular joint with redirection of the tibialis anterior tendon posterior to the navicular bone in the space between the latter and the talus. In this operation the insertion of the tibialis anterior was not detached. Later he modified the procedure by re-enforcing the ligaments on the medial side of the tarsus with a transplant from the tendocalcaneus or the plantaris tendon. Lord modified the Gleich (2) osteotomy of the calcaneus to overcome eversion and added various supplementary procedures as indicated. Clark per-

forms wedge osteotomies of the talus in two planes with base medial; a vertical one through the neck of the bone and the other to include the inferior surface.

The writer has endeavored to work out a simple technique which would raise the arch of the foot and balance the superimposed weight on its bones by postural tonus rather than by an arthrodesing operation or by wedge osteotomies.

TECHNIQUE OF OPERATION

A plastic lengthening of the tendocalcaneus is performed as a preliminary procedure so that the anterior end of the calcaneus can be elevated when the arch is raised. In the operation on the foot itself a slightly curved incision with convexity upward is made on its medial aspect from the shaft of the first metatarsal bone to the inferior extremity of the medial malleolus. The incision should pass superior to the medial aspect of the navicular bone. After the skin and superficial fascia are reflected, the larger branches of the medial tarsal artery in the region of the superior aspect of the navicular bone should be exposed under the deep fascia and ligated. The tendon of the tibialis posterior muscle is temporarily separated with a periosteal elevator from its attachment to the inferior surface of the navicular tuberosity. The medial one-half of the inferior surfaces of the navicular and first cuneiform bones are exposed in this dissection. A drill hole 6 or 7 millimeters in diameter is made vertically through the navicular bone lateral to the tuberosity from the superior to the inferior surface. The superior opening of the drill hole is made oval in shape with a gouge. A slot 2 millimeters wide is made with a high saw and very thin chisel from the drill hole to the posterior part of the medial surface of the navicular tuberosity. A small gouge is used to make a groove on the inferior surfaces of the first cuneiform and the navicular bones from the insertion of the tibialis anterior muscle to the drill hole at its inferior end. The sheath of the tibialis anterior tendon is exposed and incised in its distal 6 or 8 centimeters. After the tendon is freed down to its insertion, it is pulled posterior with a button hook and thrust through the slot in the navicular bone to a position in the drill hole and in the groove on the inferior surfaces of the navicular and first

Fig 4 Case 3 Seven months after operation

Fig 5 Case 5 Pre operative lateral view of right foot

Fig 6 Case 5 Four months after operation

of flexion. The sutures are removed through a window in the cast 2 weeks after operation. The cast is removed 7 or 8 weeks after the operation to allow firm healing of the tendocalcaneus. Obviously the operation on the foot itself would require immobilization only a short time after the incision has healed. It is important for the patient to be taught correct foot posture and gait. When walking is started the lateral side of the heel of the shoe should be lowered one-eighth to one-fourth inch, to prevent eversion strain for 6 months. Resistive exercises should be practiced daily in this interval to develop the tibialis anterior and tibialis posterior muscles.

This operation has been performed on six adolescent patients and one adult with satisfactory raising of the arch and correction of the eversion and abduction of the forefoot in each case. There has also been symptomatic relief in all cases. Originally it was thought that the procedure would be useful only in adolescents. Therefore in the pes planus of the adult the operation was performed on the right foot only with a heel cord lengthening on the left leg. The result of the flatfoot operation has been so satisfactory that operation on the left foot will be done.

One patient aged 11 years was a mulatto. As a school boy he complained of aching in his feet while standing and walking, and therefore sat on a bench while other boys played. Conservative treatment did not seem to offer much improvement in such a severe case and therefore the operation was performed, although criticism was expected for surgical treatment of a flatfoot in one of the colored race. However, the result was sufficiently good to justify the operation.

In this group of cases there were no wound infections. However, a hematoma developed in one case and the cause was traced to an injury of the branches of the medial tarsal artery during the exposure of the navicular bone. This is the reason for ligating the artery during the exposure. The first patient had more postoperative pain than the others because the sheath of the tibialis anterior tendon was not incised far enough in a proximal direction to free the tendon. This caused painful tension on the soft parts to which the tendon sheath was attached.

EFFECT OF OPERATION

This operation raises the arch of the foot by adding the power of the tibialis anterior muscle to that of the tibialis posterior near the point of primary insertion of the latter on the navicular bone. The tension on the tendon of the tibialis anterior from the position of its insertion, to the

inferior opening of the drill hole in the navicular bone, makes it act as a ligament in that part of its changed course. It re-enforces the first medial tarsometatarsal ligament and the plantar navicular cuneiform ligament and in that way helps prevent depression of the arch and abduction of the forefoot. The physiological effect of the operation is to so balance the muscle power of the foot that the weight of the body is sustained by the bones of the arch. Postural tonus of the muscles is all that is required to maintain this balance.

This operation should not be applied until after the age of 10 years because prior to that age ossification has not progressed sufficiently in the tarsal navicular bone. If performed before the navicular bone is ossified it is necessary to use a mattress suture of heavy chromic catgut to bind the two surfaces of the slot in the bone together.

When there is a contracture or spasm of the peroneal muscles, it will be necessary to perform a tenotomy or lengthen their tendons. It is obvious that this operation does not apply in most cases of rigid pes planus in which there are arthritic changes in the intertarsal joints.

CONCLUSIONS

1. Pes planus, not responding to conservative treatment, requires operative correction.
2. The arch may be raised by lengthening the tendocalcaneus and by changing the course of the tendon of the tibialis anterior muscle through a drill hole in the navicular bone to assist the tibialis posterior muscle.
3. The plantar navicular cuneiform and medial first tarsometatarsal ligaments are re-enforced by this procedure.
4. This operation changes the muscular forces which act on the foot, so that the superimposed weight is balanced on the bones of the arch by postural tonus.

of flexion. The sutures are removed through a window in the cast 2 weeks after operation. The cast is removed 7 or 8 weeks after the operation to allow firm healing of the tendocalcaneus. Obviously the operation on the foot itself would require immobilization only a short time after the incision has healed. It is important for the patient to be taught correct foot posture and gait. When walking is started the lateral side of the heel of the shoe should be lowered one-eighth to one-fourth inch, to prevent eversion strain for 6 months. Resistive exercises should be practiced daily in this interval to develop the tibialis anterior and tibialis posterior muscles.

This operation has been performed on six adolescent patients and one adult with satisfactory raising of the arch and correction of the eversion and abduction of the forefoot in each case. There has also been symptomatic relief in all cases. Originally it was thought that the procedure would be useful only in adolescents. Therefore in the pes planus of the adult the operation was performed on the right foot only with a heel cord lengthening on the left leg. The result of the flatfoot operation has been so satisfactory that operation on the left foot will be done.

One patient aged 11 years was a mulatto. As a school boy he complained of aching in his feet while standing and walking, and therefore sat on a bench while other boys played. Conservative treatment did not seem to offer much improvement in such a severe case and therefore the operation was performed, although criticism was expected for surgical treatment of a flatfoot in one of the colored race. However, the result was sufficiently good to justify the operation.

In this group of cases there were no wound infections. However, a hematoma developed in one case and the cause was traced to an injury of the branches of the medial tarsal artery during the exposure of the navicular bone. This is the reason for ligating the artery during the exposure. The first patient had more postoperative pain than the others because the sheath of the tibialis anterior tendon was not incised far enough in a proximal direction to free the tendon. This caused painful tension on the soft parts to which the tendon sheath was attached.

EFFECT OF OPERATION

This operation raises the arch of the foot by adding the power of the tibialis anterior muscle to that of the tibialis posterior near the point of primary insertion of the latter on the navicular bone. The tension on the tendon of the tibialis anterior from the position of its insertion, to the

inferior opening of the drill hole in the navicular bone, makes it act as a ligament in that part of its changed course. It re-enforces the first medial tarsometatarsal ligament and the plantar navicular cuneiform ligament and in that way helps prevent depression of the arch and abduction of the forefoot. The physiological effect of the operation is to so balance the muscle power of the foot that the weight of the body is sustained by the bones of the arch. Postural tonus of the muscles is all that is required to maintain this balance.

This operation should not be applied until after the age of 10 years because prior to that age ossification has not progressed sufficiently in the tarsal navicular bone. If performed before the navicular bone is ossified it is necessary to use a mattress suture of heavy chromic catgut to bind the two surfaces of the slot in the bone together.

When there is a contracture or spasm of the peroneal muscles, it will be necessary to perform a tenotomy or lengthen their tendons. It is obvious that this operation does not apply in most cases of rigid pes planus in which there are arthritic changes in the intertarsal joints.

CONCLUSIONS

1. Pes planus, not responding to conservative treatment, requires operative correction.
2. The arch may be raised by lengthening the tendocalcaneus and by changing the course of the tendon of the tibialis anterior muscle through a drill hole in the navicular bone to assist the tibialis posterior muscle.
3. The plantar navicular cuneiform and medial first tarsometatarsal ligaments are re-enforced by this procedure.
4. This operation changes the muscular forces which act on the foot, so that the superimposed weight is balanced on the bones of the arch by postural tonus.

universally successful in many cases. Even in those rarer unfortunate cases in which the infection has been bilateral, an uneventful clinical course followed the removal of both submaxillary salivary glands. RALPH COLP

DISRUPTION OF WOUNDS AND POSTOPERATIVE HERNIA ARE PREVENTABLE

ONE of the requisites for a good surgeon is still sound anatomical knowledge. I may be wrong in my opinion that there is a growing tendency to drift away from the old school idea of the necessity for a profound anatomical training as a stepping stone to good surgery. Twenty years ago an article entitled "Anatomical Approach to the Long Bones" was published in one of our leading surgical journals. Though an apparently uninteresting subject it immediately attracted wide attention. It said that "the average general surgeon knows the anatomy of the abdomen but so rarely operates upon the extremities that he has forgotten the anatomy of these regions." This was near the truth, but I question the statement to the effect that surgeons know the anatomy of the abdominal wall, or possibly they know the anatomy but at least they do not respect it if one can judge from the complications and sequelæ of abdominal operations which can be traced to unanatomical abdominal incisions.

One is impressed by the modern surgeon's knowledge of the anatomy and function of the abdominal viscera and the skillful and extensive operations performed upon them, at the same time one is amazed at the complete disregard of the abdominal wall in making an approaching incision. The success of the skillfully done operation is often marred by disruption of the wound or a postoperative hernia. In an effort to eliminate these complica-

tions there has been expended by the profession no lack of effort and discussion directed to the repair of the abdominal wound irrespective of structures damaged, with the result that suture material has been condemned and a different technique in closure proposed.

From a study of the records of 9,000 consecutive abdominal incisions for disruption and hernia¹ it is quite evident that those incisions planned upon anatomical lines can be depended upon and should be preferred. It is general knowledge that the wounds which cause so much dissatisfaction are the vertical upper abdominal incisions, and still they continue to be made and continue to result in hernias and disruptions. The hernias result in disability and repeated operations and the disruptions have a mortality of 35 per cent. The surgeon who would be horrified by seeing the quadriceps muscle or the Achilles tendon cut across their fibers does not hesitate to cut the posterior sheath of the rectus muscle across its fibers without realizing that this structure is the tendinous continuation of the internal oblique and transversus muscle. The suturing of tendons elsewhere may result in end-to-end union if their corresponding muscles are put at rest in a relaxed position. But since the lateral abdominal muscles are respiratory muscles they cannot be put at rest, and if vomiting or coughing occur tremendous strain is thrown upon the sutured tendons which must give way in spite of any suture technique which may be used. Due to the action of these muscles the tension upon the upper abdominal wall is in a transverse direction. If the posterior sheath is split transversely in the direction of its fibers, even across the linea alba, the wall is not weakened. If the rectus muscle is retracted and preserved, as in the Sloan incision, the structures do not tend to separate, and disruptions and postoperative

TREATMENT OF DEEP INFECTIONS OF SUBMAXILLARY TRIANGLE

INFECTIONS of the cellular tissues of the floor of the mouth deep to the submaxillary salivary gland, incorrectly called Ludwig's angina present a grave surgical condition in which energetic and radical treatment is essential. These patients as a rule are extremely ill. They are suffering not only from a profound toxemia of a virulent spreading cellulitis but also from the disastrous mechanical effects of an edematous submaxillary salivary gland pressing against the lateral pharyngeal wall and indirectly against the larynx. The diagnosis presents no difficulties. The skin over the submaxillary region while edematous and brawny, is rarely reddened. The swelling is stony hard and fluctuation is seldom obtained because the submaxillary salivary gland with its closely adherent superficial leaflet of the deep cervical fascia presents a dense unyielding barrier to the deep suppuration which is present. The mouth is par-

tially opened with great difficulty. Forced movement of the protruded tongue, which is elevated and partially fixed is painful. Examination of the mucous membrane of the floor of the mouth reveals that it is brawny, indurated, edematous and tender.

There is no doubt that a number of these deep infections which are mild in character subside spontaneously under conservative treatment, but if the clinical condition of the patient is not improved within 24 hours immediate surgery is indicated.

If the published mortality of 40 per cent in this type of case is to be definitely lowered either the local buccal incisions, or the median one extending from the under surface of the chin to the hyoid bone must be discontinued. These incisions neither insure immediate and free drainage of the infected area nor stop the progress of the infection. This can be accomplished only by the extirpation of the submaxillary salivary gland under local anesthesia.

This gland automatically blocks the free drainage of the cellular tissues of the sublingual, the submaxillary and the retromandibular spaces. Following its removal with the division of the mylohyoid muscle at right angle to its fiber, the resultant cavity is loosely packed. After operation the change is dramatic. There is immediate definite improvement which is progressive. The patient feels distinctly better, swallowing becomes easier and dyspnea invariably disappears. The floor of the mouth soon loses its inflamed appearance.

Removal of the submaxillary salivary gland in infections of the floor of the mouth has been used routinely since 1922 and has been found

universally successful in many cases. Even in those rarer unfortunate cases in which the infection has been bilateral, an uneventful clinical course followed the removal of both submaxillary salivary glands. RALPH COLP.

DISRUPTION OF WOUNDS AND POSTOPERATIVE HERNIA ARE PREVENTABLE

ONE of the requisites for a good surgeon is still sound anatomical knowledge. I may be wrong in my opinion that there is a growing tendency to drift away from the old school idea of the necessity for a profound anatomical training as a stepping stone to good surgery. Twenty years ago an article entitled "Anatomical Approach to the Long Bones" was published in one of our leading surgical journals. Though an apparently uninteresting subject it immediately attracted wide attention. It said that "the average general surgeon knows the anatomy of the abdomen but so rarely operates upon the extremities that he has forgotten the anatomy of these regions." This was near the truth, but I question the statement to the effect that surgeons know the anatomy of the abdominal wall, or possibly they know the anatomy but at least they do not respect it if one can judge from the complications and sequelæ of abdominal operations which can be traced to unanatomical abdominal incisions.

One is impressed by the modern surgeon's knowledge of the anatomy and function of the abdominal viscera and the skillful and extensive operations performed upon them, at the same time one is amazed at the complete disregard of the abdominal wall in making an approaching incision. The success of the skillfully done operation is often marred by disruption of the wound or a postoperative hernia. In an effort to eliminate these complica-

tions there has been expended by the profession no lack of effort and discussion directed to the repair of the abdominal wound irrespective of structures damaged, with the result that suture material has been condemned and a different technique in closure proposed.

From a study of the records of 9,000 consecutive abdominal incisions for disruption and hernia¹ it is quite evident that those incisions planned upon anatomical lines can be depended upon and should be preferred. It is general knowledge that the wounds which cause so much dissatisfaction are the vertical upper abdominal incisions, and still they continue to be made and continue to result in hernias and disruptions. The hernias result in disability and repeated operations and the disruptions have a mortality of 35 per cent. The surgeon who would be horrified by seeing the quadriceps muscle or the Achilles tendon cut across their fibers does not hesitate to cut the posterior sheath of the rectus muscle across its fibers without realizing that this structure is the tendinous continuation of the internal oblique and transversus muscle. The suturing of tendons elsewhere may result in end-to-end union if their corresponding muscles are put at rest in a relaxed position. But since the lateral abdominal muscles are respiratory muscles they cannot be put at rest, and if vomiting or coughing occur tremendous strain is thrown upon the sutured tendons which must give way in spite of any suture technique which may be used. Due to the action of these muscles the tension upon the upper abdominal wall is in a transverse direction. If the posterior sheath is split transversely in the direction of its fibers, even across the linea alba, the wall is not weakened. If the rectus muscle is retracted and preserved, as in the Sloan incision, the structures do not tend to separate, and disruptions and postoperative

hernia do not occur. The fact that during a period of 10 years preservation of the posterior rectus sheath has resulted in no defective wounds as compared to an experience of 5 per cent disruptions and 6 per cent abdominal hernias when the usual upper abdominal vertical incision in which the posterior sheath was cut across its fibers, gives us the authority to condemn the unanatomical vertical incision. As previously stated "Disruption of wounds and postoperative hernia in the upper

abdomen with the distressing consequences can be almost, if not completely, eliminated by the use of carefully made anatomical incisions. As a rule, busy surgeons are impatient to reach the diseased organ and resent the extra time and attention necessary to make anatomical incisions but the ease of closure, the feeling of security in regard to the wound and the added comfort of the patient more than compensates for the extra effort."

ALBERT O. SINGLETON

THE SURGEON'S LIBRARY

REVIEWS OF NEW BOOKS

THE *Compleat Pediatrician*¹ by Davison is a second and completely rewritten edition of a book which appeared first in 1934 and which was received with enthusiasm by pediatricians and men in general practice throughout the country. The author has made use of a unique method of presenting the subject. In his preface he states that the book was compiled with its emphasis on symptoms and signs as clues rather than on description, in the hope that it would be of value from a practical point of view.

The book is divided into 13 chapters. Symptoms and diseases are discussed in the first 7 chapters divided on the basis of the anatomical system chiefly involved and arranged in the order of their frequency. The first chapter, for example, is devoted to the "Respiratory Group" because in pediatric practice the largest incidence of disease is in this group.

These 7 chapters are followed by a very complete chapter on "Laboratory and Other Procedures Frequently Used in Pediatrics," a chapter on "Nutritional Requirements, Feeding and Diets," and chapters on "General, Fluid, Oxygen and Physical Therapy, and Pediatric Nursing," "Growth, Development and General Care of Children," "Physical Examination," and "Drugs and Prescriptions." In the front of the book immediately following the preface the author gives instructions for the proper use of the book. These instructions are necessary because use of the text would be difficult without knowledge of the meaning of all the reference numbers so freely used.

The book is designed to be a quick reference book for the practitioner, the student, and the teacher of pediatrics, and one that can be carried easily and be available when needed for purposes of diagnosis, therapy, and general information. It is a book that fills a very definite need in pediatrics and the present edition is a great improvement over the first.

A. H. PARMELEE

IN a compendium of 95 pages entitled *Maternal Care Complications*,² the American Committee on Maternal Welfare, Inc., has presented the essential facts relative to the 3 major causes of maternal mortality, viz. toxemias of pregnancy, obstetric hemor-

rhages, and puerperal infection. The importance of prenatal care, the early recognition of toxic symptoms, and the institution of proper therapy are stressed under the toxemias. Under hemorrhages, the causes, early and late, are outlined and the type of treatment indicated in each condition is suggested. The prophylactic phase in the treatment of puerperal infection is naturally stressed.

There is little in this manual that cannot be found in any standard textbook of obstetrics, however, its brief, simple method of presenting these subjects will make it valuable as a quick ready reference for the practitioner when he is confronted with the problem of managing any of the above mentioned complications. The widespread distribution of this book would be of great value to the practitioner.

CHESTER C. DOHERTY

HELLNER'S recent monograph, *Die Knochengeschwulste*,¹ is the fruit of a ten year study of the bone tumors at the Surgical Clinic in Muenster. In 200 pages he discusses the tumors that involve the skeletal system under 4 general divisions. Approximately one-half the book is devoted to benign and malignant tumors of osseous origin. Then benign and malignant tumors of non-osseous origin that arise in close association with bones, such as those arising from the vascular system and marrow elements, are taken into consideration. The third major division is devoted to those tumors that derive their origin from the soft parts, mucous membranes, and fistulas and secondarily invade the bones. The so called periosteal fibrosarcoma is placed in that category. The last section is allocated to the various metastatic tumors of bone. The subject matter is presented from the clinical, roentgenological, and pathological points of view.

Hellner makes a plea for the standardization of the nomenclature of bone tumors. The author emphasizes the fact that diagnosis of bone tumors rests upon the correlation of the clinical observations, the roentgenological studies, and the pathological examination of the tissues. Tribute is paid to the Registry of Bone Sarcoma of the American College of Surgeons for its important contributions. The photographs, photographic reproductions of x-ray films, and photomicrographs with which the text is extensively illustrated are excellent. A comprehensive bibliography is appended. The book can be recommended as a concise review of the present knowledge of bone tumors.

PRELIMINARY PROGRAM FOR 1939 CLINICAL CONGRESS

THE surgeons of Philadelphia, under the leadership of strong and representative committees, are planning to present a program of operative clinics and demonstrations for the twenty-ninth annual Clinical Congress of the American College of Surgeons that will cover all phases of the clinical activities of this great medical center. During the five days, October 16-20, the clinicians at the five medical schools and more than 40 participating hospitals will demonstrate to their guests the latest advances in surgical technique and operative procedures. A preliminary schedule of the operative clinics and demonstrations at the hospitals and medical schools appears in the following pages. The program will be revised and amplified during the months preceding the Congress. Clinics will be held on the afternoon of Monday, October 16, and the mornings and afternoons of each of the following four days.

In addition to the ample and well-arranged schedule of operative clinics at which the technique of a wide variety of surgical procedures will be demonstrated in the operating rooms, the committee has arranged a series of non-operative clinics in many of the large hospitals for the presentation of important work being done in many special fields. There will be demonstrations and exhibits covering general surgery, genito-urinary surgery, neurosurgery, fractures and traumatic surgery, obstetrics and gynecology, broncho-esophagology, plastic and faciomaxillary surgery, surgery of the bones and joints, thoracic surgery, ophthalmology and otorhinolaryngology. These programs are being so correlated that the visiting surgeon may be assured of the opportunity to devote his time continuously, if he so desires, to clinics dealing with the special subject in which he may be most interested. The final program will be pub-

lished and classified according to the various specialties in order to aid the visiting surgeon in the selection of the clinics which he desires to attend. A complete detailed clinical program will be posted in the form of bulletins at headquarters each afternoon for the succeeding day and published in printed form for distribution each morning.

The annual meeting of the governors and fellows of the College will be held in the Rose Garden of the Bellevue-Stratford Hotel on Thursday afternoon at 1:30 o'clock. Reports on activities of the College will be presented by the officers and chairmen of the standing committees.

The attention of fellows is called to the meetings of three important state and provincial committees to be held on Wednesday in the Palm Garden on the first floor of the hotel as follows: Judiciary committees, 9:30 a.m.; Credentials committees, 10 a.m.; Executive committees, 11 a.m.

The showing of surgical motion picture films which so faithfully depict clinical features of major interest to surgeons will be continued at this year's Congress. It is planned to present an enlarged program of both sound and silent pictures at daily exhibits in the Palm Garden of the headquarters hotel.

OBSTETRICAL DIFFICULTIES AFTER
INFANTILE PARALYSIS

An investigation of the obstetrical difficulties in patients who have had infantile paralysis is under way at the Hospital for Joint Diseases, 123d Street and Madison Avenue, in New York City. This study is being pursued under a grant from the National Foundation for Infantile Paralysis.

For a proper evaluation it is essential that as many cases as possible be obtained for study and it is necessary therefore for the investigators to contact a large number of physicians throughout the country.

Dr. Samuel Kleinberg and M. T. Horwitz at the above mentioned address would appreciate hearing from any physician who has a knowledge of any cases of this type.

be conducted an administrative panel round table discussion in which an effort will be made to cover as many aspects of hospital administration as possible with particular emphasis on maintenance of high professional standards, current economic problems and trends, and other timely subjects.

A special feature of the hospital conference will be a meeting of hospital executives on Tuesday evening when the program will deal with the future of the voluntary hospital, training of hospital administrators, etc.

At a joint session with the Association of Record Librarians of North America the subject of medical records will be considered from the standpoints of the various specialties of medicine and surgery.

There will be ample opportunity during the Congress for the visitors to inspect the hospitals in Philadelphia and vicinity.

ADVANCE REGISTRATION

The hospitals and medical schools of the Philadelphia area afford accommodations for large numbers of visiting surgeons, but to insure against overcrowding, attendance at the Congress will be limited to the number that can be comfortably accommodated at the clinics. The limit of attendance will be based upon the results of a survey of the operating rooms and laboratories of the hospitals and medical schools to determine their capacity for visitors. It is expected, therefore, that those surgeons who wish to attend the Congress will register in advance. A registration fee will be required in order to provide funds with which to meet the expenses of the Congress. A formal receipt will be issued to each surgeon registering in advance which is to be exchanged for a general admission card upon his registration at headquarters during the Congress. This card, which is not transferable, must be presented in order to secure clinic tickets and admission to scientific sessions.

A resolution adopted by the Board of Regents provides that the registration fee for fellows and endorsed junior candidates shall be \$5 00, that no fee for the 1939 Congress shall be required of initiates (class of 1939), that the fee for non-fellows attending as invited guests of the College will be \$10 00.

As in previous years, admission to clinics and demonstrations at the hospitals will be controlled by means of clinic tickets, which plan provides an efficient means for the distribution of visiting

surgeons at the various clinics and assures against overcrowding. The number of tickets issued for any clinic will be limited to the capacity of the room in which the presentation is held.

HEADQUARTERS—TECHNICAL EXHIBITION

Headquarters for the Congress will be established at the Bellevue-Stratford Hotel where there are unusual facilities for accommodating the Congress. The Grand Ballroom, Garden, Clover and Red rooms and other large rooms on the first and second floors and the roof have been reserved for scientific exhibits and conferences, registration, clinic ticket bureaus, bulletin boards, executive offices, etc. Thus, the activities of the Congress will be centralized under one roof.

The technical exhibition will be located in the Ballroom and adjacent rooms on the second floor. The registration and clinic ticket bureaus, together with the registration desk, will be centrally located on that floor. The bulletin boards, on which the daily clinical programs will be posted each afternoon, will be distributed through the exhibit rooms. Leading manufacturers of surgical instruments and supplies, x-ray equipment, operating room lights, hospital apparatus of all kinds, ligatures, dressings, pharmaceuticals, and publishers of medical books will be represented in the exhibition.

PHILADELPHIA HOTELS AND THEIR RATES

In addition to the headquarters hotel, the Bellevue-Stratford, there are many first-class hotels within a short walking distance, providing ample hotel facilities at reasonable rates. It is suggested that reservation of hotel accommodations be made at an early date at the following hotels which are recommended by the committee:

	Minimum rate with bath	
	Single	Double
Adelphia, 13th and Chestnut Sts	\$3 85	\$5 50
Barclay, Rittenhouse Square, E	4 50	7 00
Bellevue-Stratford, Broad and Walnut Sts	3 85	5 50
Benjamin Franklin, 9th and Chestnut Sts	3 85	5 50
Colonial, 11th and Spruce Sts	2 50	3 85
Drake, 1512 Spruce St	4 00	6 00
Majestic, Broad St and Girard Ave	2 50	4 00
Philadelphian, 39th and Chestnut Sts	2 75	4 40
Ritz Carlton, Broad and Walnut Sts	3 50	6 00
Robert Morris, 17th and Arch Sts	2 50	3 50
Spruce, 13th and Spruce Sts	1 50	2 50
St James, 13th and Walnut Sts	2 75	4 50
Sylvania, Juniper and Locust Sts.	3 00	5 00
Walton, Broad and Locust Sts	2 50	4 00
Warwick, 17th and Locust Sts	4 50	7 00
Wellington, 19th and Walnut Sts	4 00	6 00

SCIENTIFIC SESSIONS

The scientific sessions will include certain new features introduced at the Congress in recent years which have met with *des red succès*. The schedule of midday panel discussions has been greatly extended in order that a larger number of the visiting surgeons may have an opportunity to participate.

On Monday the initiates will assemble in the Palm Garden at 11 a m in order that the officials of the College may meet them and explain in some detail the aims and objectives of the program of the College. At this same session, the fellowship roll will be signed by the initiates. In the evening, the Presidential Meeting and Convocation will be combined and at this time the new officers inaugurated and the initiates received into fellowship. Dr Howard C Naffziger, of San Francisco, will deliver the preidential address and distinguished surgeons from foreign countries will be introduced.

Scientific meetings will be held in Irvine Hall of the University of Pennsylvania on Tuesday Wednesday and Thursday evenings in which medical men will co operate with the surgeons in presenting various phases of the interesting subjects which have been selected for presentation.

As in former years, afternoon symposia have been arranged on the subjects of cancer, fractures and traumatic surgery urology, obstetrics and gynecology and thoracic surgery. A special feature of the program includes a series of clinical demonstrations to be held at headquarters each morning for those visitors interested in the subjects of ophthalmology and otorhinolaryngology. The subcommittees in charge of these special arrangements are also planning extensive programs of operative clinics in surgery of the eye ear, nose and throat to be held in the hospitals each afternoon. Programs for special evening sessions of these groups are being prepared for Tuesday and Thursday evenings.

The midday panel discussions have become of such major interest as a feature of the Congress that the series for this year's meeting will include 13 such sessions. The program will permit the formal and informal discussion of subjects in more restricted fields than would be susceptible of treatment in the general meetings. Attendance at these conferences will necessarily be restricted to the capacity of the rooms in which they will be held. Outstanding authorities have co-operated with the College in the presentation of each one of the selected subjects and will lead direct and participate in these discussions. The general plan to be followed is that the leader will present the

subject to be discussed within a ten minute period and selected men will discuss various phases of these topics briefly after which general discussion from the floor will be encouraged.

The program committee has aimed to include a selection of material at these various scientific meetings which will make it possible for all of the general surgeons and surgical specialists attending the Congress to learn of the newer developments in their respective specialities.

GRADUATE TRAINING FOR SURGERY

Following the annual meeting of the fellows scheduled for Thursday afternoon, there will be a conference on graduate training for surgery at 3 00 p m. Raising the standards of surgery has been a primary purpose of the American College of Surgeons since its organization. This will be accomplished through the present program of the College which has stimulated added interest in this subject on the part of all its fellows and a large number of approved hospitals. The College Committee on Graduate Training for Surgery will present its report of activities for the year through its chairman Dr Dallas B. Phenix, of Chicago. Also at this time, the list of hospitals approved for graduate training for surgery in the United States and Canada will be announced. Leaders in the field of graduate medical education will present and discuss at length the various phases and problems of organization and conduct of graduate training for surgery. This is of such vital interest to the entire fellowship of the College and many practical suggestions will be offered for developing the needed systematic supervision, preceptorship and guided instruction for young surgeons.

HOSPITAL CONFERENCES

The twenty first annual Hospital Standardization Conference will open the Clinical Congress with a session in the Rose Garden at the Bellevue Stratford Hotel on Monday morning at 10 o'clock. Official announcement of the approved list of hospitals for 1939 will be made at this session.

On Monday afternoon and on Tuesday Wednesday and Thursday, both mornings and evenings, an interesting program of papers round table conferences and practical demonstrations, all dealing with various problems related to efficiency in the hospital will be presented. For Wednesday and Thursday afternoons at certain local hospitals there are planned demonstrations in administrative and technical procedures which will be of great interest to the hospital visitors. At the hospital conference on Tuesday afternoon there will

SUBJECT INDEX TO VOLUME 68

- ABDOMEN**, surgical aspects of neurogenic tumors of, 1085
- Abnormalities**, Anatomical and surgical features of ectopic kidney, 37, Modern surgical treatment of ureterocele, 611, Accessory renal vessels, their influence in certain cases of hydronephrosis, 666
- Abscess**, pulmonary, Medical treatment of bronchiectasis, 327, Acute putrid, of lung, III Roentgenographic features, 687
- Acetylcholine**, Use of drugs in surgery, ed 121
- Acid**, mandelic, Pyelonephritis and its treatment, 534
- Across Editorial Desk**, 252, 964
- Allergy**, Ocular manifestations of, 406
- American College of Surgeons**—
Address of retiring president, American College of Surgeons in retrospect and prospect on its 25th anniversary, 419
- Bone tumors**, Review of classification of, 971
- Cancer**, Symposium on, 435-471
- Clinical Congress**, Transactions 1938, New York, 257-594, Comments on 1938 meeting, 429, Plans for 1939, in Philadelphia, 977, Preliminary program, Philadelphia, 1939, 1107
- Committee on Arrangements**, Executive committees, Hospital representatives, 593
- Conference on traumatic surgery**, 579-592
- Fracture Committee**, Report on symposium on metallic fixation in fractures, 576
- Fracture Symposium**, 549-578
- Graduate training for surgery**, and the surgical specialties, 433
- Hospital standardization conference**, Twenty-first annual, 431
- Obstetrics and Gynecology**, Symposium on, 472-498
- Oration on surgery**, Our college mandate, tribute to Allen B. Kanavel, 424
- Report of symposium on metallic fixation in fractures**, 576
- Surgery on handicapped patient**, Symposium, 499-526
- Technical exhibition**, Clinical Congress, 594
- Urologic infections**, Symposium on, 527-548
- Amputation**, Cineplastic amputation, 554, Experiments concerning ligation and refrigeration in relation to local intoxication and infection, 1047
- Analeptics**, Studies of, I Coramine, 892
- Anemia**, Prevention of maternal and infant, 869
- Anesthesia**, Use of metycaine for producing block, of sacral nerves, 222, Experimental traumatic shock, further studies with particular reference to rôle of nervous system, 278, Surgical procedures in presence of diabetes mellitus, 508, Intravenous, ed 719, spinal, Use of neosynephrine in, 1021, Analysis of immediate postoperative complications in 2000 cases of inguinal hernia, 1052
- Anesthetics**, Factors determining selection and administration of, 519
- Anatomy**, Disruption of wounds and postoperative hernia are preventable, ed 1103
- Anus**, Rôle of tuberculosis in anal fistula, 191
- Arm**, Cineplastic amputation, 554, upper, Unusual lesions of muscles and tendons of shoulder girdle and, 903
- Arrhenoblastoma**, 767
- Arthritis deformans**, Aseptic necrosis of bone, I Infarction of bones in caisson disease resulting in encapsulated and calcified areas in diaphyses and in, 129, II Infarction of bones of undetermined etiology resulting in encapsulated and calcified areas in diaphyses and in, 631
- Arthroplasty**, development of, Study and end-result report of 70 cases, and reconstruction operations on hip joint, 106
- Atropine**, Use of drugs in surgery, ed 121
- Auxins**, Studies on growth stimulating effect of potassium naphthalene acetate and potassium indole butyrate, 63
- BACILLUS coli peritonitis**, Treatment of, in rabbits with escherichia coli antiserum, 34
- Bacteriology**, Bacteriological study of peritoneal fluid in perforated peptic ulcers, 1017
- Barbiturates**, Intravenous anesthesia, ed 719
- Bartholin's gland**, Carcinoma of, report of case of squamous cell epithelioma, 952
- Bedside manner**, Psychiatrist in relation to surgery, 372
- Bile ducts**, Early surgery in biliary disease, 167, Benign strictures of, with description of new method of treatment, 288
- Biopsy**, Endometrial, ed 249, Early diagnosis of cervical carcinoma, 147
- Bladder**, Sympathectomy for relief of vesical spasm and pain resulting from intractable bladder infection, 540; Obstructive uropathies, 546, Modern surgical treatment of ureterocele, 611
- Blood**, Fluid balance in puerperium, 17, Surgical problems in jaundiced patients, 499, Factors determining selection and administration of anesthetics, 519, Prevention of maternal and infant anemia, 869, Phosphatase determination in differential diagnosis of bone lesions, 1038
- Blood iodine**, levels related to recurrence of hyperthyroidism, 744
- Blood pressure**, Use of neosynephrine in spinal anesthesia, 1021
- Blood transfusion**, New and safer method of citrated, 940
- Blood vessels**, Study of superficial venous pattern in pregnancy and non-pregnant women by infra-red photography, 54, Anatomy of pelvic and urogenital diaphragms, in relation to urethrocele and cystocele, 161, Surgical procedures in presence of diabetes mellitus, 508; Aseptic necrosis of bone, II Infarction of bones of undetermined etiology resulting in encapsulated and calcified areas in diaphyses and in arthritis deformans, 631, Accessory renal vessels, their influence in certain cases of hydronephrosis, 666, anomalous, Conservative surgical treatment of non-calculous hydronephrosis, 832
- Bloodgood**, Joseph C, 965
- Bone**, Primary reticulum cell sarcoma of, 45, sarcoma, factors influencing prognosis, 67, Aseptic necrosis of, I Infarction of, in caisson disease resulting in encapsulated and calcified areas in diaphyses and in arthritis deformans, 129, Conservative treatment of fractures, 549, Fractures of, of face, 564; Aseptic necrosis of, II Infarction of, of undetermined etiology resulting in encapsulated and calcified areas in diaphyses and in arthritis deformans, 631; Fibroma of middle metacarpal, resection and reconstruction, 936, Review of classification of, tumors, 971, Present status of chronic osteomyelitis, 1007; lesions, Phosphatase determination in differential diagnosis of, 1038
- Bone repair**, Influence of vitamin D upon, healing of fractures of rachitic bones, 878

ANDREW KNOX—2 Operative and dry clinics

ST CHRISTOPHER'S HOSPITAL

J B FELDMAN—2 Squint clinic

ST LUKE'S AND CHILDREN'S HOSPITAL

F C PETERS S H BROWN and staff—9 Operations

TEMPLE UNIVERSITY HOSPITAL

WALTER I LILLIE and staff—1 Operative and dry clinics

WILLS HOSPITAL

J M GRIGCOM F C PARKER and T A O'BRIEN—2 Operative and dry clinics

WOMEN'S HOMOPATHIC HOSPITAL

J R. CRISWELL and C J V FRIES—2 Operative and dry clinic

- Fascia, strips of in hernia repair, Follow-up of hernia repair, 238
- Fascia sutures, Use of living sutures of external oblique aponeurosis in repair of inguinal hernias in adults, 113
- Fat, necrosis—granuloma of breast, 230
- Feet, infected, Surgical procedures in presence of diabetes mellitus, 508
- Female, Certain aspects of so called sterility in, 489
- Femur, Fractures of neck of, open operation and pathologic observations, new incision and new director for use of simplified flange, 87, Pauwels' reclinaton, physiological reconstruction for non-united fractures of neck of, 648, Fractures of neck of, treated with Smith-Petersen nail, analysis of 78 cases during 1937, 713
- Fibromyoma, Operative management of, in uterus at term, 699
- Fingers, Contractures due to burns, 352, Burn contractures of hand, 1066
- Finger tips, Immediate full thickness grafts to, 925
- Fistula, anal, Rôle of tuberculosis in, 191
- Flat foot, Operative treatment of pes planus, 1099
- Fluid balance, in puerperium, 17; Experimental traumatic shock, further studies with particular reference to rôle of nervous system, 278, Study of, and sodium chloride balance in patients treated with continuous suction applied to indwelling duodenal tubes, 751
- Foot, Squamous cell carcinoma of extremities, 1002, Operative treatment of pes planus, 1099
- Fossa, ischiorectal, Anatomy of pelvic and urogenital diaphragms, in relation to urethrocele and cystocele, 161
- Fractures, of neck of femur, open operation and pathologic observations, new incision and new director for use of simplified flange, 87, Supracondylar, fracture of humerus, analysis of 330 cases, 201, Evolution of, treatment, 362, Conservative treatment of, 549, of bones of face, 564, Double pin skeletal fixation in, of leg, 573, Pauwels' reclinaton, physiological reconstruction for non-united, of neck of femur, 648, Report on symposium on metallic fixation in, 576, Influence of vitamin D upon bone repair, healing of fractures of rachitic bones, 878, Immediate treatment of compound injuries, ed 961, Walking iron for immediate use on wet plaster casts, 1082
- Francis Amory septennial prize, of American Academy of Arts and Sciences, cor 970
- G**ALL bladder, Acute inflammation of, plea for conservative operation, ed 120, Early surgery in biliary disease, 167, Surgical problems in jaundiced patients, 499
- Gastro-enterostomy, Jejunoplasty, for obstruction following, or subtotal gastric resection, 703
- Gastro-intestinal tract, Surgical procedures in presence of diabetes mellitus, 508
- Glove pedicle graft, Burn contractures of hand, 1066
- Gonorrhea, Tubal resection as treatment for recurrent gonorrheal salpingitis, 810
- Graafian follicle, Intraperitoneal hemorrhage from ruptured ovarian retention cysts, corpus luteum and, cysts, 824
- Graduate training, for surgery and surgical specialties, 433, On medical education, ed. 718
- Grafts, Fate of living and dead cartilage transplanted in humans, 603, full thickness, Immediate, to finger tips 925, Wolfe, pedicle, split, glove pedicle, Burn contractures of hand, 1066
- Growth, Studies on, stimulating effect of potassium naphthalene acetate and potassium indole butyrate, 63
- H**ANDS, Purposeful splinting following injuries of, 1, Contractures due to burns, 352, Fibroma of middle metacarpal bone, resection and reconstruction, 936, Burn contractures of, 1066
- Harvey, William, op 129
- Headaches, Ocular manifestations of allergy, 406
- Hearing, Study of medical and surgical aids to, 395
- Heart, in pregnancy, Fluid balance in puerperium, 17, Medical aspects in pre-operative and postoperative care of diabetic and cardiac patients, 503, Surgical treatment of chronic constrictive pericarditis, 979
- Heart disease, Study of superficial venous pattern in pregnant and non-pregnant women by infra-red photography, 54
- Hematoma, subdural, Diagnosis and therapy of so called posttraumatic neurosis following craniocerebral injuries, 587
- Hemorrhage, Intraperitoneal, from ruptured ovarian retention cysts, corpus luteum and graafian follicle cysts, 824
- Hernia, Use of living sutures of external oblique aponeurosis in repair of inguinal, in adults, 113, Follow-up of, repair, 238, Herniation through diaphragm, 257, inguinal, Analysis of immediate postoperative complications in 2000 cases of, 1052, Injection treatment of, 1093, postoperative, Disruption of wounds and, are preventable, ed 1103
- Hip joint, Study and end-result report of 70 arthroplasties and reconstruction operations on, 106
- Hodgkin's disease, Primary reticulum cell sarcoma of bone, 45
- Hormones, Evaluation of intradermal test for pregnancy, 187, Evaluation of ovarian sterilization for breast cancer, 452, Estrogenic, and carcinogenesis, 472
- Humerus, Supracondylar fracture of, analysis of 330 cases, 201
- Hydatidiform mole, and chorio-epithelioma, ed 844
- Hydrocele testis, Improved, radical technique for repair of, 236
- Hydronephrosis, Conservative surgical treatment of non-calculous, 832
- Hyperthyroidism, Recurrent, report of 306 cases operated upon from 1928 to 1937, 347, Blood iodine levels related to recurrence of, 744
- I**LEITIS, Regional, 314
- Ileum, Surgery for ulcerative colitis, 306, Regional ileitis, 314
- Incisions, Disruption of wounds and postoperative hernia are preventable, ed 1103
- Industrial medicine, 579-592
- Infants, Prevention of maternal and, anemia, 869, Technical notes on hypertrophic pyloric stenosis, 1074
- Infection, Experiments concerning ligation and refrigeration in relation to local intoxication and, 1047, Treatment of deep, of submaxillary triangle, ed 1102
- Infra-red photography, Study of superficial venous pattern in pregnant and non-pregnant women by, 54
- Injection treatment, of hernia, 1093
- Injuries, compound, Immediate treatment of, ed 961
- Instruments and apparatus, Purposeful splinting following injuries of hand, 1, flange and director, Fractures of neck of femur, open operation and pathologic observations, new incision and new director for use of simplified flange, 87, intestinal anastomosis clamps, Technique of anastomosis using Stone clamp, 95, Wangenstein suction drainage, Modified, 118, Wollner conization, Early diagnosis of cervical carcinoma, 147, Morley gastrectomy clamp, Modified Schoemaker gastrectomy for chronic gastric ulcer, 197, Singer postural

- Brain Diagnosis and therapy of so called posttraumatic neurosis following craniocerebral injuries 587 Intra cranial solitary chondroma 677 Surgical treatment of spastic paralysis 792 Parasagittal meningiomas operative technique suggested for exposure 957
- Breast Fat necrosis—granuloma of breast 230 Evaluation of ovarian sterilization for breast cancer 452 Multiple primary malignant lesions 595 Technique of mammoplasty in conditions of hypertrophy of, 638
- Bronchi Medical treatment of bronchiectasis 327
- Bronchiectasis Medical treatment of 327
- Bunnell safety pin splint Purposeful splinting following injuries of hand 1
- Burns Studies on growth stimulating effect of potassium naphthalene acetate and potassium indole butyrate 93 Contractures due to 352 contractures of hand 1066

CAISSON disease Aseptic necrosis of bone II Infarction of bones of undetermined etiology resulting in encapsulated and calcified areas in diaphyses and in arthritis deformans 631

- Calculus renal Nephropathy ed 960
- Cancer surgery of gastric Cancer of stomach 295 Evaluation of ovarian sterilization for breast 452 Estrogenic hormones and carcinogenesis, 472
- Carcinogenesis Estrogenic hormones and 472
- Carcinoma Surgical treatment of of larynx 462 X-ray treatment of inoperable of larynx 467 Multiple primary malignant lesions 595 recurrence Cervical stump 868 Squamous cell of extremities 1002
- Carcinoma cell Mural penetration of in colon anatomic and clinical study 872
- Care Psychiatrist in relation to surgery 372, pre-operative and postoperative Medical aspects in of diabetic and cardiac patients 593 Surgical procedures in presence of diabetes mellitus 568 Immediate treatment of compound injuries ed 961
- Carpal scaphoid Acute fractures of 820
- Cartilage Fate of living and dead transplanted in humans 603
- Cataract Ocular manifestations of allergy 406
- Catgut Follow up of hernia repair 238
- Childbirth My experience with Melhado maneuver for persistent posterior position 495
- Children Primary streptococcus and pneumococcus peritonitis in children Study of 61 cases with report of 2 interesting recoveries 60
- Chloralose Experimental traumatic shock further studies with particular reference to rôle of nervous system 278
- Chondroma Intracranial solitary 677
- Chorio-angioma Consideration of certain types of benign tumors of placenta 733
- Chorio-epithelioma Hydatidiform mole and ed 844
- Classification Review of of bone tumors, 971
- Colitis surgery for ulcerative colitis 306 Multiple primary malignant lesions 595 Mural penetration of carcinoma cell in anatomic and clinical study 872 Extraperitoneal implantation of one stage resection for carcinoma 1077 surgical aspects of neurogenic tumors of abdomen 1085
- Compressed air disease Aseptic necrosis of bone I Infarction of bones in caisson disease resulting in encapsulated and calcified areas in diaphyses and in arthritis deformans 129
- Conjugate Diagonal versus x ray pelvimetry 642
- Continuous suction Study of fluid and sodium chloride balance in patients treated with applied to indwelling duodenal tubes 751
- Contractures due to burns 352

- Cooper Samuel op 723
- Coramine Studies of analeptics 892
- Cornea Ocular manifestation of allergy 406
- Corpus luteum Intraperitoneal hemorrhage from ruptured ovarian retention cysts and graafian follicle cysts 824

- DACRYOCYSTITIS** Present status of surgery of lacrimal sac 414
- Davis Loyal Editor appointed ed 120
- Deafness, Study of medical and surgical aids to hearing 303
- Decompression of intestinal tract ed 842
- Dermatitis Methods of investigation of occupational skin diseases 583
- Dermigrast 930
- Diabetes Medical aspects in pre-operative and postoperative care of diabetic and cardiac patients 593 Surgical procedures in presence of melitus 568
- Diagnosis differential Present status of chronic osteomyelitis 1007 Phosphatase determination in, of bone lesions 1035
- Diaphragm pelvis and urogenital Anatomy of in relation to urethrocele and cystocele 161 Herniation through 237 Diaphragmatic injury complicating nephrectomy method of closure 932
- Disease, caisson Aseptic necrosis of bone I Infarction of bones in resulting in encapsulated and calcified areas in diaphyses and in arthritis deformans 129
- Drugs Use of in surgery ed 121 Factors determining selection and administration of anesthetics 510
- Duodenal tubes Study of fluid and sodium chloride balance in patients treated with continuous suction applied to indwelling 751 Experiences with employment of suction in treatment of acute intestinal obstruction reiteration of indications contra indications and limitations of method 851
- Dysmenorrhea Excision of superior hypogastric plexus (presacral nerve) for primary dysmenorrhea 723

EAR Treatment of otitic meningitis due to streptococcal infection by surgery and sulfanilamide 377 Study of medical and surgical aids to hearing, 395 Ilyogenetic development of 401

- Education On medical ed 718
- Elbow Supracondylar fracture of humerus analysis of 330 cases 201
- Embryology Ilyogenetic development of ear 401
- Emmenis Certain aspects of so called sterility in female 489
- Emotions Psychiatrist in relation to surgery 372
- Endocrines Ocular manifestations of allergy 406
- Endometrium Endometrial biopsy ed 249
- Enteritis Regional 322
- Ependymoma Encapsulated intramedullary tumor in involving the whole spinal cord from medulla to conus complete enucleation with recovery 814
- Ephedrine Use of neosynephrine in spinal anaesthesia 1021
- Escherichia coli antiserum Treatment of colon bacillus peritonitis in rabbits with 34
- Eserine Use of drugs in surgery ed 121
- Esophagus Herniation through diaphragm 237
- Estrin Evaluation of ovarian sterilization for breast cancer 452
- Extremities Squamous cell carcinoma of 1002
- Eye Ocular manifestations of allergy 406

FACE Fractures of bones of 564

Fallopian tubes Tubal resection as treatment for recurrent gonorrheal salpingitis 810

Famous painting Hugh Owen Thomas, op 1 William Harvey op 129 Samuel Cooper op 723

Fascia, strips of in hernia repair, Follow-up of hernia repair, 238
 Fascia sutures, Use of living sutures of external oblique aponeurosis in repair of inguinal hernias in adults, 113
 Fat, necrosis—granuloma of breast, 230
 Feet, infected, Surgical procedures in presence of diabetes mellitus, 508
 Female, Certain aspects of so called sterility in, 489
 Femur, Fractures of neck of, open operation and pathologic observations, new incision and new director for use of simplified flange, 87, Pauwels' retraction, physiological reconstruction for non-united fractures of neck of, 648, Fractures of neck of, treated with Smith-Petersen nail, analysis of 78 cases during 1937, 713
 Fibromyoma, Operative management of, in uterus at term, 699
 Fingers, Contractures due to burns, 352, Burn contractures of hand, 1066
 Finger tips, Immediate full thickness grafts to, 925
 Fistula, anal, Role of tuberculosis in, 191
 Flat foot, Operative treatment of pes planus, 1099
 Fluid balance, in puerperium, 17, Experimental traumatic shock, further studies with particular reference to rôle of nervous system, 278, Study of, and sodium chloride balance in patients treated with continuous suction applied to indwelling duodenal tubes, 751
 Foot, Squamous cell carcinoma of extremities, 1002, Operative treatment of pes planus, 1099
 Fossa, ischio-rectal, Anatomy of pelvic and urogenital diaphragms, in relation to urethrocele and cystocele, 161
 Fractures, of neck of femur, open operation and pathologic observations, new incision and new director for use of simplified flange, 87, Supracondylar, fracture of humerus, analysis of 330 cases, 201, Evolution of, treatment, 362, Conservative treatment of, 549, of bones of face, 564, Double pin skeletal fixation in, of leg, 573, Pauwels' retraction, physiological reconstruction for non-united, of neck of femur, 648, Report on symposium on metallic fixation in, 576, Influence of vitamin D upon bone repair, healing of fractures of rachitic bones, 878, Immediate treatment of compound injuries, ed 961, Walking iron for immediate use on wet plaster casts, 1082
 Francis Amory septennial prize, of American Academy of Arts and Sciences, cor 970

GALL bladder, Acute inflammation of, plea for conservative operation, ed 120, Early surgery in biliary disease, 167, Surgical problems in jaundiced patients, 499
 Gastro-enterostomy, Jejunoplasty, for obstruction following, or subtotal gastric resection, 703
 Gastro-intestinal tract, Surgical procedures in presence of diabetes mellitus, 508
 Glove pedicle graft, Burn contractures of hand, 1066
 Gonorrhea, Tubal resection as treatment for recurrent gonorrheal salpingitis, 810
 Graafian follicle, Intrapertoneal hemorrhage from ruptured ovarian retention cysts, corpus luteum and, cysts, 824
 Graduate training, for surgery and surgical specialties, 433, On medical education, ed 718
 Grafts, Fate of living and dead cartilage transplanted in humans, 603, full thickness, Immediate, to finger tips 925, Wolfe, pedicle, split, glove pedicle, Burn contractures of hand, 1066
 Growth, Studies on, stimulating effect of potassium naphthalene acetate and potassium indole butyrate, 63

HANDS, Purposeful splinting following injuries of, 1, Contractures due to burns, 352; Fibroma of middle metacarpal bone, resection and reconstruction, 936, Burn contractures of, 1066
 Harvey, William, op 129
 Headaches, Ocular manifestations of allergy, 406
 Hearing, Study of medical and surgical aids to, 395
 Heart, in pregnancy, Fluid balance in puerperium, 17, Medical aspects in pre-operative and postoperative care of diabetic and cardiac patients, 503, Surgical treatment of chronic constrictive pericarditis, 979
 Heart disease, Study of superficial venous pattern in pregnant and non-pregnant women by infra-red photography, 54
 Hematoma, subdural, Diagnosis and therapy of so called posttraumatic neurosis following craniocerebral injuries, 587
 Hemorrhage, Intrapertoneal, from ruptured ovarian retention cysts, corpus luteum and graafian follicle cysts, 824
 Hernia, Use of living sutures of external oblique aponeurosis in repair of inguinal, in adults, 113, Follow-up of, repair, 238, Herniation through diaphragm, 257, inguinal, Analysis of immediate postoperative complications in 2000 cases of, 1052, Injection treatment of 1093, postoperative, Disruption of wounds and, are preventable, ed 1103
 Hip joint, Study and end-result report of 70 arthroplasties and reconstruction operations on, 106
 Hodgkin's disease, Primary reticulum cell sarcoma of bone, 45
 Hormones, Evaluation of intradermal test for pregnancy, 187, Evaluation of ovarian sterilization for breast cancer, 452, Estrogenic, and carcinogenesis, 472
 Humerus, Supracondylar fracture of, analysis of 330 cases, 201
 Hydatidiform mole, and chorio-epithelioma, ed 844
 Hydrocele testis, Improved, radical technique for repair of, 236
 Hydronephrosis, Conservative surgical treatment of non-calculous, 832
 Hyperthyroidism, Recurrent, report of 306 cases operated upon from 1928 to 1937, 347, Blood iodine levels related to recurrence of, 744
 ILEITIS, Regional, 314
 Ileum, Surgery for ulcerative colitis, 306, Regional ileitis, 314
 Incisions, Disruption of wounds and postoperative hernia are preventable, ed 1103
 Industrial medicine, 579-592
 Infants, Prevention of maternal and, anemia, 869, Technical notes on hypertrophic pyloric stenosis, 1074
 Infection, Experiments concerning ligation and refrigeration in relation to local intoxication and, 1047, Treatment of deep, of submaxillary triangle, ed 1102
 Infra-red photography, Study of superficial venous pattern in pregnant and non-pregnant women by, 54
 Injection treatment, of hernia, 1093
 Injuries, compound, Immediate treatment of, ed 961
 Instruments and apparatus, Purposeful splinting following injuries of hand, 1, flange and director, Fractures of neck of femur, open operation and pathologic observations, new incision and new director for use of simplified flange, 87, intestinal anastomosis clamps, Technique of anastomosis using Stone clamp, 95; Wangenstein suction drainage, Modified, 118; Wollner conization, Early diagnosis of cervical carcinoma, 147, Morley gastrectomy clamp, Modified Schoemaker gastrectomy for chronic gastric ulcer, 197, Singer postural

- drainage table Medical treatment of bronchiectasis, 327, hearing devices, Study of medical and surgical aids to hearing 395 arm prostheses Cineplastic amputation 554 Double skeletal pin fixation in fractures of leg 573, metallic fixation Report on symposium on in fractures 576 Leydig fracture device Smith Petersen nail Fractures of neck of femur treated with analysis of 78 cases during 1937 713 Stomach and intestinal tubes Decompression of intestinal tract, ed 842 Jacob's bladder drainage Harris' bladder retractor and boomerang needle and ligature carrier Suprapubic prostatectomy 918 Hustin blood transfusion New and safer method of citrated blood transfusion 940 Bladder retractor prostatic specimen boomerang needle Morsan catheter Reconstruction operation for adenomatous disease of prostate 1060 Walking iron for immediate use on wet plaster casts 108 trusses Injection treatment of hernia, 1093
- Intestinal tract** Influence of papaverine on muscular tone of, 749 Decompression of, ed 842
- Intestines** anastomosis of Technique of using Stone clamp 95 Modified Wangensteen suction drainage 118 Surgery for ulcerative colitis 306 Regional ileitis 314 Regional enteritis 32 Results of repeated operations upon stomach especially for gastrojejunal ulcers 334 Jejunoplasty for obstruction following gastro-enterostomy or subtotal gastric resection 703 Experiences with employment of suction in treatment of acute intestinal obstruction reiteration of indications contra indications and limitations of method 851 Mural penetration of carcinoma cell in colon anatomic and clinical study 872 Extraperitoneal implantation of colon one stage resection for carcinoma 1077 Surgical aspects of neurogenic tumors of abdomen 1085
- Intoxication** Experiments concerning ligation and refrigeration in relation to local and infection 1047
- Iron deficiency** Prevention of maternal and infant anemia 869
- JAUNDICE** Benign strictures of bile ducts with new method of treatment, 288 Surgical problems in jaundiced patients 409
- Jaw** Fractures of bones of face 664
- Jejunum** Jejunoplasty for relief of obstruction following gastro-enterostomy or subtotal gastric resection 703
- Jejunoplasty** for obstruction following gastro-enterostomy or subtotal gastric resection 703
- Joints** Study of present status of chronic osteomyelitis 1007
- Jones, Sir Robert** splint of Purposeful splinting following injuries of hand 1
- KANAVEL** Allen B. Editor appointed ed 120 Our College mandate tribute to, 424
- Kidney** in pregnancy Fluid balance in puerperium, 17 ectopic Anatomical and surgical features of 37 Surgical procedures in presence of diabetes mellitus 508 Renal infection and nephrolithiasis 527 Pyelonephritis and its treatment 534 Obstructive uropathies 546 Modern surgical treatment of ureterocolic 611 Accessory renal vessels their influence in certain cases of hydronephrosis 666 Conservative surgical treatment of non-calculus hydronephrosis 832 Diaphragmatic injury complicating nephrectomy method of closure 932 Nephropexy ed 960
- Knee joint** tuberculosis 222 cases treated by operative fusion 1079
- LABOR** Obstetrical influences on weight curve of newborn 179 Management of third and fourth stages of labor based on 21 000 deliveries 234 My experience with Melhado maneuver for persistent posterior position 495 Operative management of fibromyomas in uterus at term 699
- Lacrimal sac** Present status of surgery of 414
- Laminectomy** Encapsulated intramedullary tumor involving whole spinal cord from medulla to conus complete enucleation with recovery 814
- Larynx** Laryngeal tuberculosis surgical treatment including collapse therapy 390 Surgical treatment of carcinoma of 462 X-ray treatment of inoperable carcinoma of 467 Tracheotomy 782
- Leg** Double pin skeletal fixation in fractures of 573
- Lewin** baseball splint Purposeful splinting following injuries of hand 1
- Ligation** Experiments concerning and refrigeration in relation to local intoxication and infection 1047
- Limbs** artificial Cineplastic amputation, 554
- Lipiodol**, Effect of in subarachnoid space 945
- Lips** Contractures due to burns 352
- Liver** Surgical problems in jaundiced patients 409 Factors determining selection and administration of anesthetics 510
- Ludwig's angina** Treatment of deep infections of submaxillary triangle ed 1102
- Lungs** Medical treatment of bronchiectasis 327 Primary pulmonary malignancy treatment by total pneumonectomy analysis of 79 collected cases and present status of 7 personal cases 435 Palliative irradiation of metastatic tumors in 457, Acute putrid abscess of III Roentgenographic features 687
- MALIGNANCY** Carcinoma of body of uterus clinical and pathological review 30 Primary pulmonary treatment by total pneumonectomy, analysis of 79 collected cases and present status of 7 personal cases 435 Multiple primary malignant lesions 595 Mural penetration of carcinoma cell in colon anatomic and clinical study 872
- Mammoplasty** Technique in conditions of hypertrophy of breast, 658
- Master Surgeons of America** Joseph C. Bloodgood 965
- Mecholyl**, Use of drugs in surgery ed 121
- Medical training** On medical education ed 718
- Melhado maneuver** My experience with for persistent posterior position 495
- Memoirs** Sir David Wilkie 123
- Meningioma** Parasagittal, operative technique suggested for exposure 957
- Meningitis** Treatment of otitic due to streptococcal infection by surgery and sulfanamide 377
- Menstruation** Excision of superior hypogastric plexus (presacral nerve) for primary dysmenorrhea 723
- Metacarpal** Fibroma of middle bone resection and reconstruction 936
- Method** Parker F. F. Technique of anastomosis using Stone clamp 95 Schoemaker gastrectomy Modified for chronic gastric ulcer 197 Walms-Sullivan Benign strictures of bile ducts with new method of treatment, 288 Finsterer Results of repeated operations upon stomach especially for gastrojejunal ulcers 334 Le Fort colopeliosis Watkins interposition Multiple plastic operations in management of prolapsus uteri 481 Wertheim operation for cancer of uterus 486 Melhado My experience with maneuver for persistent posterior position 495 Parnell's retraction physiological reconstruction for non united fractures of neck of femur 643 Hubbs spine fusion Spondylolisthesis

- 774, Tubby, Chandler, Foerster, Surgical treatment of spastic paralysis, 792; Wangenstein suction, Experiences with employment of suction in treatment of acute intestinal obstruction, reiteration of indications, contra-indications, and limitations of method, 851, Hustin blood transfusion, New and safer method of citrated blood transfusion, 940
- Metycaine**, Use of, for producing block anesthesia of sacral nerves, 222
- Morphine**, Use of drugs in surgery, ed 121, Influence of papaverine on muscular tone of intestinal tract, 749
- Mouth**, Treatment of deep infections of submaxillary triangle, ed 1102
- Muscles**, shoulder, Unusual lesions of, and tendons of shoulder girdle and upper arm, 903
- Muscle tone**, Influence of papaverine on muscular tone of intestinal tract, 749
- NAFFZIGER**, Howard C, op 257
- National Foundation for Infantile Paralysis, Obstetrical difficulties after infantile paralysis, cor 1106
- Neck**, Contractures due to burns, 352
- Necrosis**, Fat, granuloma of breast, 230
- Nembutal**, Experimental traumatic shock, further studies with particular reference to rôle of nervous system, 278
- Neoprontosil**, Treatment of otitic meningitis due to streptococcic infection by surgery and sulfanilamide, 377
- Neosynephrine**, Use of, in spinal anesthesia, 1021
- Nephrolithiasis**, Renal infection and, 527
- Nephropexy**, ed 960
- Nerves**, sacral, Use of metycaine for producing block anesthesia of, 222, optic, Ocular manifestations of allergy, 406, hypogastric, sacral, Sympathectomy for relief of vesical spasm and pain resulting from intractable bladder infection, 540, presacral, Excision of superior hypogastric plexus (presacral nerve) for primary dysmenorrhea, 723, resection, Surgical treatment of spastic paralysis, 792
- Nervous system**, Experimental traumatic shock, further studies with particular reference to rôle of, 278
- Neurosis**, Diagnosis and therapy of so called posttraumatic, following craniocerebral injuries, 587
- Newborn**, care of, Obstetrical influences on weight curve of, 179
- Nose**, Fractures of bones of face, 564
- OBSTETRICAL**, Obstetrical influences on weight curve of newborn, 179, Management of third and fourth stages of labor, based on 11,000 deliveries, 224; Diagonal conjugate versus x-ray pelvimetry, 642; Obstetrical difficulties after infantile paralysis, cor 1106
- Occupational skin disease**, Methods of investigation of, 583
- Operation**, fusion, Knee joint tuberculosis, 222 cases treated by, 1029
- Ophthalmia**, sympathetic, Ocular manifestations of allergy, 406
- Orbit**, Fractures of bones of face, 564
- Osteomyelitis**, Present status of chronic, 1007
- Ovary**, Evaluation of ovarian sterilization for breast cancer, 452, Multiple primary malignant lesions, 595, Arrhenoblastoma, 767, Intraperitoneal hemorrhage from ruptured ovarian retention cysts, corpus luteum and graafian follicle cysts, 824, Hydatidiform mole and chorio-epithelioma, ed 844
- PAIN**, Sympathectomy for relief of vesical spasm and, resulting from intractable bladder infection, 540, pelvic, Excision of superior hypogastric plexus (presacral nerve) for primary dysmenorrhea, 723
- Papaverine hydrochloride**, Influence of, on muscular tone of intestinal tract, 749
- Paralysis**, spastic, Surgical treatment of, 792
- Patient**, Psychiatrist in relation to surgery, 372, handicapped, Factors determining selection and administration of anesthetics, 519
- Pauwels' reclinant**, physiological reconstruction for non-united fractures of neck of femur, 648
- Pedicle flaps**, Burn contractures of hand, 1066
- Pelvimetry**, Diagonal conjugate versus x-ray pelvimetry, 642
- Pelvis**, Anatomy of pelvic and urogenital diaphragms, in relation to urethrocele and cystocele, 161, Obstructive uropathies, 546, Diagonal conjugate versus x-ray pelvimetry, 642
- Penis**, New radical operation for carcinoma of bulbous urethra, new use for, 77
- Pericarditis**, Surgical treatment of chronic constrictive, 979
- Pericardium**, Surgical treatment of chronic constrictive pericarditis, 979
- Perineum**, Anatomy of pelvic and urogenital diaphragms, in relation to urethrocele and cystocele, 161
- Peritoneal fluid**, Bacteriological study of peritoneal fluid in perforated peptic ulcers, 1017
- Peritonitis**, Primary streptococcus and pneumococcus, in children, study of 61 cases with report of 2 interesting recoveries, 760
- Pes planus**, Operative treatment of, 1099
- Pharynx**, Surgical treatment of carcinoma of larynx, 462
- Phlebitis**, Intravenous anesthesia, ed 719
- Phosphatase**, determination in differential diagnosis of bone lesions, 1038
- Phylogeny**, of ear, Phylogenetic development of ear, 401
- Pitressin**, Use of drugs in surgery, ed 121
- Pituitary gland**, Arrhenoblastoma, 767

- Pleura**, Diaphragmatic injury complicating nephrectomy, method of closure, 932
- Plexus**, superior hypogastric, Excision of (presacral nerve) for primary dysmenorrhea, 723
- Pneumococcus**, Primary streptococcus and, peritonitis in children, study of 61 cases with report of 2 interesting recoveries, 760
- Pneumectomy**, Primary pulmonary malignancy, treatment by total, analysis of 79 collected cases and presentation of 7 personal cases, 435
- Poliomyelitis**, Obstetrical difficulties after infantile paralysis, cor 1106
- Posttraumatic neurosis**, Diagnosis and therapy of so called, following craniocerebral injuries, 587
- Potassium indole butyrate**, Studies on growth stimulating effect of potassium naphthalene acetate and, 63
- Potassium naphthalene acetate**, Studies on growth stimulating effect of, and potassium indole butyrate, 63
- Pregnancy**, Fluid balance in puerperium, 17, Study of superficial venous pattern in pregnant and non-pregnant women by infra-red photography, 54; Evaluation of intradermal test for, 187, My experience with Melhado maneuver for persistent posterior position, 495, Operative management of fibromyomas in uterus at term, 699, Prevention of maternal and infant anemia, 869

Presentation occiput posterior Experience with Melhado maneuver for persistent posterior position 495
 Prolapsus uteri Multiple plastic operations in management of 431
 Prostate Early phases of prostatic hyperplasia 155 Suprapubic prostatectomy 918 Reconstruction operation for adenomatous disease of 1060
 Prostatectomy Suprapubic 918
 Prostaglandin Use of drugs in surgery ed 121
 Psychiatrist in relation to surgery 372
 Puerperium Fluid balance in 17
 Pyelonephritis and its treatment 534
 Pylorus Technical notes on hypertrophic pyloric stenosis 1074

RADIUS Influence of vitamin D upon bone repair healing of fractures of rachitic bones 878
 Refrigeration Experiments concerning attention and in relation to local intoxication and infection 1047
 Respiratory tract Study of medical and surgical aids to hearing 305
 Rest Purposeful splinting following injuries of hand 1
 Resuscitation Studies of the anaesthetics I Coramine 892
 Retina Ocular manifestations of allergy 406
 Rib Fate of living and dead cartilage transplanted in humans 603
 Roentgen ray Evolution of fracture treatment 362
 Roentgen therapy Palliative irradiation of metastatic tumors in lungs 457 Surgical treatment of carcinoma of larynx 462 X ray treatment of inoperable carcinoma of larynx 467
 Roentgenography Diagonal conjugate versus x ray pelvimetry 64 Acute putrid abscess of the lung 111 Roentgenographic features 687

SARCOVA Ewing's reticulum cell primary sarcoma of bone 45 Ewing's reticulum cell bone sarcoma factors influencing prognosis 67
 Salivary gland Treatment of deep infections of submaxillary triangle ed 1102
 Salpingitis Tubal resection as treatment for recurrent gonorrheal 810
 Scaphoid Acute fractures of carpal 820
 Schwannoblastoma Surgical aspects of neurogenic tumors of abdomen 1085
 Scrotum Improved radical technique for repair of hydrocele testis 236
 Serum therapy Treatment of colon bacillus peritonitis in rabbits with escherichia coli antiserum 34
 Shock Experimental traumatic further studies with particular reference to rôle of nervous system 278 Immediate treatment of compound injuries ed 901
 Shoulder girdle Unusual lesions of muscles and tendons of and upper arm 903
 Silex Medical control of and tuberculosilrosis 519
 Silk Follow up of hernia repair 238
 Silk sutures Technique of thyroidectomy permitting use of 801 cor 910
 Skin Methods of investigation of occupational diseases 513 Squamous cell carcinoma of extremities 1007
 Skin defects Growth stimulating effect of potassium naphthalene acetate and potassium indole butyrate 63
 Skin grafting Dermigraft 930
 Skin Regional ileitis 314
 Skull Diagnosis and therapy of so called posttraumatic neurosis following craniocerebral injuries 587 Intracranial solitary chondroma 677
 Sodium chloride balance Study of fluid and in patients treated with continuous suction applied to indwelling duodenal tubes 751

Spinal canal Effect of injection of lipiodol in subarachnoid space 945
 Spinal cord Encapsulated intramedullary tumor level 24 whole spinal cord from medulla to conus complete enucleation with recovery 814
 Splints Purposeful splinting following injuries of hand 1
 Split grafts Burn contractures of hand 1066
 Spondylolisthesis 774
 Standards for sterilizer controls Controlling operating room sterilizers ed 247
 Stenosis pyloric Technical notes on hypertrophy 104
 Sterility Certain aspects of so called sterility in female 439 Arrhenoblastoma 767
 Sterilization Evaluation of ovarian for breast cancer 431
 Sterilizers Controlling operating room ed 247
 Stomach Modified Wengenstein suction drainage 113 Modified Schoemaker gastrectomy for chronic gastric ulcer 197 Herniation through diaphragm 157 Cancer of 295 Surgery for ulcerative colitis 308 Results of repeated operations upon especially for gastroenteral ulcer 334 Jejunoplasty to obstruction following gastroenterostomy or subtotal gastric resection 103 New aseptic double valved tubogas to tomy 789
 Stomach tube Decompression of intestinal tract ed 842
 Streptococcus Primary and pneumococcus peritonitis in children study of 61 cases with report of 2 interesting recoveries 760
 Subarachnoid space Effect of lipiodol in 945
 Submaxillary triangle Treatment of deep infections of ed 1102
 Suction Experiences with employment of in treatment of acute intestinal obstruction reiteration of indications, contra indications and limitations of method 851
 Sulfanilamide Treatment of otitic meningitis due to streptococcus infection by surgery and 377 Pyelonephritis and its treatment 534 Primary streptococcus and pneumococcus peritonitis in children study of 61 cases with report of 2 interesting recoveries 760
 Surgeon Psychiatrist in relation to surgery 372
 Surgery traumatic Purposeful splinting following injuries of hand 1 Use of drugs in ed 121 Asepsis in Controlling operating room sterilizers ed 247 teaching of Graduate training for surgery and surgical specialties 433 plastic Fate of living and dead cartilage transplanted in humans 603 plastic Technique of mammoplasty in conditions of hypertrophy of breast 658 teaching of On medical education ed 718 plastic Dermigraft 930
 Sutures living Use of external oblique aponeurosis in repair of inguinal hernias in adults 113 Technique of thyroidectomy permitting use of silk 801 cor 970 Analysis of immediate postoperative complications in 1000 cases of inguinal hernia 1052
 Sympathectomy for relief of vesical spasm and pain resulting from intractable bladder infection 540
 Sympathicoblastoma Surgical aspects of neurogenic tumors of abdomen 1085

TENDONS Unusual lesions of muscles and of shoulder girdle and upper arm 903
 Test intradermal Evaluation of for pregnancy 187
 Rubin Certain aspects of so called sterility in female 489 pregnancy Hydatidiform mole and chorion-epithelioma ed 844
 Testis Improved radical technique for repair of hydrocele 236
 Thelin Estrogenic hormones and carcinogenesis 472
 Therapy collapse Laryngeal tuberculosis surgical treatment including 390
